a. Breast milk jaundice is a separate entity that is attributed to a change in the chemical or physical composition of breast milk; it usually occurs after the first 4 to 7 days of life (Deshpande & Wagle, 2017). Bilirubin levels can reach 12 to 20 mg/dL between 8 and 15 days and may remain elevated for as long as 3 months. The infant appears healthy with normal weight gain and stool output, and no evidence of RBC hemolysis is seen. However, it is recommended that bilirubin levels greater than 12 mg/dL or persistent into the third week of life may warrant further investigation (Flaherman et al., 2017; Preer & Philipp, 2011). Breast milk jaundice is not well understood, but the following factors, as summarized by Deshpande and Wagle (2017), are believed to play a role: (a) Two substances found in breast milk, pregnanediol and nonesterified fatty acids, interfere with bilirubin conjugation or increase enterohepatic circulation, resulting in resorption of bilirubin from the intestine. They are thought to inhibit glucuronyl transferase, the enzyme necessary for bilirubin conjugation in the liver. However, the role of these two substances in the interference with glucuronyl transferase activity remains questionable. (b) An increase in enterohepatic bilirubin due to increase of beta-glucuronidase activity in breast milk and subsequently the intestines of breastfed infants as well as the delayed establishment of enteric flora. (c) A defect in the UGT gene *UGT1A1*, which is responsible for conjugation and elimination of bilirubin. (d) Mutation of the solute carrier organic anion transporter protein SLCO1B1, which results in reduced hepatic uptake of unconjugated bilirubin. (e) Presence of inflammatory cytokines in human milk, in particular IL-1-beta and IL-6. Both of these are known to be cholestatic and reduce uptake, metabolism, and excretion of bilirubin. (f) High levels of epidermal growth factor (EGF) in breast milk and the serum have been found in neonates with breast milk jaundice. It is thought that the increased EGF enhances bilirubin absorption and uptake, contributing to the presence of jaundice, as well as (g) serum alpha-fetoprotein levels are higher in these infants, but the significance of this is yet to be determined (Deshpande & Wagle, 2017).
b. When breastfeeding is discontinued, the bilirubin level falls within 24 to 48 hours, dropping to half its previous peak level by 48 hours. With resumption of breastfeeding, the bilirubin level starts to rise but at a much slower pace. Interruption of breastfeeding is not recommended; instead, continued and frequent breastfeeding is encouraged. However, the healthcare provider has the option to supplement nursing with formula or to interrupt breastfeeding and substitute formula, depending on the degree of bilirubin elevation. Supplementation of nursing with water or glucose water does not appear to have any effect on bilirubin levels in healthy term infants.

Drugs That Interfere With Bilirubin Conjugation. Certain medications ingested by the mother and passed transplacentally to the fetus (e.g., salicylates, sulfa preparations) can interfere with the ability of albumin to bind bilirubin. Administration of these drugs to the newborn can produce the same effect. Other medications, such as sodium benzoate, a commonly used preservative, compete with bilirubin for albumin binding sites.

Hypothyroidism. Hypothyroidism is one of the more common metabolic disorders associated with hyperbilirubinemia. Of all infants with hypothyroidism, 10% have elevated bilirubin levels lasting several weeks to months. The suspected mechanism for jaundice is theorized to be a delay in glucuronosyltransferase synthesis or impairment of hepatic proteins that bind bilirubin and remove it from the plasma. The plasma membrane of liver cells may also be altered, resulting in decreased bilirubin influx into the hepatic cells (Kaplan et al., 2015).

Acidosis and Hypoxia. As previously stated in the discussion of kernicterus, a drop in serum pH alters albumin's ability to bind bilirubin. The accompanying increase in the production of free fatty acids promotes competition between fatty acids and bilirubin for binding sites.

Abnormal Bilirubin Excretion. Any disease state resulting in abnormal bilirubin excretion can raise serum bilirubin levels significantly. This is seen in hepatic dysfunction secondary to such entities as hypoxia or asphyxia, bowel obstruction, ileus, and congestive heart failure. However, these conditions have a tendency to elevate both the conjugated and unconjugated bilirubin levels. The diminished bowel motility associated with these conditions lengthens the time during which beta-glucuronidase, which is naturally present in the gut, can act on conjugated bilirubin in the stool. This enzymatic reaction converts conjugated bilirubin into the unconjugated form, which is reabsorbed into the intravascular compartment through the enterohepatic circulation. Direct hepatocellular damage associated with cholestasis and bacterial and viral infections can further impair the liver's ability to conjugate bilirubin (Kaplan et al., 2015).

Treatment of Hyperbilirubinemia

Phototherapy. Phototherapy reduces unconjugated bilirubin through photooxidation and photoisomerization, which changes bilirubin into water-soluble forms that can bypass the need for conjugation in the liver and be readily excreted in bile and urine (Maisels, 2015). Photooxidation involves the oxidation of bilirubin pigment deposited in the skin and its conversion into colorless products that can be excreted into the urine. Of the total body bilirubin concentration, 15% can undergo photodegradation through oxidation. Photoisomerization involves the conversion of bilirubin polymers present in the skin into excretable isomers. When the natural form of bilirubin is exposed to blue light at certain wavelengths, it undergoes photoisomerization. This changes it from a tetrapyrrole, a lipid-soluble substance, into five water-soluble isomers. Four of these isomers are excreted into bile without undergoing conjugation. Two are unstable isomers that are incorporated into bile and

must be promptly eliminated from the gastrointestinal tract as a component of stool or they revert to their natural forms, resulting in resorption of bilirubin from the gut and recirculation into the plasma. Two other isomers remain relatively stable and account for most of the bilirubin found in bile. The fifth isomer, lumirubin, is a stable, water-soluble form of bilirubin that is eliminated more rapidly through urine and bile (Bhutani & Lamola, 2017). Its conversion is the rate-limiting step in the conversion of bilirubin for elimination by phototherapy and, thus, plays a critical role in the decrease in bilirubin levels associated with phototherapy (Kaplan et al., 2015).

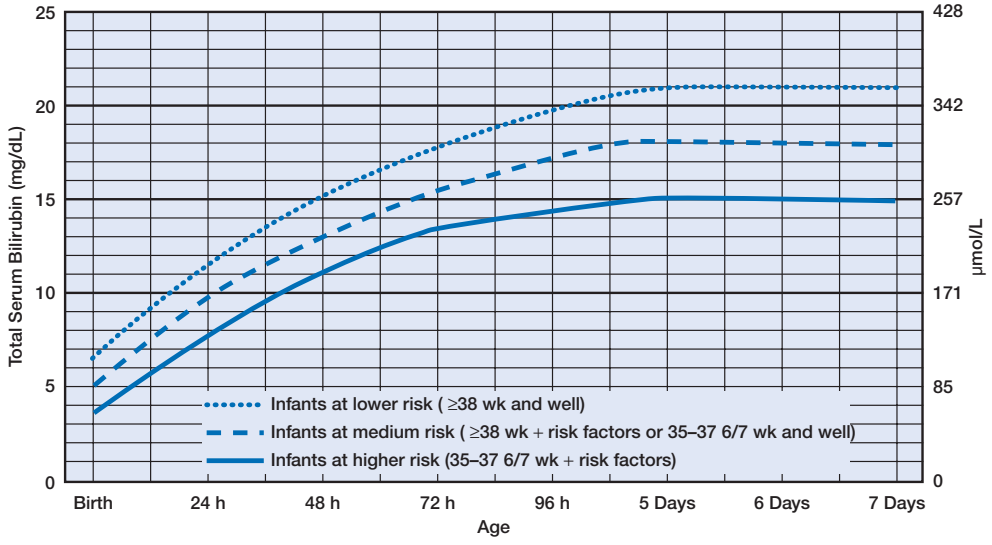
Phototherapy, alone, is not adequate therapy for a rapidly rising bilirubin level, but it is effective in treating moderate hyperbilirubinemia that has not reached or exceeded levels known to be associated with kernicterus and in reducing the need for exchange transfusions after the first 12 hours of life. The effectiveness of phototherapy is influenced by spectral qualities of the light, intensity of the light or spectral irradiance, distance between the light and the infant's skin, body surface area exposed to the light, cause of jaundice, and TSB when phototherapy is initiated (Maisels et al., 2004). Intensive phototherapy can produce a decline of 2 mg/dL of TSB within 4 to 6 hours (Bhutani et al., 2011) and can produce a reduction in the initial TSB by 30% to 40% within the first 24 hours of treatment (AAP Subcomittee on Hyperbilirubinemia, 2004). This is a reflection of the length of exposure necessary for phototherapy to exhibit its effectiveness. The AAP Provisional Committee for Quality Improvement & Subcommittee on Hyperbilirubinemia (Maisels et al., 2004) revised a set of guidelines for the initiation of phototherapy (Figure 13.6) and exchange transfusion (Figure 13.7) in infants greater than or equal to 35 weeks' gestation. Suggested TSB levels for initiation of phototherapy and exchange transfusion for the preterm infant based on gestational age are found in Figure 13.8.

Recommended levels for the use of phototherapy or exchange transfusion must be adjusted downward for prematurity, acidosis, hypoxia, respiratory distress, asphyxia, and neurologic decompensation (Figure 13.7). Diminished bilirubin-binding capacity of albumin and decreased amounts of circulating albumin expose these infants to increased amounts of free bilirubin, which can easily cross the blood–brain barrier and increase the susceptibility of the infant to bilirubin toxicity.

Although no significant adverse effects are attributed to the use of phototherapy, it is not without associated side effects. Some of these problems include dermal rash, lethargy, abdominal distention, possible eye damage, dehydration caused by increased insensible water loss through the skin and digestive tract, thrombocytopenia, hypocalcemia, and secretory diarrhea possibly as a result of a temporary intestinal lactose deficiency. Another effect of phototherapy seen in infants with a significant direct bilirubin component is "bronze baby" syndrome. This syndrome is thought to be due to skin deposition or a photoproduct of bilirubin decomposition, possibly copper porphyrins, which causes bronzing of the skin and urine. Although no harmful effects can be attributed to the bronzing, it can last for several weeks to several months and is somewhat alarming to parents (Kaplan et al., 2015).

The administration of albumin to an infant undergoing phototherapy may reduce the amount of bilirubin available in the skin for photoisomerization. In an attempt to saturate the increased available albumin binding sites, free bilirubin is drawn into the vascular compartment from the skin, where phototherapy exerts its effect. For this reason, use of albumin in the infant undergoing phototherapy should be carefully weighed.

Collaborative Management. Infants who require phototherapy benefit most from light in the blue-green spectrum in the wavelength range at which photoisomerization occurs most efficiently: that is,



- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin <3.0 g/dL (if measured).
- For well infants 35-37 6/7 weeks can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 weeks and at higher TSB levels for those closer to 37 6/7 weeks.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2-3 mg/dL (35-50 mmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors.

425 to 550 nm. In addition to the appropriate wavelength, effective illumination must be maintained. Spectroradiometric readings of at least 8 to 10 μW/cm^2/nm are required to produce the isomer lumirubin. Intensive phototherapy requires an irradiance of greater than 30 μW/cm^2/nm (Blackburn, 2017). For optimum therapy, phototherapy units should be checked for adequacy of light levels by nursing or bioengineering staff. Prolonged exposure to phototherapy lights may cause retinal damage, which can be minimized with adequate eye protection. Phototherapy units and eye protection should be removed for short periods throughout the day to provide the infant with visual stimulation and interaction with parents and caregivers. Nurses should also be aware that they may experience headaches from prolonged exposure to phototherapy lights.

Infants undergoing phototherapy require temperature stabilization appropriate for their size and overall condition. A larger infant who is basically well can be nursed in an open crib, but the sick term, premature, or low-birth-weight (LBW) infant requires temperature control through the use of open warmers or closed incubators. Adequate fluid intake and compensatory fluid adjustments for increased insensible water and stool loss may be required to prevent dehydration in these infants. While the infant is receiving phototherapy, bilirubin levels must be monitored frequently to assess the effectiveness of therapy and the need for exchange transfusion. Because phototherapy lights can alter blood bilirubin results, the lights should be turned off when drawing blood for serum bilirubin determinations.

Many hyperbilirubinemic infants, who are healthy and not in need of thermoregulation or exchange transfusion, can be cared for at home as long as the AAP guidelines are met. The parents of these infants must have access to home phototherapy equipment and a medical supply company to service the equipment, as well as the support of their medical caregiver. If the infant can remain normothermic in an open crib without clothing, home phototherapy may be considered a cost-effective alternative to hospitalization. The same precautions regarding protective eye covering and adequate fluid intake must be observed in these infants. Frequent determination of bilirubin levels is required to ensure adequate treatment, and blood may be drawn daily for this purpose at the physician's office, at the neighborhood hospital laboratory, or by a home healthcare worker.

Pharmacologic Agents. Intravenous immunoglobulin (IVIG) is administered to newborn infants diagnosed with either Rh or ABO incompatibility with the goal of reducing or eliminating the need for an exchange transfusion. It is hypothesized that IVIG may interfere with receptors in the reticuloendothelium that are required to induce hemolysis and, thus, reduce the rate of hemolysis. However, while the available evidence shows a significant decrease in the need for exchange transfusions when treated with IVIG, methodological issues limit the strength of the available evidence (Zwiers, Scheffer-Rath, Lopriore, de Haas, & Liley, 2018). The AAP Provisional Committee for Quality Improvement & Subcommittee on Hyperbilirubinemia (Maisels et al., 2004) recommends that affected infants should receive IVIG 500 to 1,000 mg/kg over 2 hours for TSB rising despite intensive phototherapy or if the TSB is within 2 to 3 mg/dL of the exchange transfusion level. It should be noted that promising work with administration of IVIG to women with alloimmunized pregnancies may delay the development of fetal anemia and thus the need for postnatal exchange transfusions (Zwiers et al., 2018).

Phenobarbital is thought to accelerate bilirubin excretion by increasing its uptake and conjugation by the liver and by increasing its excretion by enhancing bile flow. However, no increased benefit is noted that cannot be achieved with phototherapy alone and, thus, it is not routinely used to treat hyperbilirubinemia. At this time, no other medications have been approved in the United States as therapy for inhibition of bilirubin synthesis. There is evidence to suggest that metalloporphyrins may be effective in controlling or reducing hyperbilirubinemia in the term and preterm

infant. Metalloporphyrins are inhibitors of heme oxygenase, the rate-limiting enzyme involved in the degradation of heme to biliverdin, an intermediate in the synthesis of bilirubin (Bhutani et al., 2016) However, further clinical trials are needed before metalloporphyrins may be routinely used to manage hyperbilirubinemia.

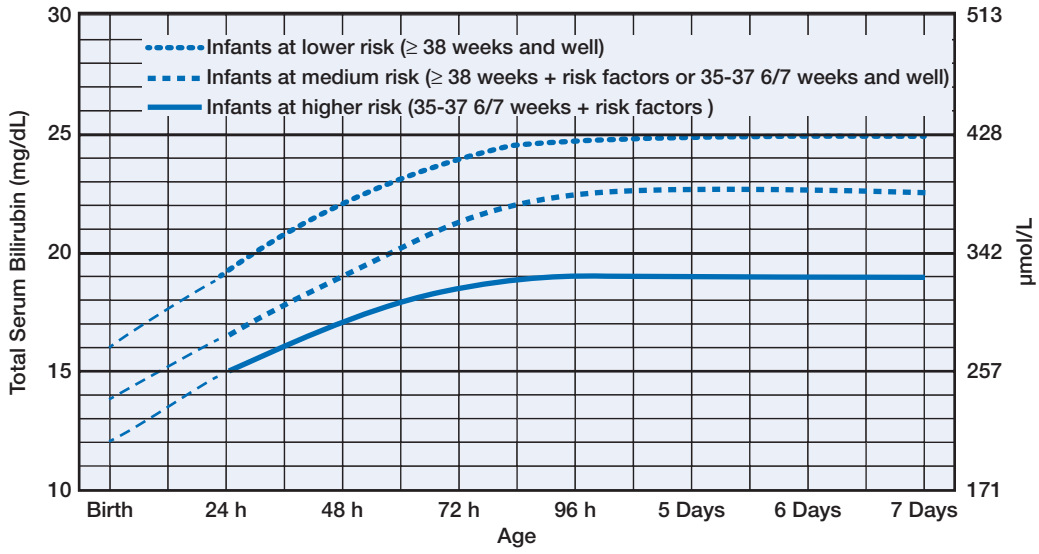
Exchange Transfusion. Once done frequently in NICUs, exchange transfusions are now rarely done and only to treat extreme hyperbilirubinemia or metabolic issues. An exchange transfusion may be necessary if bilirubin levels start to approach those associated with kernicterus despite phototherapy, to protect the CNS status of the jaundiced infant. The objective of this procedure is to remove bilirubin and the antibody-coated RBCs from the newborn's circulation. In addition, exchange transfusion removes some of the circulating maternal antibodies and Rh-positive fetal RBCs while potentially normalizing the Hct. After a single-volume exchange, 75% of the newborn's RBC mass is removed; a double-volume exchange removes 85% to 90% of the cells. However, bilirubin removal is much less effective; only 25% of the infant's total body bilirubin is removed during a double-volume exchange. This probably occurs because the major portion of bilirubin is in the extravascular compartment, an area not affected by the exchange of blood volume. Rebound in bilirubin levels occurs within 1 hour of the exchange, with posttransfusion levels rising as high as 55% of preexchange values.

Although EBF remains the primary condition requiring exchange transfusion, the procedure can also be used to reduce levels of circulating metabolic toxins or exogenous drugs and to reestablish a normal Hct without further volume overload in anemia-induced congestive heart failure. The mortality rate for exchange transfusions is approximately 3 in 1,000 procedures. This rate includes death during the procedure or within 6 hours after its completion but excludes hydropic, kernicteric, or moribund infants (Diab & Luchtman-Jones, 2015; Maisels et al., 2009).

The following criteria are used to determine the need for and timing of exchange transfusions, particularly in infants with EBF (Maisels et al., 2004):

- A cord-blood bilirubin level over 4.5 mg/dL in term infants and 3.5 mg/dL in preterm infants
- A hemoglobin level under 8 g/dL and a bilirubin level over 6 mg/dL within 1 hour of delivery in a term infant
- A hemoglobin level under 11.5 g/dL and a bilirubin level over 3.5 mg/dL within 1 hour of delivery in a preterm infant
- An increase in bilirubin levels by 0.5 mg/dL/hour despite phototherapy
- A bilirubin level over 20 to 25 mg/dL in an uncompromised term infant, 18 mg/dL in the high-risk term newborn, and 10 to 18 mg/dL in the preterm infant, depending on gestational age and condition (Figure 13.9)
- A bilirubin level over 10 to 17 mg/dL in a stressed or very immature preterm infant, over 10 to 12 mg/dL if hypoxia and acidosis are present

- Identical criteria are used to determine the need for repeated exchange transfusion. With more liberal use of phototherapy and appropriate fluid management, exchange transfusions are infrequently necessary (Diab & Luchtman-Jones, 2015).



- **The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.**
- **Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high pitched cry) or if TSB is ≥5 mg/dL (85 µmol/L) above these lines.**
- **Risk factors - isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.**
- **Measure serum albumin and calculate B/A ratio (See legend).**
- **Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.**
- **If infant is well and 35-37 6/7 weeks (median risk) can individualize TSB levels for exchange based on actual gestational age.**

Side Effects of Exchange Transfusion

Exchange transfusion can have a marked effect on the cardiovascular status and the intravascular compartment, which is reflected in pressure changes, volume fluctuations, and biochemical balance. Significant morbidities such as apnea/bradycardia, anemia, air embolism, infection, cyanosis, necrotizing enterocolitis, vasospasm, thromboembolism, and death can also occur as a result of an exchange transfusion.

Collaborative Management of the Infant Undergoing an Exchange Transfusion. In addition to the general nursing care required by a sick infant, specific stabilization procedures are necessary for a successful exchange transfusion.

ANEMIA

Pathophysiology

An infant is considered anemic if the hemoglobin or Hct value is more than two standard deviations below normal for his or her gestational age group. During the neonatal period, several abnormalities can evoke states of both acute and chronic anemia in the newborn. These forms of anemia often precede and occur independently of the natural propensity for physiologic anemia that exists as a common entity among all infants, both term and preterm. The conditions that most commonly trigger these pathologic anemias are acute or chronic episodes of hemorrhage, acute or chronic RBC destruction and hemolysis, and blood sampling for laboratory analysis.

Acute Anemia. The physical presentation of acute anemia is more intense than that seen in the chronic form, because the causes of acute anemia are more emergent, life threatening, and disruptive to the homeostasis of the infant (Box 13.2). **Emergency Alert: The resulting cardiovascular collapse, followed closely by respiratory failure, can overwhelm the neonate with only marginal reserves. Immediate intervention and replacement of lost intravascular volume are often required to achieve stabilization.** An infant experiencing an acute anemic episode (hemorrhage being the most common cause) has symptoms reflecting compromise of the cardiorespiratory system: shock, poor peripheral perfusion, poor respiratory effort or respiratory distress, tachycardia, pallor, lethargy, and hypotension. Before signs of acute anemia become apparent, the hemoglobin level must fall precipitously below 12 g/dL.

Acute blood loss results in a recognizable sequence of symptoms based on the volume loss.

- Between 7.5% to 15% volume loss: Little change is noted in heart rate and blood pressure, but stroke volume and subsequent cardiac output are reduced. Peripheral vasoconstriction occurs, resulting in diminished blood flow to the skeletal muscles, gut, and carcass.
- Between 25% to 25% volume loss: Hypotension and shock become apparent. Cardiac output is reduced, and peripheral vasoconstriction is present. Low tissue oxygen levels and acidosis become apparent.

Chronic Anemia. Prolonged, or chronic, anemia may not require rapid intravascular volume expansion, but it is by no means completely benign, as is seen with EBF or chronic twin-to-twin transfusion (Box 13.3). In both of these conditions, infants may require removal of intravascular volume and replacement with a volume of a higher Hct before stabilization is achieved. Because these infants have had considerable time to adjust to chronic blood loss or hemolysis, the changes in vital signs may reflect poor oxygen-carrying capacity rather than hypovolemia. On physical

Box 13.2

CAUSES OF ACUTE ANEMIA IN THE NEWBORN

Obstetric Accidents, Malformations of the Placenta and Cord

- Rupture of a normal umbilical cord
  - Precipitous delivery
  - Entanglement
- Hematoma of the cord or placenta
- Rupture of an abnormal umbilical cord
  - Varices
  - Aneurysm
- Rupture of anomalous vessels
  - Aberrant vessel
  - Velamentous insertion
  - Communicating vessels in multilobed placenta
- Incision of placenta during cesarean section
- Placenta previa
- Abruptio placentae
- Uterine rupture

Occult Hemorrhage Before Birth

- Fetoplacental
  - Tight nuchal cord
- Cesarean section
- Placental hematoma
- Fetomaternal
  - Traumatic amniocentesis
  - After external cephalic version, manual removal of placenta, use of oxytocin
  - Spontaneous
  - Chorioangioma of the placenta
  - Choriocarcinoma
- Twin-to-twin
  - Chronic
  - Acute

Internal Hemorrhage

- Intracranial
- Giant cephalohematoma, subgaleal, caput succedaneum
- Adrenal
- Coagulopathies
- Retroperitoneal
- Gastric
- Ruptured liver or spleen
- Pulmonary

Box 13.3

CAUSES OF CHRONIC ANEMIA IN THE NEWBORN

Immunity Disorders

- Rh incompatibility
- ABO incompatibility
- Minor blood group incompatibility
- Maternal autoimmune hemolytic anemia
- Drug-induced hemolytic anemia

Infection

- Bacterial sepsis
- Viral infections

Congenital Infections

- Syphilis
- Malaria
- Cytomegalovirus
- Rubella
- Toxoplasmosis
- Disseminated herpes
- Disseminated intravascular coagulation

Macroangiopathic and Microangiopathic Hemolytic Anemias

- Cavernous hemangioma
- Large-vessel thrombi
- Renal artery stenosis
- Severe coarctation of aorta

Iron Deficiency Anemia

Galactosemia

Hereditary Disorders of the Red Cell Membrane

- Hereditary spherocytosis
- Hereditary elliptocytosis
- Hereditary stomatocytosis
- Other rare membrane disorders

Pyknocytosis

Red Cell Enzyme Deficiencies

Most Common are:

- glucose-6-phosphate dehydrogenase deficiency
- pyruvate kinase deficiency
- 5′-nucleotidase deficiency
- glucose-6-phosphate isomerase deficiency

examination, pallor is usually accompanied by hepatosplenomegaly, a reflection of the body's attempt to compensate for blood loss through extramedullary hematopoiesis. The blood smear may also reflect the long-standing nature of the problem; RBCs appear hypochromic and small, and a greater number of immature RBCs are seen.

Common Causes of Pathologic Anemia in the Newborn

Hemorrhage. Hemorrhage is one of the most common causes of pathologic anemia in the newborn. There are many different types of hemorrhage, but they can be classified into four distinct categories, each of which will be discussed in the text that follows.

Fetal–Maternal Transfusion Caused by Transplacental Hemorrhage. This phenomenon occurs in approximately 50% to 75% of all pregnancies and can be an acute or a chronic process. An estimated 5.6% of pregnancies involve a fetal–maternal transfusion in the range of 11 to 30 mL of blood; another 1% involve an exchange of more than 30 mL. Fetal–maternal transfusions can be verified by the presence of fetal cells in the maternal circulation, which can be detected with the erythrocyte rosette test and the Kleihauer–Betke acid elution test for fetal hemoglobin in maternal blood. The erythrocyte rosette test specifically detects fetal RBCs. The Kleihauer–Betke test consists of an acid wash of a maternal blood smear followed by staining. Fetal hemoglobin resists elution from intact RBCs in an acid solution. Intact cells containing fetal hemoglobin can be distinguished microscopically, when stained, from adult erythrocytes. The presence of stained erythrocytes suggests contamination of maternal blood by fetal blood. This test is useful in identifying fetal RBCs in the mother's blood as long as no underlying condition increases the amount of fetal hemoglobin in the mother's blood.

Twin-to-Twin Transfusion. This phenomenon, which can be both acute and chronic, occurs in 15% to 33% of all monochorionic (monozygotic) twins, in which the placentas tend to be fused. The anastomosis is usually between an artery of one placenta and a vein of the other, although vascular connections may be artery to artery or vein to vein. In the chronic form of twin-to-twin transfusion, the size difference between twins can be helpful in determining the donor and the recipient. When the weight difference exceeds 20%, the smaller twin is always the donor. When the weight difference is less than 20%, either twin may be the donor. In such cases, Hct values prove useful in determining the donor and the recipient. The donor twin is anemic, and the blood count reflects increased hematopoiesis, as evidenced by an elevated reticulocyte count and increased numbers of immature RBCs. The recipient develops polycythemia but can exhibit signs of congestive heart

failure and pulmonary or systemic hypertension. Laboratory data usually show a difference of 5 g/dL between donor and recipient hemoglobin values. Stillbirths are common in twin-to-twin transfusion, and both twins are at risk.

Obstetrical Accidents. Many obstetrical problems, especially those that occur before labor and delivery, can result in chronic as well as acute blood loss. Long-standing problems, such as placenta previa or partial abruption, usually result in anemia. However, acute hemorrhage rather than anemia is the case in problems that occur at the time of delivery. Examples are severe abruption, severing of the placenta during cesarean section, uterine rupture, or umbilical cord rupture as a result of sudden tension on a short or tangled cord. A tight nuchal cord can reduce blood volume in a newborn by approximately 20%. Holding a newly delivered infant above the placenta can also reduce the Hct and blood volume because of the gravitational drainage of blood from the newborn into the placenta.

Internal Hemorrhage. A drop in the Hct during the first 24 to 72 hours that is not associated with hyperbilirubinemia is usually attributed to internal hemorrhage. Bleeding can occur in various parts of the body secondary to birth trauma or preexisting anomalies. The areas of potential hemorrhage in the head include the subdural, subarachnoid, intraventricular, intracranial, and subgaleal spaces. Infants can lose an estimated 10% to 15% of their blood during an intraventricular or intracranial hemorrhage. In cases of traumatic delivery or vacuum extraction, extensive scalp bleeding can result in the subgaleal space as a result of the emissary vein rupturing. Significant blood loss can occur as the subgaleal space can hold up to 240 mL of blood. Blood loss in the head can be estimated by measuring the increase in the head circumference. Each centimeter of increase represents an estimated 38 mL of blood lost from the intravascular compartment. Hemorrhage into the liver, kidneys, spleen, or retroperitoneal space can also occur in association with traumatic and breech deliveries.

Hepatic rupture occurs in approximately 1.2% to 5.6% of stillbirths and neonatal deaths; half of the hemorrhages are subcapsular. Infants with this disorder tend to be stable for 24 to 48 hours and then suddenly deteriorate. This deterioration seems to coincide with rupture of the capsule and hemoperitoneum. Hepatic rupture carries a poor prognosis, but rapid surgery preceded by multiple transfusions can save the infant. Splenic rupture is associated with severe EBF and should be suspected at the time of exchange transfusion if the central venous pressure is low rather than elevated. Signs of splenic rupture include scrotal swelling and peritoneal effusion without free air. Adrenal hemorrhage is seen more often in the infant of a diabetic or prediabetic mother and is characterized by a flank mass with bluish discoloration of the overlying skin.

RED BLOOD CELL DESTRUCTION AND HEMOLYSIS

Maternal–Fetal Blood Group Incompatibilities

Isoimmunization, as in ABO and Rh incompatibility, accounts for most cases of neonatal hemolysis. A reduced RBC life span caused by hemolysis is usually associated with a rise in the bilirubin level, 1 g of hemoglobin yielding 35 mg of bilirubin. Infants who have received intrauterine transfusions or exchange transfusions for blood group incompatibilities are predisposed to a hyporegenerative anemia that develops within the first few months of life. The pathophysiology is considered to be bone marrow suppression, possibly as a result of the increased amount of hemoglobin A received during the blood transfusions.

Acquired Defects of the Red Blood Cells. This hemolytic problem is seen in bacterial sepsis and viral infections, especially congenital infections such as syphilis, rubella, toxoplasmosis, CMV, or herpes, once referred to as TORCH, as well as human immunodeficiency virus and hepatitis. Drug-induced RBC destruction, caused by either maternal ingestion or direct administration of the drug to the newborn, is another common cause of hemolysis. An example of this would be the hemolysis that could occur with administration of iron supplements to an infant with vitamin E deficiency.

Congenital Defects of the Red Blood Cells. Defects resulting in destruction of the RBCs can involve the cell membrane, enzymatic system, or hemoglobin component, as in glucose-6-phosphate dehydrogenase (G6PD) deficiency, thalassemia, and hereditary spherocytosis. Although these conditions can cause hemolysis in the newborn period, they are rare diseases.

Blood Sampling. Blood loss that occurs secondary to sampling is one of the two most frequent causes of chronic anemia in infants, the other being physiologic anemia of the newborn and premature infant. For sick term infants, phlebotomy losses can account for 4% to 5% of blood volume, and in premature infants weekly phlebotomy losses in the first 4 weeks of life average 15% to 30% of their total blood volume (Widness, 2008). For those infants that had DCC, the DCC could lessen the amount of anemia, but a study by Elimian et al. (2014) demonstrated that this was not the case for premature neonates. **Quality and Safety: Prudent blood sampling may eliminate unnecessary blood volume depletion and reduce the need for replacement transfusion therapy.** Accurate recording of blood lost to sampling can prove beneficial in the assessment of a sick infant's circulatory status and volume needs. However, perfusion status and Hct values may be better determinants of the need for volume expansion or blood transfusions.

Differential Diagnosis

History. Acute and chronic anemia often can be distinguished from each other and from other problems by analyzing the family history for anemia or jaundice. The maternal history should be carefully examined for evidence of drug ingestion that may affect RBC life span or production, bleeding during the pregnancy or labor, or other incidents surrounding the delivery that may contribute to blood loss in the newborn.

Laboratory Findings. The type of anemia often can be identified on the basis of laboratory studies that evaluate RBC content and form.

- Hct and hemoglobin levels can define the type as well as the degree of anemia. Blood loss during acute hemorrhage is rapid, with little evidence of the compensatory hematopoiesis seen in chronic anemia. RBCs are of normal size and have a normal hemoglobin mass, and no significant increase is seen in the number of immature RBCs. Hemoglobin values initially may not reflect hemorrhage because the intravascular volume contracts and masks volume loss. It may take 3 to 4 hours for intravascular equilibration to occur before the hemoglobin accurately reflects the extent of the hemorrhage. The site of hemoglobin or Hct sampling is important for obtaining accurate information, because capillary sticks on an infant in shock reflect venous stasis. A more accurate sample at this time would be from an arterial or venous source.
- Reticulocyte counts are useful in differentiating chronic and acute forms of anemia. Increased numbers of immature RBCs reflect the degree of hematopoietic activity in response to anemia. Increased hematopoiesis requires a time lapse between the occurrence of anemia and stimulation of the hematopoietic centers.

- Peripheral blood smears are helpful in evaluating iron content and the size and shape of the RBC, which vary in different forms of anemia.
- Blood typing, Rh determination, and Coombs testing can help identify blood group incompatibilities as causes of anemia.

Treatment

Collaborative Management of the Infant With Acute Anemia. The following measures are used to stabilize the condition of an infant with acute anemia:

- Basic resuscitation of the infant experiencing precipitous blood loss often includes stabilization of the airway by means of intubation and ventilation.
- Rapid line placement for fluid replacement, volume expansion, and blood sampling may require use of the umbilical vein or artery. Central venous pressure measurements can be helpful in assessing the degree of volume loss and the amount of replacement needed.
- If acute volume expansion is required, normal saline is the volume expander of choice at 10 to 20 mL/kg. If time allows, fresh frozen plasma or low-titer, type O-negative blood can be used at the dosing of normal saline until a type and cross-match replacement is available. In an emergency situation, blood taken from the fetal side of the placenta after it is delivered in a sterile manner can also be infused into the neonate. Failure to respond may indicate continuing internal hemorrhage.
- After the infant's condition has been stabilized, laboratory tests and a physical examination should be performed to determine the cause of the anemia and to rectify the problem.
- Examination of the placenta and maternal blood sample testing for fetal hemoglobin may prove useful in determining the cause of the blood loss.

Emergency Alert: Anemia in the premature infant is a complication of being born prematurely or physiologic anemia, as well as phlebotomy losses related to lab draws. Anemia can be lessened by questioning the necessity of standing labs with the practitioner to eliminate unnecessary labs.

As with all newborns, the principles of care (provision of warmth, monitoring of vital signs, ongoing assessment, and accurate determination of intake and output) are essential to the well-being of the infant who has suffered acute blood loss. After initial stabilization, nursing care must include modifications that either eliminate recurrence of precipitous events or prevent further blood loss. Providing safe care to such infants requires adequate knowledge of the principles and procedures involved in volume expansion and the use of blood products. A review of the use of blood products can be found at the conclusion of this chapter.

Collaborative Management of the Infant With Chronic Anemia. The major focus of therapy for the infant with chronic anemia is control or elimination of the cause of the anemia. Several forms of chronic anemia in term and preterm infants are linked to dietary deficiencies that can be eradicated by replacement therapy. Chronic forms of anemia requiring symptomatic therapy can also be treated with transfusion therapy and erythropoietin.

Dietary Supplementation. The three major dietary factors that affect RBC production are iron, folate, and vitamin E. Because all three increase in amount with increasing gestational age, premature birth predisposes the immature infant to anemia as a result of insufficient stores.

Without the benefit of iron supplementation, the hematopoiesis necessary to maintain a normal hemoglobin level depletes the infant's iron reserves by the time birth weight is doubled. Various factors can further contribute to iron deficiency anemia, such as low birth weight, low initial hemoglobin levels, and blood loss through trauma, hemorrhage, or sampling. In the term infant, exhaustion of iron reserves normally occurs by 20 to 24 weeks postnatal age, but this happens much earlier in the preterm infant. Iron stores needed for hemoglobin production are present in insufficient quantities at birth in the premature infant, making supplementation necessary during the first 2 to 4 months to prevent iron deficiency anemia.

In any gestational age group, iron depletion first becomes evident in reduced serum ferritin levels (serum ferritin being a measure of accumulated iron stores) and in the disappearance of stainable iron from the bone marrow. A subsequent reduction in the mean corpuscular volume of the RBC is followed by a drop in the hemoglobin level. Although prophylactic iron supplementation does not prevent the initial fall in hemoglobin, the administration of 1 mg/kg/day for exclusively breastfed infants or breastfed infants that receive 50% of their nutrition through breast milk starting at 4 months of age, and 2 mg/kg/day of supplemental iron, should supply preterm infants starting at 1 month of age with adequate reserves; 2 to 4 mg/kg/day is recommended in iron-deficient infants or those receiving erythropoietin. Term infants on formula do not need supplementation as commercial formula has iron (Baker et al., 2010).

Folate is the generic description for folic acid and its related compounds. Folate is a component of the B-complex vitamins involved in the maturation of RBCs, particularly the synthesis of DNA, which controls nuclear maturation and division. Because bone marrow is one of the body's faster growing and more proliferative tissues, folic acid deficiency diminishes its ability to produce RBCs, resulting in a megaloblastic anemia.

High amounts of folate are present at birth in both term and preterm infants, but these levels drop rapidly, especially in LBW infants. It is estimated that approximately 68% of infants weighing less than 1,700 g have subnormal levels of folate at 1 to 3 months of age. However, only a few infants actually develop anemia. Human milk and soy-based products contain an adequate amount of natural folate, but commonly used commercial products must be artificially enriched. Premature infant formulas are adequately enriched to satisfy a premature infant's folate needs provided that intake is sufficient. Because folate is absorbed in the duodenum and jejunum, any disease or medication that affects the absorptive surface of these areas can impair folate absorption (Gallagher, 2015).

Vitamin E, an antioxidant, is valuable in protecting the RBC membrane from destruction due to lipid peroxidation. Deficiency of this nutrient shortens the life span of the cell by exposing the unprotected, unsaturated membrane lipids to peroxidation and hemolysis. Infants are born in a state of relative vitamin E deficiency that is more intense in the smaller and more premature infants. Vitamin E is required in increasing amounts as the intake of polyunsaturated fatty acids increases. Deficiency becomes apparent in infants of birth weights less than 1,500 g at approximately 4 to 6 weeks of age, resulting in decreased hemoglobin levels ranging from 7 to 10 g/dL. The administration of iron supplementation in the presence of vitamin E deficiency will intensify the hemolytic response. Signs and symptoms, as with many neonatal diseases, mimic those of other disease entities that occur in the neonatal period. One of the more obvious symptoms is edema of the feet, lower extremities, and scrotal area. The appearance of the RBCs may vary, but abnormalities usually include fragmented or irregularly shaped cells, presence of spherocytes, and thrombocytopenia. Infant formulas are now enriched with adequate amounts of vitamin E, provided formula intake is sufficient.

Transfusion Therapy. In the past, of all preterm infants admitted to a NICU, approximately 90% received one transfusion in the first 6 weeks of life; 50% received cumulative transfusions in excess of their total circulating RBC mass. Today, transfusions have declined as the result of the improved treatment and prevention of neonatal lung disease, the reduction of blood loss from gas and chemistry analysis, early protein and adequate iron supplementation, as well as the use of transfusion guidelines (Gallagher, 2015). In determining which infants may need subsequent transfusions after the first 2 weeks of life, gestational age of less than 30 weeks is the best predictor, regardless of severity of illness, number of transfusions during the first week, complications, or Hct level at birth. Only 14% of infants of more than 30 weeks' gestation require transfusions after 2 weeks of age.

Although a critically ill infant is generally maintained with an Hct level above 40%, the benefits of transfusion therapy in the convalescent infant remain controversial. When the effects of transfusion therapy in the convalescent infant were studied, the elimination of symptoms attributed to anemia was not a consistent finding. In premature infants with an Hct level below 30%, apnea, bradycardia, dyspnea, feeding difficulties, poor weight gain despite good calorie intake, lethargy, tachypnea, tachycardia, and increased cardiac output and oxygen consumption appear to be relieved by transfusion therapy in some studies. There appears to be no overall relationship between Hct values and physiologic symptoms such as apnea, bradycardia, or changes in heart and respiratory rates, nor does abatement of these symptoms follow transfusion therapy (Gallagher, 2015).

In light of the controversy surrounding transfusions, evidence of impaired tissue oxygenation remains the ultimate criterion for the use of blood products. Measurement of lactic acid levels may prove helpful in determining which infants may benefit from transfusion therapy. When the oxygen-carrying capacity of hemoglobin is insufficient for tissue needs, anaerobic metabolism occurs, leading to excess production of lactic acid. Monitoring of lactic acid levels and transfusing only those infants with elevated levels may aid in establishing more sound criteria for transfusion therapy.

Several methods of blood preparation and use have been evaluated to minimize donor exposure and reduce the potential for transmitted disease. Studies suggest that packed RBCs with a shelf life of more than 5 days, and up to 42 days, are safe for use in neonatal transfusions (Nunes dos Santos & Trindade, 2011). This finding, combined with the use of a sterile connection device that allows multiple aseptic entries into a unit of blood, would permit the use of a designated unit for each infant at risk for multiple transfusions, thereby significantly reducing donor exposure (Nunes dos Santos & Trindade, 2011). The desire to limit donor exposure must inevitably be balanced by the limited availability of banked blood. Multiple users on a blood unit may reduce wastage but may possibly expose an infant to multiple donors.

Blood administered to the newborn is often irradiated, which causes cell membrane disruption and potassium leakage from the cell. The decision by the U.S. Food and Drug Administration to change its recommendations for the maximum storage time of irradiated blood from 42 to 28 days affects the length of use of a designated unit. Although older blood appears to be safe to administer, it is not recommended for rapid transfusions, administration of large aliquots, exchange transfusions, or treatment of coagulopathies.

The establishment of transfusion criteria can effectively minimize donor exposure. These guidelines help determine which infants would benefit from transfusion on the basis of symptoms, Hct value, and severity of illness (Fasano, Said, & Luban, 2015; Nunes dos Santos & Trindade, 2011).

Recombinant Human Erythropoietin Therapy. Cloning of the human erythropoietin (HuEPO) gene in 1985 resulted in the production of large amounts of HuEPO for use as an exogenous stimulant of erythroid progenitor cells in patients with anemia. HuEPO acts primarily on CFU-E, derivatives of the hematopoietic stem cells in the bone marrow and the precursors of the RBCs (Figure 13.9). Studies from the United States and England have shown the use of recombinant erythropoietin to be an effective replacement for transfusion therapy in raising the hemoglobin level in hyporegenerative anemia and end-stage renal disease. Further studies of preterm infants have demonstrated that HuEPO maintains the Hct level during the phase of normal anemia of the premature infant, with good proliferation of erythroid progenitor cells in response to HuEPO.

HuEPO attained recognition as a standard of care for anemia of prematurity, because several clinical trials established its effectiveness in reducing both the number of transfusions and the cumulative volume of transfused blood needed in treated patients. A Cochrane review of literature by Aher and Ohlsson (2012) showed in comparing early versus late erythropoietin usage for preventing RBC transfusion for preterm and/or LBW infants that early erythropoietin (before 8 days of age) did not significantly reduce the use of one or more RBC transfusions or the number of transfusions per infant compared to late administration of erythropoietin. They did find a statistically significant increased risk of retinopathy of prematurity of any stage in those in the early treatment groups as well as for retinopathy greater than stage 3, which is concerning. Aher and Ohlsson also looked at late erythropoietin usage to prevent RBC transfusion in preterm and/or LBW infants. In this review they found that the administration of erythropoietin at 8 days or after did decrease the use of one or more RBC transfusions and the number of transfusions per infant. There was no decrease or increase in clinically important adverse outcomes with the late use of erythropoietin. They noted that donor exposure was not reduced as all infants had had a transfusion prior to the administration of the erythropoietin.

The use of erythropoietin in treating anemia of prematurity varies according to the physician and institution where the neonate is hospitalized. If used, the usual response in preterm infants given HuEPO is an increase in blood levels of erythropoietin and reticulocytes, as well as RBC volume, 2 to 3 weeks after initiation of therapy. The accepted dosage of erythropoietin is 150 to 1,500 U/kg/week divided into two to five doses. The commonly used dose is 250 U/kg/dose. The dose is given subcutaneously in rotating sites three times a week for 10 doses and should have supplemental iron given (Lexicomp Online, 2018).

HuEPO has been evaluated for its effectiveness as an alternative to transfusion therapy for treatment of anemia in premature infants caused by (a) blood sampling, with administration beginning within the first 2 days of life, (b) physiologic anemia of prematurity, with therapy starting at 1 to 4 weeks of age, and (c) anemia of bronchopulmonary dysplasia, with treatment starting at 3 months of age.

Serum ferritin levels decline rapidly after initiation of HuEPO therapy in infants with normal pretreatment ferritin levels, despite prophylactic iron supplementation of 2 mg/kg/day. This predisposition to the development of iron deficiency anemia underlines the need for increased iron supplementation in infants treated with HuEPO. Also documented as side effects of HuEPO therapy are transient thrombocytosis shortly after the initiation of therapy and transient neutropenia. The transient neutropenia can last as long as 2 months after discontinuation of therapy. It has been postulated that this phenomenon is due to a stimulant effect of HuEPO on megakaryocyte progenitors and a negative

effect on granulocyte–monocyte progenitor cells. Before HuEPO was proven effective in raising Hct levels, its use was projected to eliminate the need for one third of all transfusions in premature infants.

PHYSIOLOGIC ANEMIA OF THE NEWBORN AND ANEMIA OF THE PREMATURE INFANT

Shortly after birth, the physiologic regulator of RBC production, erythropoietin, falls to barely perceptible levels because the relative intrauterine hypoxia that stimulated its release in-utero is no longer present. Erythropoietin levels remain low until another hypoxic stimulus occurs, one created by the normal drop in the hemoglobin level that marks physiologic anemia of the newborn. This drop in the hemoglobin level is due to decreased marrow production of RBCs secondary to diminished circulating erythropoietin levels, a shorter life span of the neonatal RBC with destruction of fetal hemoglobin, and hemodilution caused by growth.

The drop in hemoglobin that prompts the postnatal rise in erythropoietin directly correlates with the infant's gestational age and birth weight (Figure 13.11). The smaller and more immature infant reaches a lower nadir at an earlier postnatal age. The hemoglobin level in the term newborn reaches a nadir of 11.4 g/dL ±0.9 in the first 2 to 3 months of life and plateaus at this level for approximately 2 more months before it gradually increases. Although there is no significant difference in cord-blood hemoglobin levels between term infants and preterm infants born after 32 weeks' gestation, the drop in hemoglobin occurs earlier in the preterm infant, is more precipitous, and reaches a lower nadir. Starting at 2 weeks of age, the preterm infant has a drop in hemoglobin of 1 g/dL/week for the first several weeks; the nadir at 6 to 8 weeks of age is 2 to 3 g/dL lower than that of the term infant. An infant weighing 1,000 to 1,500 g at birth will have a mean hemoglobin nadir of 8 g/dL at 4 to 6 weeks of age.

Infants who have undergone exchange transfusion or multiple transfusions also have a greater fall in their hemoglobin level in the first 3 months of life. This phenomenon theoretically may be due to improved oxygen delivery to tissue associated with the replacement of fetal hemoglobin with adult hemoglobin. Adult hemoglobin has less affinity for oxygen because of the structural difference of the globin portion of the hemoglobin molecule. This, coupled with the increased amount of 2,3-disphosphoglycerate present in the blood, allows adult hemoglobin to release oxygen to the tissue more easily. Improved tissue oxygenation effectively lowers serum erythropoietin levels (Figure 13.11), resulting in decreased RBC production. Consequently, an infant undergoing intrauterine transfusion, exchange transfusion, or frequent postnatal transfusions has improved tissue oxygenation and a decreased erythropoietin level.

The switch in the predominant site of erythropoietin production during fetal life from the liver to the kidneys occurs concurrently with the change in hemoglobin to a more mature form. Hepatic production of erythropoietin in response to hypoxia is not as rapid as the kidneys' response, an adjustment that actually spares the fetus from polycythemia in-utero. However, persistence of this hepatic pathway after premature birth may explain why the premature infant's Hct values reach a lower nadir that persists longer compared with the term infant. Although erythropoietin levels are reduced in the early newborn period, the erythroid progenitor cells in the bone marrow are exceedingly sensitive to erythropoietin and respond rapidly as blood levels increase. The normal erythropoietin level in infants beyond the newborn period is 10 to 20 U/mL.

Treatment

Physiologic anemia does not usually require any form of treatment. With good nutrition, the hemoglobin level in the term infant should start to rise by 3 months of age. With adequate nutrition and iron supplementation, the hemoglobin level in the preterm infant should start to increase by 5 months of age, eventually attaining hemoglobin values comparable to those of the term infant. Controversy remains though for the preterm infant with symptomatic anemia of prematurity on how to best treat the infant.

The controversy is on the use of blood transfusion of packed red blood cells (PRBC) versus recombinant erythropoietin (EPO) therapy. PRBC transfusion has been the mainstay of treatment for symptomatic anemia of prematurity, but with increasing evidence on complications of transfusions and concern of exposure to multiple donors the use of it has been questioned. Complications associated with blood transfusions are infections, fluid overload and electrolyte imbalances, exposure to plasticizers, hemolysis, hypoglycemia, hyperkalemia, hypocalcemia, transfusion reactions

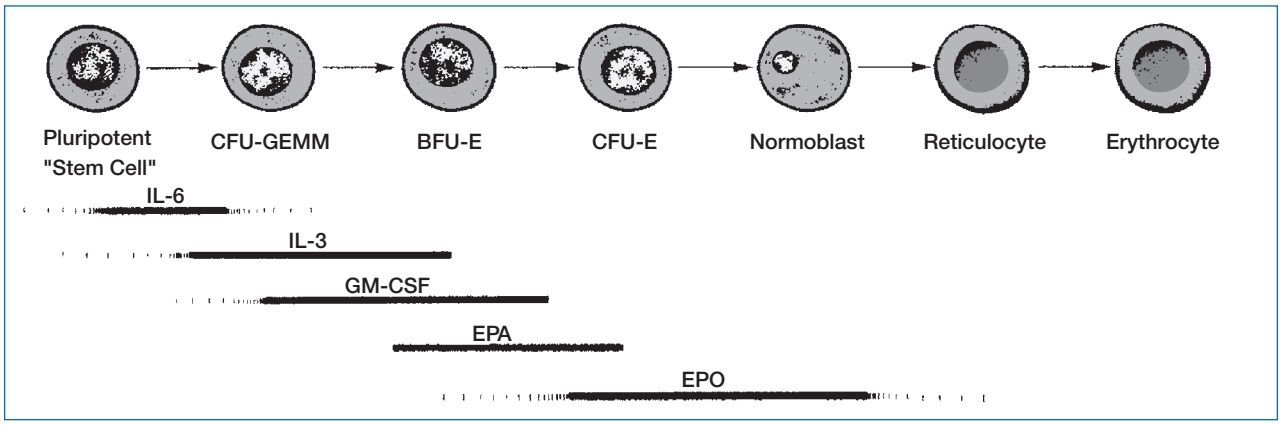

FIGURE 13.10 The principal action of human recombinant erythropoietin is on the derivatives of the hematopoietic stem cells in the bone marrow that have been designated erythrocyte colony-forming units (CFU-E), the precursors of the red blood cell (RBC).

BFU-E, erythrocyte burst-forming units; CFU-GEMM, colony-forming units—granulocytes, erythroid cells, macrophages, and megakaryocytes; EPA, erythroid potentiating activity; EPO, erythropoietin; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-3, interleukin-3; IL-6, interleukin-6.

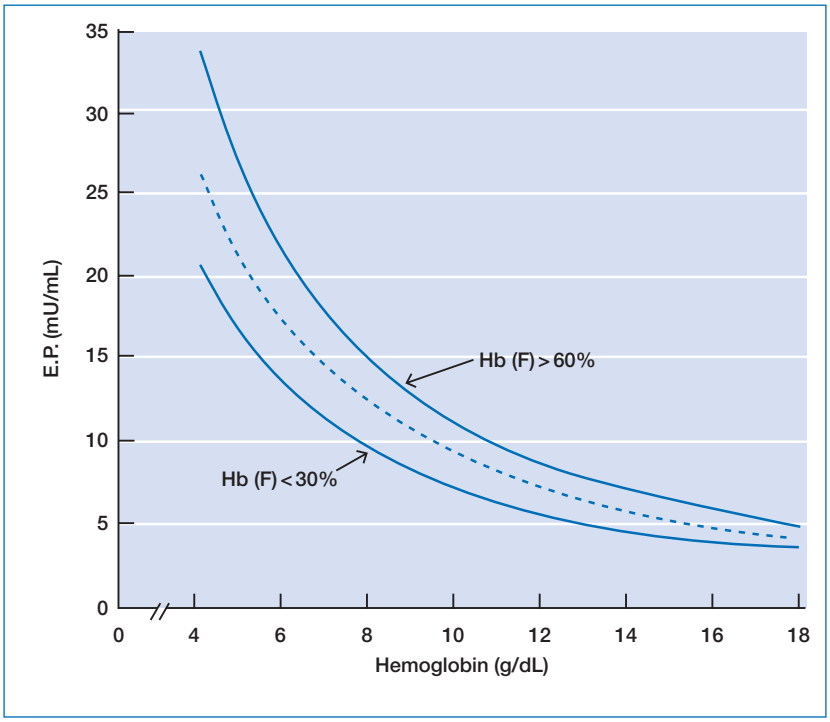

FIGURE 13.12 Because of the differences in oxygen affinity between adult and fetal hemoglobin, variations in the percentage of available fetal hemoglobin (hemoglobin F) affect erythropoietin levels. Improved oxygen uptake but decreased unloading at the tissue level is associated with hemoglobin F. Therefore, the stimulus for erythropoietin production is diminished with lower concentrations of hemoglobin F (<30%). With higher concentrations (60%) of hemoglobin F, the stimulus response is an increase in erythropoietin production. At identical total hemoglobin levels, the stimulus for erythropoietin production is increased whenever the percentage of hemoglobin F exceeds the adult norm.

(though rare), necrotizing enterocolitis, and intraventricular hemorrhage (Cassady, 2016; Fasano et al., 2015).

An alternative to blood transfusion is the use of HuEPO to prevent anemia. Premature neonates have physiologically lower levels of EPO and use pharmacologically available HuEPO to stimulate bone marrow production of RBCs and decrease the number of blood transfusions. As stated earlier, a Cochrane review in 2012 compared early (before 8 days of life) versus late EPO (on or after 8 days of life) usage in premature infants. The early group had decreased RBC transfusions and donor exposures, but it did not eliminate the transfusions and did not affect mortality or morbidities, except to increase the incidence of retinopathy of prematurity. The late group decreased the number of RBC transfusions, but not total blood volume. In both studies infants had received RBC transfusion prior to the administration of EPO. The authors concluded that efforts should be made to limit transfusions and donor exposure in the first days of life. Stable larger infants respond better to EPO than more extremely premature infants. It is important to note that in 2007 the Food and Drug Administration (FDA) put out a Black Box warning for the use of EPO in the adult population due to the increased risk of death, myocardial infarctions, stroke, venous thrombosis, and cancer progression. There are pros and cons to each therapy and the controversy continues. The question of which one is best has not yet been answered conclusively.

Polycythemia

Pathophysiology. Polycythemia is defined as a peripheral venous Hct level over 65%, or a Hct level two standard deviations above the mean. Polycythemia occurs in 4% to 5% of the total population of newborns, in 2% to 4% of term infants appropriate for gestational age, and in 10% to 15% of infants either small or large for gestational age. It has not been observed in infants of less than 34 weeks' gestation. Although the fetus lives in a low-Po_2 environment that should induce a polycythemic response, it protects itself by keeping Hct levels below 60%. This may be a function of slower fetal hepatic response to hypoxia compared with rapid renal response after birth. The average Hct on the first day of life is approximately 50% in the term infant and the preterm infant of more than 32 weeks' gestation and 45% in the preterm infant of less than 32 weeks' gestation. During the first 4 to 12 hours of life, hemoglobin and Hct values rise due to fluid shifts and then equilibrate, especially in infants receiving large placental transfusions.

The choice of sampling site can affect Hct values considerably, particularly during the early newborn period when peripheral circulation may be somewhat sluggish. Infants younger than 1 day of age either lack or have diminished cutaneous vasoregulatory mechanisms that reduce peripheral perfusion. Capillary blood sampling sites will have the highest Hct, then blood from a peripheral site, with central blood having the lowest Hct. Compared with venous samples, the Hct levels of capillary samples are 5% to 15% higher, and those of umbilical vessel or arterial samples are 6% to 8% lower.

The main concern with polycythemia is that it can impair peripheral circulation by increasing blood viscosity and reducing the flow rate. As blood viscosity increases, vascular resistance increases in the peripheral circulation and the microcirculation of the capillaries throughout the body. Three major factors determine blood viscosity: Hct, plasma viscosity (osmolality), and deformability of the RBCs. With Hct levels below 60% to 65%, blood viscosity increases in a linear fashion, but viscosity exponentially increases at higher Hct levels (Diab & Luchtman-Jones, 2015).

Variations in the components of plasma affect blood viscosity independent of the Hct. Abnormal composition of plasma protein, electrolytes, and other metabolites can either decrease or increase plasma viscosity. Such an increase in the presence of a high Hct level further increases blood viscosity and reduces the blood flow rate. The ability of cells to modify their shape to successfully traverse the peripheral vascular bed and microcirculation also affects the blood flow rate. The degree of deformability of the cell determines its ability to pass through small vascular spaces; the greater the deformability of the cell, the quicker its passage. Less deformable cells can increase blood viscosity by occluding small vessels, causing sludging in the microcirculation that can lead to thrombosis and tissue ischemia.

The two major types of polycythemia are (1) the active form, which is caused by the production of an excess number of RBCs in response to hypoxia and other poorly defined stimuli; and (2) the passive form, which is caused by RBC transfusion to an infant secondary to maternal–fetal transfusion, twin-to-twin transfusion, or DCC (Diab & Luchtman-Jones, 2015).

Active Polycythemia. Tissue hypoxia, regardless of the cause, elicits an increase in erythropoietin that stimulates RBC production. In the fetus, erythropoietin is produced initially by the liver and then by the kidneys, the adult production site. The kidneys' potential to release erythropoietin is active by 34 weeks' gestation. At this time, a renal erythropoietic factor reacts with a substance in the plasma to produce erythropoietin, the RBC stimulating factor. Hypoxia of the tissues adjacent to the renal tubules, where erythropoietin is produced, is the potent stimulator of this factor's release.

Many factors can lead to tissue hypoxia associated with the active form of polycythemia. These factors include the following:

1. Maternal factors that result in reduced placental blood flow
   - Pregnancy-induced hypertension
   - Older maternal age
   - Maternal renal or heart disease
   - Severe maternal diabetes (Hct values of 64% or higher are found in 42% of infants of a diabetic mother and 30% of gestational infants of a diabetic mother)
   - Oligohydramnios
   - Maternal smoking (the mechanism is thought to be production of carbon monoxide that crosses the placenta and induces a state of tissue hypoxia in the fetus)
2. Placental factors
   - Placental infarction
   - Placenta previa
   - Viral infections, especially TORCH
   - Postmaturity
   - Placental dysfunction that results in a small-for-gestational-age (SGA) infant
3. Fetal syndromes
   - Trisomies 13, 18, and 21
   - Beckwith–Wiedemann syndrome (Diab & Luchtman-Jones, 2015; Kandasamy, 2017)

Passive Polycythemia. Passive polycythemia is a result of increased fetal blood volume caused by maternal–fetal transfusion, or twin-to-twin transfusion, with one twin being polycythemic and the other anemic. A diagnosis of maternal–fetal transfusion can be considered when (a) the infant's blood is found to contain larger amounts than expected of adult hemoglobin, IgA, or IgM; (b) RBCs in the infant's blood have maternal blood group antigens, if the mother's and the infant's blood groups are different; or (c) XX cells are found in an XY infant. In twin-to-twin transfusion, morbidity and mortality are comparable in both groups of affected infants, with one twin being anemic and the other polycythemic.

Clinical Manifestations. Symptoms of polycythemic hyperviscosity, which are usually evident within the first few days

after birth, reflect compromise of various organ systems. The most commonly seen findings include the following:

1. Neurological symptoms
   - Lethargy or irritability
   - Hypotonia
   - Tremulousness
   - Exaggerated startle
   - Poor suck
   - Vomiting
   - Seizures
   - Apnea
2. Cardiovascular symptoms
   - Plethora
   - Cardiomegaly
   - Electrocardiographic changes (right and left atrial hypertrophy, right ventricular hypertrophy)
3. Respiratory symptoms
   - Respiratory distress
   - Central cyanosis
   - Pleural effusions
   - Pulmonary congestion and edema
   - Persistent pulmonary hypertension of the newborn
4. Hematological symptoms
   - Hyperbilirubinemia
   - Thrombocytopenia
   - Elevated reticulocyte level
   - Coagulopathies
   - Hepatosplenomegaly
   - Renal and/or cerebral vein thrombosis
5. Gastrointestinal symptoms
   - Poor feeding
   - Necrotizing enterocolitis
6. Genitourinary symptoms
   - Oliguria
   - Hematuria
   - Proteinuria
7. Metabolic symptoms
   - Hypocalcemia
   - Hypoglycemia (Diab & Luchtman-Jones, 2015; Kandasamy, 2017)

Hypoglycemia found in conjunction with polycythemia can be a reflection of (a) increased glucose consumption by an overabundant number of RBCs; (b) increased cerebral extraction of glucose secondary to hypoxia; (c) a state of hyperinsulinemia caused by increased erythropoietin levels; or (d) decreased hepatic glucose production as a result of sluggish hepatic circulation. Hyperbilirubinemia associated with polycythemia is a reflection of increased by-products of RBC destruction.

The complications of polycythemia center around the increased resistance to blood flow related to hyperviscosity; blood flow to all organ systems is impaired by sluggish circulation. Pulmonary blood flow can be dramatically compromised, resulting in pulmonary hypertension, retained lung fluid, and respiratory distress syndrome. Taxation of the heart by an increased vascular load can lead to congestive heart failure and left to right shunting across the foramen ovale or ductus arteriosus. **Emergency Alert: Sludging of blood in the microcirculation of the kidneys can lead to renal vein thrombosis and renal failure.** Impairment of blood flow to the bowel can lead to necrotizing enterocolitis (Kandasamy, 2017).

Treatment. Although most infants with polycythemia are asymptomatic or minimally symptomatic, the Hct level and the presence of symptoms, even if minimal, should form the basis of treatment. Majority of neonates will need to be observed for cardiac and respiratory status, have Hct drawn every 6 to 12 hours, and observed for signs of the problems noted in the previous list. For those with a Hct level between 65% to 75%, supportive treatment of fluid boluses of normal saline to prevent the Hct from increasing any further is needed (Kandasamy, 2017).

Partial exchange transfusions were standard treatment for infants that were symptomatic with Hct levels between 60% to 65% or for infants that were asymptomatic with a Hct level greater than 65% due to increased incidence of neurological abnormalities or changes, but are now controversial if they do more harm than good. The AAP still supports partial exchange transfusion for polycythemia but admits that no evidence is available to support that a partial exchange transfusion improves long-term neurological outcomes.

Partial exchange has been to show a dramatic improvement in symptomatic infants, relieving congestive failure and improving CNS function. It also corrects hypoglycemia, relieves respiratory distress and cyanosis, and improves renal function (Kandasamy, 2017).

If a partial exchange transfusion is done, normal saline is the replacement fluid of choice for the removed aliquot of blood. Plasmanate, 5% albumin, or fresh frozen plasma has been used in the past, but due to the advent of stricter precautions for prevention of viral transmission by blood products, use of these items would not seem advisable (Kandasamy, 2017). The formula for calculating the partial replacement of blood volume is: blood volume [patient's Hct − desired Hct] / patient's Hct. The blood volume is the patient's weight × 90 mL/kg of blood.

Collaborative Management of the Infant With Polycythemia. The care of any newborn infant should include a screening Hct determination for polycythemia by 12 hours of age. This allows both detection of polycythemia and adequate observation before symptoms become apparent. Because the initial sample is usually obtained by heel stick or finger stick, detection of a high value should be followed by venipuncture confirmation. The infant should be kept adequately hydrated and closely monitored for hypoglycemia and hypocalcemia. A Hct value over 65% should prompt careful observation of the infant for any symptoms associated with hyperviscosity. If symptoms appear, the infant should undergo partial exchange transfusion. During the partial exchange, the same care should be provided as that given during a single-volume or double-volume exchange transfusion.

COMMON COAGULATION DISORDERS IN THE NEWBORN

Vitamin K Deficiency Bleeding

The liver produces most of the clotting factors, including those of the prothrombin complex. Adequate function of this complex requires the specific action of vitamin K, which is continuously synthesized by bacteria in the bowel. Vitamin K is not directly involved in the synthesis of these factors but is required for the conversion of precursor proteins produced by the liver into active factors having coagulant capabilities. Vitamin K is especially necessary for conversion of prothrombin binding sites into forms that can bind calcium, which is required for the completion of many steps in the clotting cascade.

Vitamin K–dependent factors reach approximately 30% to 70% of adult levels in the cord blood of term infants but quickly drop to half that amount if the infant is not given vitamin K. Because these factors are dependent on gestational age, the more

premature the infant, the lower the levels at birth. The exaggerated drop after birth may be due to poor placental transfer of maternal vitamin K, immature liver function, and delayed synthesis of vitamin K by the bowel. Vitamin K–dependent factors slowly rise but do not reach normal adult levels until approximately 9 months of age. Administration of approximately 0.5 to 1.0 mg of vitamin K can prevent this decline and normalize the prothrombin time (Blackmon et al., 2003).

Hemorrhage during the early neonatal period that can be attributed to a deficiency of vitamin K–dependent factors is classified as vitamin K deficiency bleeding (VKDB) or hemorrhagic disease of the newborn. The incidence is 1/100,000 live births in developed countries in infants who receive vitamin K prophylaxis and 1.7/1,000 for infants who do not receive the prophylaxis at birth, which is 81 times higher incidence (Warren, Miller, Traylor, Sidonio, & Morad, 2013). There are three identified forms of VKDB—early, classic, and later VKDB. The early form, the least common type, is characterized by bleeding within the first 24 hours of life in the scalp, subperiosteal, skin, intracranial, intrathoracic, or intraabdominal sites.

Early bleeding is usually associated with maternal anticonvulsant therapy. It is theorized that anticonvulsants may induce fetal hepatic enzymes involved in the degradation of already low levels of fetal vitamin K. Early neonatal bleeding cannot be prevented by postnatal administration of vitamin K. Daily antenatal administration of large doses of oral vitamin K (10 mg) to mothers receiving anticonvulsant therapy for at least 10 days before delivery was found to be beneficial to the newborn. Vitamin K crosses the placenta, elevating newborn levels of vitamin K for 10 days after birth, with the increase in levels correlating with the timing of the last prenatal dose.

The classic form of VKDB usually occurs during the first 2 to 7 days of life and manifests as generalized and, occasionally, dramatic bleeding. The most common sites are the gastrointestinal tract, umbilicus, circumcision site, skin, and internal organs. Classic VKDB was common in the United States until 1961 when the AAP made the recommendation for the administration of vitamin K to all newborns at birth. The cause of VKDB is now mostly due to parental refusal of the vitamin K shot at birth for multiple reasons. Reasons given by parents in a report by Warren et al. (2013) were: (a) vitamin K is not needed for healthy babies especially if they aren't being circumcised, (b) vitamin K increases the chances of childhood cancer, (c) oral vitamin K supplementation is adequate, (d) breast milk contains more than enough to keep my baby from bleeding, and (e) the baby clotting ability is normal at 8 days of life. All of these reasons are myths and need to be addressed with parents who refuse vitamin K prophylaxis. While breast milk has vitamin K, it is inadequate to make up the deficiency of vitamin K an infant is born with, considering the limited amounts the infant initially takes, if the infant did not receive prophylactic vitamin K. **Emergency Alert: VKDB can be devastating to the newborn infant and is preventable by the provision of a vitamin K injection within 6 hours of birth. It is of utmost importance for the neonatal nurse to dispel any misconceptions regarding vitamin K administration with parents of newborns.**

The late form of VKDB occurs after the first week of life up to 6 to 9 months of age, with the average presentation being between 14 days and 3 months. Late-onset VKDB is more devastating than the early form because of the higher incidence of intracranial hemorrhage (the risk approaches 63%). Permanent neurologic sequelae are seen in 24% of affected infants, and the mortality rate can be as high as 14%. This form of hemorrhagic disease is associated with chronic disease states that interfere with fat absorption or the performance of intestinal flora, as well as parental refusal of vitamin K at birth in breastfed infants. Both early and late hemorrhagic disease of the newborn is intensified in breastfed infants. Definitive diagnosis rests on a history of lack of vitamin K prophylaxis at birth and a prolonged prothrombin time that measures the prothrombin complex clotting factors (Factors II, VII, IX, and X). One test, the protein induced by vitamin K absence or antagonist-II (PIVKA-II) test, is useful in identifying proteins induced by vitamin K deficiency that appear in the plasma of vitamin K–deficient infants. These proteins consist of the inert and functionally defective precursors of prothrombin that are produced when vitamin K levels are deficient.

Several factors can predispose an infant to hemorrhagic disease of the newborn. Almost all these factors involve some form of hepatic dysfunction. The most obvious predisposing factor is the failure of an infant to receive prophylactic vitamin K postnatally. Other risk factors include maternal ingestion of anticonvulsants and coumarin anticoagulants (which interfere with the action of the prothrombin complex factors), birth asphyxia, prolonged labor, and breastfeeding.

Human milk has lower vitamin K content than cow's milk. Infants receiving a commercial formula for 24 hours have prothrombin times similar to those of infants receiving vitamin K after birth. Infants with hepatic dysfunction or bowel malabsorption, although not found strictly in the early neonatal period, can develop vitamin K deficiency despite having received prophylaxis at birth. Such disorders as chronic diarrhea, biliary atresia, hepatitis, cystic fibrosis, and prolonged parenteral nutrition do not allow adequate vitamin K production and can result in low prothrombin complex factors. These infants benefit from weekly vitamin K supplementation (1 mg given intramuscularly), the dose recommended by the AAP Committee on Fetus and Newborn (Blackmon et al., 2003) for postnatal newborn prophylaxis. The suggested preparation for administration to the newborn is the natural aqueous solution of vitamin K rather than the synthetic preparation, which can cause hemolysis. Because of preterm infants' hepatic immaturity and inability to effectively synthesize clotting factors, these infants' response to vitamin K is not as predictable as that of term infants.

Controversy continues over whether intramuscular or oral prophylaxis should be used. At one time, intramuscular administration of vitamin K was linked to the occurrence of childhood cancers; however, this charge has not been substantiated by research. The use of one or two oral doses of vitamin K as an effective treatment is also disputed, and research is needed to determine its efficacy. Research continues in an effort to determine the appropriate timing and number of oral doses of vitamin K and to develop a better oral preparation. Alternative therapies are also being investigated, including antenatal maternal dosing to prevent antenatal intraventricular hemorrhage and postnatal maternal dosing as prophylaxis in the breastfed infant.

Active bleeding caused by VKDB of the newborn consists of parenteral administration of vitamin K in a slow infusion or subcutaneously if unable to obtain venous access. Infants may also require blood replacement or the use of fresh frozen plasma for immediate clotting factor replacement and the use of prothrombin complex concentrates for severe bleeding or intracranial hemorrhage (Diab & Luchtman-Jones, 2015).

Hemophilia

Pathophysiology. Hemophilia A and B are the most common inherited bleeding disorders and are clinically indistinguishable. Classic hemophilia (hemophilia A) is the most frequently inherited coagulation abnormality, accounting for 90% of all genetically

linked coagulopathies and 80% to 85% of all hemophilias, whereas hemophilia B (Christmas disease) occurs in 10% to 15% of cases. Both diseases are X-linked recessive disorders and are passed from mother to son. Hemophilia A is caused by Factor VIII deficiency and hemophilia B is caused by a Factor IX deficiency. Both factors are essential in normal thrombin production. They are needed for the activation of the pathway of Factor X, which converts prothrombin to thrombin. The absence of either factor severely impairs the body's ability to generate both thrombin and fibrin. A hemophiliac's problem is not that of bleeding more rapidly, but of abnormal clot formation. This results in hemorrhage with a potential for significant blood loss. When the clot does form it is often fragile, and rebleeding can occur if proper treatment does not occur.

The severity of the disease is dependent on the baseline level of Factor VIII or Factor IX. Levels of 1% to 2% are associated with severe disease, 2% to 5% with moderate disease, and over 5% with mild disease, a level at which active bleeding rarely occurs. In a retrospective study of hemophiliacs, approximately 44% of a group of severe hemophiliacs were symptomatic during the first week of life, whereas only 14% of a mildly affected group displayed any bleeding during the first 7 days of life (Schulman, 1962).

Diagnosis. Over 50% of hemophiliacs are diagnosed in the neonatal period and have bleeding from a circumcision site, scalp, umbilicus, intramuscular injection site, heel stick site, or brain, with the most common site being a subdural hemorrhage (Diab & Luchtman-Jones, 2015). Not all severe hemophiliacs bleed after circumcision in the early newborn period. The reason for this is unknown, but it has been suggested that tissue thromboplastin release, caused by the circumcision clamp on the foreskin, may initiate the extrinsic pathway and clotting cascade, preventing excessive bleeding. In addition, the use of vacuum or forceps can increase the chance of a hemophiliac bleeding in the brain.

Laboratory tests will be needed to determine if the infant is a hemophiliac. Tests needed will be a partial thromboplastin time, which will be prolonged, both Factor VIII and IX with the affected factor being decreased, and a prothrombin time, a thrombin time, and platelet count which will be relatively normal. Hemophilia A is easier to diagnose in the neonatal period than hemophilia B as Factor IX is reduced at birth and in preterm infants, which can delay diagnosis.

Prenatal diagnosis is possible through amniocentesis or chorionic villus biopsy. Diagnosis involves measurement of the ratio of factor antigen to coagulant antigen in blood samples of fetuses of more than 20 weeks' gestation. If diagnosed with Factor VIII deficiency, the infant should also be evaluated for von Willebrand disease.

Treatment. If diagnosed prenatally, vacuum extraction, forceps, fetal scalp electrodes, and fetal scalp blood sampling should be avoided. There is no consensus on delivery mode, and this should be determined based on maternal and neonatal factors.

Postnatally, the ultimate goal in the treatment of hemophilia is to raise the defective or deficient factor to a level that will prevent significant bleeding. For significant bleeding prior to diagnosis, fresh frozen plasma at 15 to 25 mL/kg should be given, and after diagnosis the specific factor should be given. To have replacement products be as free as possible of transfusion-transmissible diseases, it is recommended that recombinant products be used rather than plasma-derived products. Recombinant Factor VIII concentrates are preferred for hemophilia A, whereas recombinant Factor IX is preferred for hemophilia B (Diab & Luchtman-Jones, 2015; Drelich, 2019; Zaiden, 2017).

Desmopressin (DDAVP, 1-deamino-8-D-arginine vasopressin) is now the treatment of choice for mild to moderate hemophilia A or von Willebrand disease. This medication is not effective in the treatment of hemophilia B. The effectiveness and applicability of this therapy in the newborn are still unknown, but currently it is not recommended if the infant is younger than 3 months of age (Lexicomp Online, 2018).

Von Willebrand Disease

Von Willebrand disease is a disorder of the vWF, which contributes to the adherence of platelets to the endothelium and serves as a carrier protein for Factor VIII. A deficiency in this factor leads to mucocutaneous and postsurgical bleeding, or if it is absent or markedly reduced, it can lead to bleeding in joints and muscles similar to hemophilia A due to the reduction of Factor VIII. vWF levels are high at birth and in the neonatal period; thus, the chance of any bleeding being from von Willebrand disease is low. Since vWF serves as a carrier for Factor VIII, those who do present with bleeding will have signs and symptoms consistent with Factor VIII deficiency.

Infants with von Willebrand disease will present with similar symptoms as hemophiliacs with bleeding into the joints and intracranially. Lab tests to diagnose von Willebrand disease are bleeding time, activated partial thromboplastin time, platelet function screen, blood type, Factor VIII coagulant activity, vWF antigen, vWF activity, and multimetric analysis (Diab & Luchtman-Jones, 2015). Treatment methods are similar to those for hemophilia.

Thrombocytopenia

The normal range of platelets is 150,000 to 450,000/mm^3; the average count in the newborn is approximately 250,000/mm^3. Platelet counts below 150,000/mm^3 are considered abnormal and should be subject to investigation for a possible pathological process. Platelet function in the neonate reaches normal adult levels between the fifth and ninth postnatal days. Although 14% of all preterm infants and 4% of all term infants are thrombocytopenic, with platelet counts below 150,000/mm^3, not all of these infants are ill and will be treated.

Thrombocytopenia is the most common bleeding disorder in the newborn, with 20% to 35% of all NICU admissions and 70% of infants born at less than 1,000 g having the diagnosis during their NICU stay (Sallmon & Sola-Visner, 2012). Of the affected infants, 50% will have platelet counts less than 100,000/mm^3 and 20% will have platelet counts less than 50,000/mm^3 (Cantor, 2015). However, the pathogenesis of the thrombocytopenia can be determined in only 60% of these infants. Abnormalities of the platelet count are due to increased destruction or decreased production, and the underlying cause is mediated by maternal, placental, neonatal, or iatrogenic factors. In most thrombocytopenic newborns, platelet counts are low as a result of increased destruction rather than bone marrow depression. The overall mortality rate for infants with thrombocytopenia is 34%; 22% of these infants exhibit a bleeding diathesis. Infants with a platelet count below 20,000/mm^3 are at particularly high risk for bleeding.

Maternal Factors. Thrombocytopenia is the most common form of hemostatic problem present during pregnancy; 5% to 7% of healthy mothers have platelet counts below 150,000/mm^3. Some of the maternal factors associated with thrombocytopenia are maternal drug ingestion (e.g., chloramphenicol, hydralazine, tolbutamide, and thiazides), maternal eclampsia and hypertension, placental infarction, and immune-mediated maternal platelet antibodies.

Immune-Mediated Maternal Platelet Antibodies

Idiopathic Thrombocytopenia. With immune-mediated thrombocytopenia, in which maternal antibodies destroy platelets, 80% of cases are caused by the autoimmune form, or maternal idiopathic thrombocytopenic purpura (ITP), which strikes women during the second to third decade of life. ITP, now also referred to as autoimmune thrombocytopenia, is a preexisting condition in which maternal lymphocytes produce IgG antiplatelet antibodies (PAIgG) that attack maternal platelets, usually reducing the platelet count to below 150,000/mm^3. These antibodies are specifically directed at platelet antigen and bind to platelets, which are then phagocytized by cells carrying a specific receptor, the Fc receptor. The greatest number of cells with this receptor is found in the reticuloendothelial system of the spleen, which is also the major site of PAIgG production. ITP is often confused with HELLP syndrome, which, in addition to a low platelet count, involves hemolysis and elevated liver enzymes.

Because IgG can cross the placenta, fetal platelets can also be destroyed by the transplacental passage of platelet antibodies, resulting in thrombocytopenia in the fetus and newborn. The mortality rate is 1% to 10% in these affected infants, and the condition can persist postnatally for as long as 4 months.

Neonatal Alloimmune Thrombocytopenia. The remaining 20% of immune-mediated thrombocytopenia are caused by an alloimmune (isoimmune) reaction in which maternal antibodies are produced against foreign fetal platelets (paternally inherited), whereas maternal platelet levels remain normal. This reaction occurs when fetal platelets, which have an antigen not found on maternal platelets, pass into the maternal circulation. The resultant generation of maternal antibodies in response to the fetal platelets is similar to the mechanism behind Rh incompatibility. Unlike Rh incompatibility, alloimmune thrombocytopenia affects 33% to 50% of first pregnancies. The mother develops IgG antibodies that eventually cross into the fetal circulation, resulting in platelet destruction. The PlA1 alloantibodies are responsible for 50% to 80% of neonates with alloimmune thrombocytopenia. This phenomenon occurs in approximately one in 2,000 to one in 5,000 live births. The mortality rate of 10% to 15% in alloimmune thrombocytopenia is higher than that in ITP, because bleeding tends to be more severe. The incidence of intracranial hemorrhage in-utero is reported to be as high as 10% to 15%, with most cases occurring between 30 and 35 weeks' gestation. Treatment consists of transfusion of maternal platelets, exchange transfusion, and use of IVIG. Platelets usually normalize in the newborn by 4 weeks of age.

Antenatal Treatment. The goal of antenatal treatment is to prevent bleeding complications and not severe thrombocytopenia in the newborn. The cornerstone of antenatal treatment is maternal administration of IVIG to the newborn (Winkelhorst, Oepkes, & Lopriore, 2017). IVIG works by (a) diminishing the production of antiplatelet antibodies, (b) interfering with antibody attachment to the surface of the platelets, and (c) reducing platelet destruction by interfering with phagocytic receptors in the reticuloendothelial system. Corticosteroids, specifically prednisone, can be administered with the IVIG. Corticosteroids support the efficacy of IVIG and improve outcomes, but they are not as effective by themselves. Corticosteroids are often given in conjunction with IVIG to reduce the side effect of headaches experienced by mothers who receive IVIG treatment (ACOG Committee on Practice Bulletins—Obstetrics, 2016; Winkelhorst et al., 2017). Pacheo et al. (2011) developed an algorithm based on risk stratification for the administration of IVIG therapy that ACOG bases their 2016 recommendations on. In the algorithm, the administration of steroids and IVIG is based on previous infants with thrombocytopenia with intracranial bleeding (ICH) after 28 weeks' gestation or before 28 weeks' gestation. For mothers who have had no previous infants with ICH, at 20 weeks' gestation, IVIG would be started at 0.5 g/kg/week and prednisone at 0.5 mg/kg/day or IVIG at 2 mg/kg/week. At 32 weeks, IVIG would be given at 2 mg/kg/week and prednisone at 0.5 mg/kg/day. Delivery of the babies is by cesarean section at 37 to 38 weeks' gestation after lung maturity tests are documented. For mothers who have had a previous infant with thrombocytopenia with ICH after 28 weeks' gestation, they would receive 1 g/kg/week of IVIG starting at 12 weeks' gestation, increasing the dose to 2 g/kg/week at 20 weeks or adding prednisone at 0.5 mg/kg/day, and at 28 weeks' gestation given 2 mg/kg/week of IVIG and prednisone at 0.5 mg/kg/day, with delivery by cesarean section at 35 to 36 weeks' gestation after lung maturity tests are documented. Mothers who have had a previous infant with ICH before 28 weeks' gestation should receive IVIG at 2 g/kg/week at 12 weeks' gestation, adding prednisone at 0.5 mg/kg/day at 20 weeks' gestation, and delivering the baby at 35 to 36 weeks' gestation by cesarean section after lung maturity tests are documented. For all three categories, vaginal deliveries are recommended only if percutaneous umbilical cord sampling at 32 weeks shows a platelet count of more than 100,000/mm^3 (Pacheo et al., 2011).

Postnatal Treatment. Postnatal treatment is based on the infant's clinical condition and severity of the thrombocytopenia. Treatment consists of a platelet transfusion as the first line of therapy, IVIG, steroid therapy (prednisone, 1–5 mg/kg/day), or an exchange transfusion with blood less than 2 days old. The major difference in therapy between ITP and alloimmune thrombocytopenia is the use of antigen negative platelets or, if not available, then washed, irradiated, maternal platelets in infants with alloimmune thrombocytopenia.

Neonatal Factors

Neonatal factors associated with thrombocytopenia include asphyxia, an Apgar score of less than 7, DIC, exchange transfusion, infection, smallness for gestational age, necrotizing enterocolitis, hyperbilirubinemia and phototherapy, meconium aspiration, cold injury, polycythemia, pulmonary hypertension, and cardiopulmonary bypass procedure.

Treatment of thrombocytopenia caused by neonatal factors consists initially of amelioration of the underlying problem, followed by symptomatic treatment with platelet transfusion. Transfusion therapy should be considered if platelet counts are in the range of 50,000 to 100,000/mm^3 and active bleeding is present. Platelet transfusion should be considered when the level is below 20,000 to 50,000/mm^3 for stable preterm infants, less than 30,000 to 100,000/mm^3 for unstable preterm infants, and 20,000 to 30,000/mm^3 for term infants even if active bleeding is not present. Transfusion with 10 to 15 mL/kg of platelets will generally yield an increase of 50,000 to 100,000 μL as long as there are no predisposing factors for continued platelet destruction (Diab & Luchtman-Jones, 2015; Pacheo et al., 2011).

Disseminated Intravascular Coagulopathy

DIC is marked by a generalized deficiency of coagulation factors and platelets, which leave the infant predisposed to hemorrhage. Because this condition is triggered by a preexisting illness and does not occur independently, treatment consists of identification and resolution of the underlying problem. Releases of tissue factor and substantial injury to endothelial cells are the two major mechanisms that precipitate DIC (Hall, 2016). The factors most often associated with bleeding that occurs secondary to DIC are

obstetrical complications such as perinatal asphyxia and placental abruption, respiratory distress syndrome, hypoxia, hypotension, necrotizing enterocolitis, and sepsis. Occasionally thrombosis of large vessels can trap platelets and consume an amount of clotting factors sufficient to cause DIC. Mortality rates reach 60% to 80% in infants with DIC who experience severe bleeding (Diab & Luchtman-Jones, 2015).

There is no single laboratory test for DIC, but a combination of tests that help to confirm DIC, which can be difficult to diagnose in the early stages. The best diagnosis is made with taking the clinical picture as well as lab results into consideration. The hematological picture of DIC (Table 13.7) reflects a depletion of platelets, prothrombin, fibrinogen, angiotensin III (AT III), protein C, and Factors V, VIII, and XIII. The prothrombin time and partial thromboplastin time are prolonged and are not corrected by the addition of fresh frozen plasma to the blood sample. The fibrinolytic system is also stimulated, as evidenced by the presence of degradation products of fibrinolysis (i.e., fibrin degradation products or fibrinolytic split products). A commonly used test, measurement of D-dimer, serves as an evaluation of the activation of the fibrinolytic system in that it measures degradation of cross-linked fibrin. However, the D-dimer test may not be very helpful in the newborn because the result is commonly positive in infants who do not have a consumptive coagulopathy (Diab & Luchtman-Jones, 2015).

Successful treatment of DIC depends on alleviation of the underlying cause and maintaining adequate oxygenation and circulation in the neonate. Palliative treatment consists of replacement of deficient clotting factors with fresh frozen plasma and cryoprecipitate, platelet transfusions, and exchange transfusion. Heparin is used infrequently because it carries a higher risk of hemorrhage; it is used only when large-vessel thrombosis occurs (Diab & Luchtman-Jones, 2015).

Protein C and S Deficiency. Protein C and S are two of several anticoagulant proteins and are inherited in an autosomal dominant pattern. Heterozygous deficiency causes increased incidence of thrombosis, but is rare in the neonatal period. Homozygous protein C or S deficiency will present in the neonatal period and can occur in the first few hours to days of life. Patients affected by a protein C or S deficiency will present with purpura fulminans, severe DIC, and life-threatening thrombosis. Diagnosis is done with laboratory tests that are consistent with DIC, and there is no measurable protein by assay. Treatment, if done early, can improve clinical outcomes. Treatment consists of the administration of fresh frozen plasma. A protein C concentrate is available in the United States for compassionate use only. Patients with this disease will need to be on lifelong warfarin therapy (Diab & Luchtman-Jones, 2015).

TABLE 13.7

LABORATORY FINDINGS IN DISSEMINATED INTRAVASCULAR COAGULATION

Laboratory Test	Results
Platelet count	Decreased
Prothrombin time	Prolonged
Partial thromboplastin time	Prolonged
Fibrinogen	Decreased
Factor V and VIII	Decreased
Factor VII and IX	Normal
Angiotensin III	Decreased
Protein C	Decreased
Heparin cofactor II	Decreased
Fibrin	Elevated
Fibrinogen degradation products	Elevated
D-dimer	Increased
Hematocrit	Decreased
Bleeding time	Prolonged
Red blood cell on smear	Fragmented

Walsh (Eds.), *Fanaroff and Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (10th ed., pp. 1294–1343). Philadelphia, PA: Elsevier.

Differential Diagnosis of Newborn Coagulopathies

Analysis of a number of factors can often aid in the identification of the specific coagulopathy affecting an infant. Careful evaluation of the following factors can pinpoint the correct diagnosis and influence the choice of therapy or intervention:

- A familial history of a bleeding disorder, such as hemophilia
- A maternal history of a bleeding disorder, as in autoimmune thrombocytopenia
- An obstetrical history that suggests a possible abnormality, as in maternal alloimmunization or hypofibrinogenemia
- An adverse neonatal history, such as with hypoxia or asphyxia
- Failure to administer prophylactic vitamin K at birth
- Physical manifestations of a bleeding disorder (e.g., obvious bleeding, the presence or absence of petechiae or ecchymosis) and the infant's overall condition
- Laboratory data that identify specific abnormalities, such as specific coagulation factor deficiencies, thrombocytopenia, and prolonged prothrombin time, partial thromboplastin time, and clotting times

Collaborative Management of a Coagulopathy

Care of an infant with a bleeding diathesis should be aimed at prevention of further injury or bleeding. Supportive care of fragile tissue and limiting the number of blood draws from sites other than central catheters are of great importance in the infant who lacks adequate clotting factors to control bleeding. Appropriate administration of platelets, clotting factors, or blood products requires the correct equipment, the correct method of administration, and conscientious monitoring of vital signs to ensure effective

therapy without causing further harm to the infant. Wise decisions regarding replacement blood products are now important in light of the severe and potentially lethal sequelae of acquired infection. Adopting guidelines for transfusion therapy may safeguard infants and eliminate unnecessary exposure to blood products (see Transfusion Guidelines for Newborns). Monitoring of laboratory tests to determine continuing needs and the efficacy of therapy is important throughout the infant's course of therapy.

When blood or blood products are administered, the infant must be evaluated continuously for signs of fluid overload and untoward reaction. Although blood reactions are rare in the newborn, they tend to occur within the first 15 minutes of blood or blood product administration. Signs of such reactions include rashes, tachycardia, hypertension, hematuria, cyanosis, and hyperthermia. Throughout the acute course of illness, the Hct values and the state of perfusion, rather than the percentage of the infant's blood volume removed, should govern the decision on whether to transfuse. Symptoms of hypovolemia include metabolic acidosis, hypotension, poor perfusion, tachycardia, cyanosis, and shock (Diab & Luchtman-Jones, 2015).

SUPPORT OF THE FAMILY OF THE INFANT WITH HEMATOLOGIC DISORDER

An ill neonate is a crisis for families as no one expects their baby to be born prematurely or ill. When a diagnosis of a hematologic disorder occurs, the physician should discuss with the parents the disease, cause, treatment, and outcomes. Parents have a role in deciding the goals of the care to be delivered to their baby, but they cannot make an informed decision unless they have been presented complete and reliable information. Unfortunately, many times this type of information may not be available until after the acute phase of the disease.

During care of the infant with a hematologic disorder, healthcare professionals should keep the parents informed of what is occurring with their newborn and parents' wishes should be honored, if appropriate. More discussion of the care of the family is discussed in the chapters in Unit VI.

BLOOD COMPONENT REPLACEMENT THERAPY

Whole Blood

This product is not used for routine volume expansion because of the Hct dilution that occurs. It is used in surgical procedures that require large volumes of blood for replacement, for exchange transfusions, and for priming heart-lung oxygenators for extracorporeal membrane oxygenation (Fasano et al., 2015).

Packed Red Blood Cells

Blood is "hard spun" to concentrate cells (Hct 70–90) and to allow the supernatant to be removed. Because of this form of preparation, less volume can be administered. Packed RBCs can be reconstituted with normal saline, 5% albumin, or fresh frozen plasma. Packed RBCs can be used in exchange transfusions or in the treatment of anemia in the acutely ill or symptomatic convalescent infant (Fasano et al., 2015; Patel & Josephson, 2018).

Washed Red Blood Cells

For additional protection, RBCs can be washed to remove as much of the plasma, nonviable RBCs, WBCs, and metabolic wastes, especially potassium, as possible. After washing, washed RBCs contain 10% to 20% fewer RBCs and 99% of plasma proteins and 85% of WBCs are removed (Keir, Wilkinson, Andersen, & Stark, 2016).

Frozen Deglycerolized Red Cells

Frozen storage of deglycerolized RBCs allows preservation of rare units of blood, but the cost of preparation increases considerably. In addition, this product tends to have a higher potassium content and hemoglobin concentration. Centrifuging it, removing the supernatant, and diluting it to the desired Hct level tend to control these problems (Lagerberg, 2015).

Fresh Frozen Plasma

Fresh frozen plasma provides a rich source of coagulation factors to treat acquired coagulation factor deficiencies; 10 to 15 mL/kg, which contains 1 IU/mL of all clotting factors, raises the overall level of clotting factor activity by 20% to 30%. Fresh frozen plasma can often normalize prolonged prothrombin and partial thromboplastin times in the newborn who has a generalized deficiency in quantity and activity of available clotting factors (Fasano et al., 2015; Patel & Josephson, 2018).

Platelets

Platelet transfusions are administered either therapeutically or prophylactically to prevent or decrease the risk of hemorrhage induced by thrombocytopenia or other platelet abnormalities. In stable infants, a platelet count of less than 30,000/μL will result in a transfusion of platelets, and a count of less than 50,000/μL in clinically unstable infants will prompt consideration of a transfusion. The infusion of 10 to 15 mL/kg of platelets should result in an increase in the platelet count of 50,000 to 100,000/μL. An important caveat: Platelets require a special administration set for proper infusion (Fasano et al., 2015; Patel & Josephson, 2018).

Granulocytes

Granulocytes, which are used for infusion in septic infants with severe neutropenia, are prepared from fresh donor blood through the process of plasmapheresis. WBCs are removed from the unit of blood, but a large number of RBCs remain. For this reason, the donor unit must be typed and cross-matched to the infant for blood type and Rh compatibility. WBCs are usually irradiated to eliminate donor T cells in an effort to prevent graft-versus-host responses. Granulocytes are infused at 10 to 15 mL/kg. They are given on a daily basis until the infant's clinical status and neutrophil count improve. Infants must be monitored for signs of pulmonary reactions and febrile transfusion reactions. The efficacy of granulocyte transfusions remains controversial (Fasano et al., 2015).

Cryoprecipitate

This form of plasma preparation is rich in Factors VIII and XIII and fibrinogen and is useful in the treatment of hemophilia. Because it is a single-donor collection, the risk for infection is lower than with pooled substances. Each bag of cryoprecipitate transfused raises fibrinogen levels by 100 mg/dL (Fasano et al., 2015; Patel & Josephson, 2018).

Factor Concentrates

Factor concentrates are used as specific therapy for identified factor deficiencies. Factor concentrates are available commercially and are an option for treatment after consultation with hematology. It is important to remember that infants often do not require treatment during the neonatal period as they may not exhibit signs of bleeding (Saxonhouse, 2018).

Protocols

Management of Jaundice in the Newborn Nursery. Knowing which neonate will or will not develop sequelae as a result of hyperbilirubinemia is the challenge that healthcare professionals must face when caring for the newborn. The neonatal nurse is a key player in recognizing the onset of hyperbilirubinemia and in notifying the practitioner.

A major factor that makes a newborn more prone to developing more severe jaundice is prematurity. The more premature a baby is, the greater the risk. One of the several reasons for this is that the premature infant liver has a delay in reaching maximum concentrations of uridine diphospho-glucuronosyltransferase (UGT), the substance that helps with the breakdown of bilirubin. The premature baby may feed less than a term baby, which leads to fewer bowel movements, another essential component in eliminating bilirubin from the body (Kaplan et al., 2015). The late preterm infants are especially at risk, as they often do not appear ill and are hence referred to as the "great pretenders," pretending to be healthy newborns.

As stated earlier in this chapter, the sequelae related to hyperbilirubinemia is acute bilirubin encephalopathy (transient mild encephalopathy) and chronic bilirubin encephalopathy (kernicterus) (Kaplan et al., 2015). Kernicterus is a preventable disease if a newborn's jaundice is recognized and managed properly. The AAP in 1994 developed guidelines for healthcare professionals to manage hyperbilirubinemia in the newborn, revised them in 2004, clarified them in 2009, and at the writing of this chapter the AAP was revising the guidelines. A study by Burke et al. (2009) showed that since the implementation of the AAP 1994 guidelines the incidence of hospitalizations with a diagnosis of kernicterus in the United States has decreased, showing that proper adherence to the AAP guidelines helps to prevent long-term sequelae of hyperbilirubinemia.

Transfusion Guidelines for Newborns

As discussed earlier in this chapter, there are risks associated with transfusions and because of that there are now more restrictive guidelines for when to transfuse an infant. The following are current recommendations based on evidence.

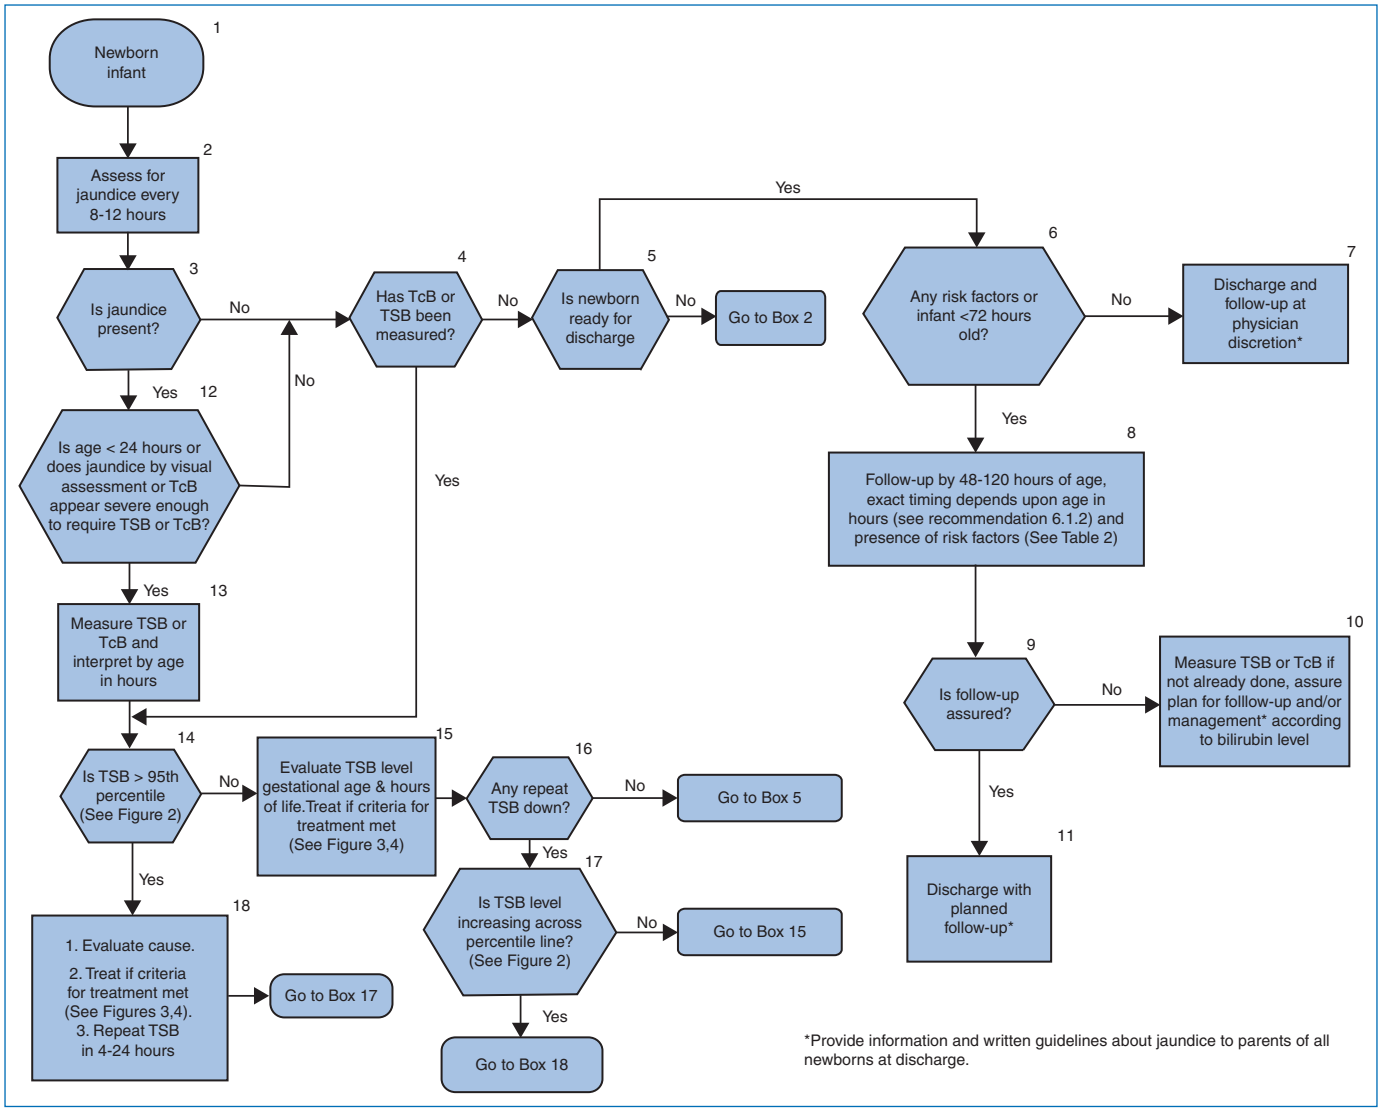

FIGURE 13.13 Algorithm for the management of jaundice in the newborn nursery.

TcB, transcutaneous bilirubin; TSB, total serum bilirubin.

Source: Maisels, M. J., Baltz, R. D., Bhutani, V. K., Newman, T. B., Palmer, H., Rosenfeld, W., . . . Weinblatt, H. B. (2004). Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics, 114,* 297–316. doi:10.1542/peds.114.1.297

General Principles of Transfusion

1. For both term and preterm infants, the need for transfusion is based on the infants' need for increased oxygen to the tissue as evidenced by the clinical picture of the infant.
2. Measurement of the Hgb and Hct values should be obtained from the central circulation when determining the need for a transfusion. If unable to obtain a central Hgb and Hct, a heel stick may be obtained after warming the heel for 3 to 5 minutes.
3. The recommended volume of transfusion is 20 mL/kg for term and preterm infants needing transfusion, unless their Hct level is greater than 29%, in which case they would get 10 mL/kg. If infant is small with a Hct level greater than 29%, then it can be used if significant blood loss from phlebotomy is anticipated.
4. If the infant has received HuEPO, then the reticulocyte count, the postnatal day of age, the need for additional oxygen, and the overall status of the infant need to be considered in addition to the Hgb and Hct values.
5. Leukocyte-reduced and irradiated PRBC should be used for all neonatal transfusions to prevent transfusion reactions in the neonate.
6. CMV-negative PRBC should be used for neonates, but especially for immunodeficient neonates, those awaiting transplants, or premature neonates of CMV-negative mothers to prevent CMV transmission.
7. Blood should be given over 2 to 4 hours, unless hemodynamically unstable or with hypovolemia due to blood loss, in which case it should be given over 1 to 2 hours.
8. Fetuses and neonates with a hemolytic disease that need an exchange transfusion or transfusion have to have blood that is compatible with their blood.
9. O-negative whole blood should only be used as a last resort in neonates, as it contains antibodies against A and B blood groups and leukocytes.

Transfusion for Acute Blood Loss. For acute blood loss, immediate fluid resuscitation with 0.9% normal saline at 10 mL/kg should be given while obtaining the blood.

Blood transfusions should be given to infants who have:

1. Acute blood volume loss greater than 20%
2. Acute blood volume loss greater than or equal to 10% with signs of decreased oxygen delivery
3. An ongoing hemorrhage

Transfusion for Chronic Blood Loss. Blood transfusions for infants with chronic blood loss is based on Hgb and Hct levels, the need for oxygen/respiratory support, and age.

SUMMARY

This chapter outlines the common hematologic neonatal problems and evidence-based interventions. The nurse's role is crucial to improve outcomes. Anticipation of problems, very thorough assessment, and ongoing evaluation of treatment response are key to providing the best possible care.

CASE STUDY

■ **Identification of Problem.** A 4-day-old infant is admitted to the NICU with a history of jaundice and lethargy from his local pediatrician's office. A TSB test drawn at the pediatrician's office had a result of 38 mg/dL.

■ **Assessment: History and Physical.** The baby boy was born at 37 weeks' gestation at 3.2 kg to a 28-year-old, gravida 2, para 1, AB 1 mother of Asian descent. The pregnancy was complicated by a positive Group B bacterial streptococcal culture, and the mother was treated with prophylactic antibiotics prior to delivery. The baby was born by vacuum-assisted vaginal delivery. The baby was vigorous at birth with Apgar scores of 8 and 9. The mother's blood type was O positive and the baby's blood type was A positive. The Coombs test was positive. The breastfed infant had an unremarkable course at the delivery hospital but was noted to be jaundiced at 32 hours of age. A TSB was done with a result of 12.8 mg/dL. He was discharged home at 46 hours of age.

On admission to the NICU, the infant was noted to be severely jaundiced but pink. His vital signs were within normal limits with an axillary temperature of 98.5°F, heart rate of 150 beats/min, respiratory rate of 55 breaths/minute, and blood pressure of 60/36 mmHg with a mean of 48 mmHg. His weight on admission was noted to be 2.72 kg, a 15% loss. His examination was nonremarkable, except for his decreased response to stimuli, poor muscle tone, poor suck, and a decreased Moro. His glucose screen was 50.

■ **Differential Diagnosis.** Many conditions are known to cause jaundice and lethargy in the newborn. The most common are hyperbilirubinemia, ABO incompatibility, G6PD, hypothyroidism, dehydration secondary to inadequate breastfeeding, sepsis, and kernicterus.

■ **Diagnostic Tests.** To determine the cause of the jaundice and lethargy, a CBC with differential, repeat TSB, electrolytes, calcium, glucose, and liver function tests, as well as T4/thyroid-stimulating hormone (TSH), G6PD screen, a hemoglobin electrophoresis, and blood culture all need to be ordered.

■ **Working Diagnosis.** The baby's repeat bilirubin was 40 mg/dL; his CBC showed a WBC of 12.2/mm^3, with 35% segs, and 4% bands; his hemoglobin was 10.0 g%; his Hct was 28%, and his reticulocyte count was 3%. The G6PD screen was adequate. Electrolytes, liver function tests, calcium, and glucose were all within normal limits, and the free T4 was 1.1 ng/dL (NL: 0.9–2.1), but TSH was 25.76 mIU (NL: 1.7–9.1). The hemoglobin electrophoresis was "A, F." These test results suggest a working diagnosis of hyperbilirubinemia secondary to ABO incompatibility and hypothyroidism.

■ **Development of Management Plan.** The main goal for an infant with a bilirubin of 40 mg/dL is to reduce the bilirubin level as quickly as possible to prevent kernicterus. While the blood is being typed and cross-matched, the infant needs to be placed in a neutral thermal environment, made NPO, have a peripheral IV placed and IV fluids of D10.2NS with 20 KCl/L at 120 mL/kg/hour, and started on antibiotics. An attempt should be made to do a cutdown of the umbilical cord to place an umbilical vein and arterial catheter for the exchange transfusion. Double phototherapy lights need to be started immediately.

■ **Implementation and Evaluation of Effectiveness.** A double-volume exchange transfusion was done over 3 hours. The infant received calcium and glucose boluses during the transfusion for low calcium and glucose. Phototherapy lights were continued after the transfusion. His laboratory tests of TSB, electrolytes, CBC with differential, glucose, and calcium were repeated after the exchange transfusion was completed. His postprocedure TSB level was 23 mg/dL.

During the exchange transfusion the baby became apneic, which required intubation and the need for ventilation for 1 day. He received antibiotics for 2 days and phototherapy for 4 days. He was started on Synthroid for his abnormal TSH.

On day of life 10, the TSB was 10 mg/dL. On examination, the infant was slightly hypertonic. A BAER was normal, but an MRI was consistent with kernicterus. He was discharged home with a referral made to the neonatal developmental clinic and early intervention to follow his developmental status.

EVIDENCE-BASED PRACTICE BOX

Anemia of prematurity is a common occurrence in premature infants due to factors discussed earlier in this chapter. The treatment mainstay for this condition has been transfusion with PRBCs, but in the past decade there have been decreasing numbers of blood transfusions given to ill and premature neonates for reasons discussed earlier in this chapter. The decreased incidence of using PRBCs is related to several studies as well as the use of HuEPO.

Bell et al. (2005) published their randomized clinical trial that compared a restrictive versus liberal transfusion guideline. The goal of the trial was to determine if restrictive transfusion guidelines in premature infants decreased the number of transfusions and number of donor exposures without increasing adverse outcomes. The study enrolled 100 premature neonates between 500 and 1,300 g that were assigned to one of the two groups with similar gestational ages and birth weights. The results showed that the liberal group had more transfusions, though not more donor exposures. The infants in the restrictive transfusion group were more likely to have an intraparenchymal brain hemorrhage or periventricular leukomalacia as well as having more apnea and bradycardic episodes.

A large multi-center randomized controlled trial study called the Premature Infant in Need of Transfusion (PINT; Kirpalani et al., 2006) looked at the effect of transfusions in premature babies less than 1,000 g and the primary outcome of death before discharge. Secondary outcomes were incidences of retinopathy of prematurity, bronchopulmonary dysplasia, or abnormal brain ultrasound at discharge. The infants were assigned to either a restrictive or liberal blood transfusion algorithm based on Hct within 48 hours of birth. The trial had over 400 infants and the two groups had similar numbers with infants of similar weights and gestational ages. Results of the study demonstrated that the restrictive transfusion group had less transfusions, but there was no statistical difference in the primary or secondary outcomes.

In 2011, Fredrickson et al. published a small clinical trial of 41 infants with birth weights between 500 and 1,300 g at birth. The trial examined effects of a low or high Hct threshold for transfusion on oxygen transport, lactic acid, oxygen consumption, and cardiac output. The study results showed that while both groups had an increase in systemic oxygen transport and a decrease in lactic acid following a transfusion, neither group had a significant change in oxygen consumption as a result of a transfusion. The only difference noted was that the low Hct group did have a decrease in cardiac output after the transfusion, implying that the neonates had increased their cardiac output to increase oxygenation due to anemia. The results from this study, though the numbers were small, showed that neonates with low Hct could benefit from transfusions.

Study results vary, though it appears that the restrictive transfusion guideline has the advantage of less exposure to blood with no more significant adverse outcomes. Clinical trials need to continue on this subject in the neonatal period as well as look at the long-term neurodevelopmental outcomes as the children get older.

CHAPTER 14

Musculoskeletal System

Ashlea D. Cardin

INTRODUCTION

The human body is active, responsive, and constantly moving. The development of its functional motor skills is dependent upon the development of the musculoskeletal system. The musculoskeletal system comprises bones, joints, ligaments, muscles, bursa, fascia, and tendons. From an anatomic structural standpoint, infants, children, and adults differ in many ways: body size proportions, tissue thickness, body fat composition, bone density, muscle fiber type, joint structure development, muscle tone, posture, and bone, muscle, and ligamentous strength (Alexander, Boehme, & Cupps, 1993; Huelke, 1998; Hunter, Lee, & Altimier, 2015). For infants, the uterine environment functions to support and reinforce musculoskeletal symmetry, strength, physical stature, range of motion, and muscle tone (O'Brien, 2015). Flexible uterine walls assist in returning the infant from an extended posture to one that is flexed, midline, and supported circumferentially (Hunter et al., 2015). Additionally, the uterine environment supports hand-to-mouth activity, considered necessary for future participation in daily living activities such as feeding and playing.

This chapter provides a review of typical musculoskeletal development during the neonatal period and also describes musculoskeletal problems seen in the period. Collaborative management is discussed, as well as the long-term implications of the functional and aesthetic concerns encountered with musculoskeletal dysfunction.

EMBRYOLOGY

An extensive discussion of embryology is beyond the scope of this chapter; however, a brief review is provided. Prenatal development is divided into two stages: the embryonic period (first trimester) and the fetal period (second and third trimester) (Liu & Thompson, 2019). The embryonic period is characterized by maximal organogenesis and lasts from the end of the first week until the eighth week of gestation. Rapid cell division during organogenesis renders an organ vulnerable to any disturbance that might result in aberrant development. Functional and minor morphologic abnormalities may occur any time during gestation. The embryo originates from three cell layers: the ectoderm, the endoderm, and the mesoderm. The embryonic mesoderm gives rise to the articular, muscular, and axial and appendicular skeletal systems.

The articular system, or joints, can be classified into three types: fibrous, cartilaginous, and synovial. Fibrous joints are those in which two bones are separated only by dense fibrous connective tissue, as seen in cranial sutures. Cartilaginous joints (such as the symphysis pubis and between the intervertebral discs of the spine) have hyaline cartilage or fibrocartilage between the two bony surfaces. The elbow and knee are examples of synovial joints. In these joints, the adjoining bone ends are covered with a thin cartilaginous layer and joined by a ligament lined with a synovial membrane. Ligaments hold bones together; the capsule encases the joint to provide support and protection. The synovial membrane secretes a lubricant referred to as *synovial fluid*, a source of nutrition for the articular cartilage. Synovial joints are the most mobile, yet can withstand pressure and provide stability between the bones, especially during weight bearing. The articular system begins to develop during the sixth week of gestation, with functional joints being present by the end of the eighth week. Joints allow motion to occur. Box 14.1 lists common terminology used to describe types of motion and the planes in which motion occurs.

Muscle origin and insertion, muscle fiber arrangement, types of muscle contraction, arthro- and osteokinematics, muscle tissue, and movement characteristics are important for clinicians to consider Groups of myotubes, the primordia of skeletal or striated muscle, are apparent by the end of the eighth week of gestation. As the myotubes enlarge, the appearance of myofilaments is evident in interior regions. Growth of myofilaments leads to mature muscle fibers. Postnatal development of muscle fibers continues both in number and in size. Muscle development depends on proper innervation, evident at 8 to 10 weeks of gestation. Without this innervation, the muscles atrophy. The mother can detect intrauterine fetal movements at 16 weeks of gestation. Infants born prior to 31 weeks gestational age have immature muscle fibers, neuromuscular junctions, and diminished flexor tone. Muscle tone development occurs caudocephally, with lower extremity tone beginning at about 33 to 35 weeks post menstrual age and upper extremity tone increasing around 35 to 37 weeks (Byrne & Garber, 2013).

The skeleton develops by intramembranous bone formation and endochondral ossification. It gives shape and support to the body, protects vital organs, and provides structure for muscular attachments. Bones are soft, develop cephalocaudally, and are made up of several types of tissue (fibrous, cartilaginous, osseous, nervous, vascular). Upper limbs develop more quickly than the lower limbs, and several days elapse between the development of the

Box 14.1

JOINT MOTIONS AND PLANES OF MOVEMENT

- Abduction: movement in the coronal plane that moves a limb laterally away from the body
- Adduction: movement in the coronal plane that moves a limb medially toward or across the midline of the body
- Dorsiflexion: movement at the ankle that brings the top of the foot toward the anterior leg
- Eversion: foot movement involving the intertarsal joints of the foot in which the bottom of the foot is turned laterally, away from the midline
- Extension: movement in the sagittal plane that increases the angle of a joint (straightens the joint); motion involving posterior bending of the vertebral column or returning to the upright position from a flexed position
- Flexion: movement in the sagittal plane that decreases the angle of a joint (bends the joint); motion involving anterior bending of the vertebral column
- Horizontal abduction: holding arm at shoulder height, moving the shoulder backward
- Horizontal adduction: holding arm at shoulder height, moving the shoulder across body
- Hyperextension: continuation of extension beyond the normal range of motion
- Inversion: foot movement involving the intertarsal joints of the foot in which the bottom of the foot is turned toward the midline
- Palmar flexion: bending the wrist toward the palm
- Planes of Movement:
    - Sagittal plane (lateral plane): a vertical plane running from front to back; divides the body or any of its parts into right and left sides; extension and flexion motions occur in this plane
    - Coronal plane (frontal plane): a vertical plane running from side to side; divides the body or any of its parts into anterior and posterior portions; abduction and adduction motions occur in this plane
    - Axial plane (transverse plane): a horizontal plane; divides the body or any of its parts into upper and lower parts; rotation occurs in this plane
- Plantar flexion: movement of the ankle toward the surface of the foot
- Pronation: movement that combines eversion, dorsiflexion, and abduction
- Scapular abduction: shoulder girdle protraction, or rounding the shoulders forward
- Scapular adduction: shoulder girdle retraction, or squeezing the shoulder blades together
- Supination: movement that combines inversion, plantar flexion, and adduction
- Trunk/neck lateral bending: occurs to right and left sides
- Ulnar and radial deviation: hand movement toward little finger side and hand movement toward thumb side
- Wrist extension/dorsiflexion: bending the wrist away from the palm toward the lower arm

Sources: Betts, J. G., Desaix, P., Johnson, E., Johnson, J. E., Korol, O., Kruse, D., . . . Young, K. A. (2013). Anatomy & physiology (pp. 345–349). Houston, TX: Rice University. Retrieved from https://opentextbc.ca/anatomyandphysiology/chapter/9-5-types-of-body-movements; Lippert, L. S. (2011). *Clinical kinesiology and anatomy* (5th ed.). Philadelphia, PA: F. A. Davis; National Cancer Institute. (n.d.). *Anatomical terminology*. Retrieved from https://training.seer.cancer.gov/anatomy/body/terminology.html

upper limbs and that of the lower limbs. The vertebral column is initially of a cartilaginous form, with ossification beginning during the embryonic period and reaching completion in early adulthood. Ossification is evident in all long bones by 12 weeks gestation, with arms, legs, fingers, and toes typically recognizable at this stage. The fetal period represents a time of further growth and development. At birth, an infant's skeleton is primarily cartilaginous and made up of more than 300 bones. Throughout childhood and into adulthood, the infant's bones will fuse and ossify, resulting in the 206 bones typically seen in an adult skeleton.

POSITIONAL TERMINOLOGY

As an infant's body learns to move and reposition itself, it is imperative that clinicians understand the infant's motoric developmental sequence and the terms that describe those changes from anatomical position:

- Anterior/ventral: front of the body or a position close to the front
- Posterior/dorsal: back of the body or a position close to the back
- Medial: toward the midline of the body
- Lateral: away from the midline of the body
- Supine: lying on back; face is upward
- Prone: lying on stomach; face is downward
- Side lying: lying on side with neutral/midline orientation
- Distal: away from the trunk
- Proximal: toward the trunk
- Cephalo or cranial: close to the head
- Caudal: close to the feet
- Superior: refers to the position of a body structure above another
- Inferior: refers to the position of a body structure below another
- Superficial: position of relative depth; on top of
- Deep: position of relative depth; underneath
- Contralateral: refers to opposite side of body
- Ipsilateral: refers to same side of body
- Valgus: describes an abnormal position in which a distal body part is bent outward and away from the midline of the body
- Varus: describes an abnormal position in which a distal body part is positioned inward, toward the midline of the body
- Subluxation: incomplete dislocation or a displaced joint
- Dislocation: complete separation of one articulating joint surface from another
- Reduction: restoration of a body part to a normal position

MUSCULOSKELETAL ASSESSMENT

Maternal history is reviewed for uterine anomalies that may compromise fetal movement and growth, such as the bifid uterus, the division of the uterine cavity into two segments. Additional maternal and a family history that are important include family members, especially siblings, with musculoskeletal anomalies; presence of oligohydramnios (reduced amniotic fluid volume); and fetal movement during gestation and the birthing process.

Detailed observation is the key tool for assessing the neonatal musculoskeletal system. Visual inspection should begin in one body region—that is, cephalic or caudal—and progress along the body in an organized fashion from proximal to distal. For the initial examination, place the infant in a quiet resting state to assess posture, positioning, and identification of any obvious anomalies.

Box 14.2

MUSCULOSKELETAL CONDITIONS

- Arthrogryposis multiplex congenita, or multiple congenital joint contractures
- Congenital upper and lower limb defects, which can be caused by maternal exposure to known risk factors, genetic abnormalities, growth restriction, mechanical forces, and so forth
  - Absence of limbs
  - Amniotic band syndrome: occurs when tears in the amnion get wrapped around digits, limbs, or other parts of the body
  - Congenital talipes equinovarus: *clubfoot*
  - Syndactyly: fingers and/or toes that failed to separate
  - Polydactyly: duplication of fingers and/or toes
  - Undergrowth or overgrowth of limbs
- Fractures and/or bowing of bones
  - Birth trauma
  - Greenstick fracture: occurs when one side of bone is broken and the other bent
  - Epiphysis/growth plate fracture
  - Bowing: angular deformity of bones, typically long bones
- Hip dysplasia or dislocation: instability of the femoral head in the acetabulum, allowing the hip joint to become partially or completely dislocated
- Positional deformities
  - Intrauterine
  - Acquired, from prolonged hospitalization
  - Home based/post discharge: examples include torticollis, plagiocephaly, hip contractures
- Orofacial clefts: incomplete closure of the palate and/or lip
- Craniosynostosis: premature closing/fusion of the fibrous cranial sutures
- Plagiocephaly: misshapen head (Bialocerkowski & Vladusic, 2008)
  - Brachycephaly: wide, flattened back of head
  - Dolichocephaly or scaphocephaly: long, narrow head
- Structural disorders of the spine
  - Spinal deformities
    - Kyphosis: abnormally rounded upper back
    - Scoliosis: spine is curved sideways
    - Lordosis: excessive in-curving at the base of the spine, or *swayback*
  - Torticollis: congenital, positional, birth injury; tightness of the neck musculature causing the head to tilt to one side and rotate to the other
- Skeletal dysplasias: bone and cartilage disorders affecting the fetal skeleton
  - Achondroplasia: *dwarfism* or short stature
  - Hypochondroplasia
  - Thanatophoric dysplasia
  - Osteogenesis imperfecta congenita: *brittle bone disease*
  - Thrombocytopenia-absent radius syndrome

Active movement by the infant allows the clinician to view muscle tone and active ranges of motion. Manipulation is used to assess passive range of motion, including joint mobility. Caution should be taken when assessing infant range of motion, as it is often a stressful and potentially painful or harmful experience for the neonate. Radiologic studies as well as simple body measurements aid the healthcare provider in the identification of covert or hidden musculoskeletal deformities such as hip dysplasias and the absence of bony structures.

In developing a differential diagnosis, the clinician must be aware that a combination of deformities present in a neonate may be a small part of a larger syndrome. Conversely, congenital anomalies that present in combination may be a coincidental finding (Box 14.2). Musculoskeletal conditions may be accompanied by acute and/or chronic pain, limitations in mobility, decreased functional ability, and reduced dexterity (World Health Organization, 2018).

TYPES OF MUSCULOSKELETAL DYSFUNCTION

Abnormalities of the neonatal musculoskeletal system can range from a subtle brachydactyly (shortened fingers or toes) to congenital amputation, to a fatalistic form of osteogenesis imperfecta (OI) congenita. Causes range from uterine malpositioning of the fetus to autosomal dominant disorders. Neurologic, infectious, and/or genetic conditions can affect musculoskeletal development, as can post-procedural disorders of the musculoskeletal system (e.g., birth trauma). Regardless of the clinical significance, an overt structural defect can become the focus of parental attention. Assessment of the musculoskeletal system—which can have multiple normal variants—and knowledge of pathogenesis, sequelae, treatment, and prognoses for deformities of this system are imperative to the clinician. Delay in diagnosis and treatment may be implicated as a cause of a less than favorable outcome of the musculoskeletal deformity. Deformities of the musculoskeletal system create not only functional problems but, in some cases, visible defects as well. The type of dysfunction may greatly affect how the parent views the neonate and the infant's potential for positive growth and development. Appropriate education of the family by the healthcare professional is often paramount to a beneficial outcome because many musculoskeletal disorders require compliance with long-term therapy.

ARTHROGRYPOSIS MULTIPLEX CONGENITA

Historically, the term *arthrogryposis* (curved, hooked joint) has been used not only to provide a description of a clinical appearance but also as a diagnosis for various conditions (Figure 14.1). As a group of conditions, arthrogryposis multiplex congenita is considered rare, occurring in 1 out of every 3,000 to 12,000 births.

FIGURE 14.1 Distal fixed joints: arthrogryposis.

The common denominator for more than 400 known conditions is the presence of multiple congenital joint contractures and is typically characterized by decreased fetal movement (Lakhani et al., 2017). Many of these conditions are syndromes unrelated to a chromosomal or genetic problem.

Pathogenesis

Classic arthrogryposis (also termed *amyoplasia*) describes limitation of movement in multiple joints that is present at birth. In distal arthrogryposis, the hands and feet are involved but larger joints are spared (Kimber, 2015). Due to the variety of comorbidities that may be associated with these conditions, the etiology is varied. With decreased movement, extra connective tissue forms around the joints of the fetus and fixes them in position. This may be related to abnormal development of the muscles, tendons, and/or joints as listed in Table 14.1. In some cases, the fetus may be prevented from normal movement due to restrictions within the uterus from multiple pregnancies or abnormalities of the uterine structure. Maternal diseases, such as myasthenia gravis or myotonic dystrophy, may be related to arthrogryposis, as well as the use of certain medications or infections in the mother. Intrauterine vascular compromise is another potential associated factor, with damage to developing muscles and nerves due to decreased blood flow (O'Flaherty, 2001). Finally, abnormalities of the central nervous system (CNS) in the fetus may be a cause, such as spinal muscle atrophy or cerebro-oculo-facial-skeletal syndrome (Table 14.1).

Clinical Manifestations

Arthrogryposis is characterized by limited movement of the affected joints. The distal joints are more frequently affected than proximal joints. Talipes equinovarus (clubfoot) is almost universal, and the wrists are typically flexed. The elbows and knees can be in a flexed or extended position. Dimpling may be noted at the elbows and knees. Shoulders are internally rotated. Normal skin creases overlying the joints are often absent, suggesting an onset of arthrogryposis in the early intrauterine period. Changes in facial features may also be seen, including micrognathia (an undersized chin, which can interfere with breathing and eating).

Diagnosis

A thorough evaluation is required to determine the cause of arthrogryposis. This process may begin prenatally. Decreased fetal movement and joint contractures are often seen on prenatal ultrasound. Polyhydramnios may be seen secondary to decreased fetal swallowing. Prenatal imaging may reveal other physical characteristics that lead to suspicion of certain syndromes. Amniocentesis may provide information leading to a genetic diagnosis. **Quality and Safety: A detailed family history is essential to detect evidence of an inherited disorder. Maternal pregnancy and labor/delivery history should be reviewed carefully.** Physical examination of the infant with careful description of the affected joints is needed, as well as detailed evaluation of the muscle mass and tone and function of the nervous system. Radiographic and ultrasound evaluation is needed to determine the presence of other congenital anomalies, as this may help link the contractures to a specific syndrome. Detailed imaging of the brain and spinal cord is indicated. Muscle biopsy and nerve conduction tests may be recommended. Genetic testing is also required. If a specific genetic etiology or specific syndrome is detected, a more accurate assessment of long-term prognosis can be made.

TABLE 14.1

ETIOLOGY OF DECREASED FETAL MOVEMENT

Category	Examples
Myopathic	
Abnormal muscle function secondary to failure of muscle formation or degeneration	Congenital muscular dystrophy Absence of muscles
Neuropathic	
Abnormal nerve function or innervation that involves either CNS or the peripheral nervous system	Drugs or toxins CNS malformations: decreased number of anterior horn cells
Abnormal connective tissue	Abnormal formation of bone, cartilage, tendons, or connective tissue
Mechanical Limitation	
Produces compression within the uterus	Twins; Multiples Amniotic rupture Oligohydramnios Benign uterine myomas

CNS, central nervous system.

Management

Excluding infants with severe CNS dysfunction, infants with multiple congenital contractures have a good prognosis. The goal of management is to achieve and maintain an acceptable range of motion in the affected joints. During the newborn period, it is often a challenge to hold and care for these infants due to the extended or flexed position of the extremities and the reduced ability to manipulate the contracted limbs. Occupational and physical therapy should be initiated early in the neonatal period, to begin strengthening muscles, improving range of motion, and addressing challenges to daily living activities (occupations). Splints and casts may be implemented, specifically molded and shaped for each limb depending on the severity of contractures and positioning (Figure 14.2). Occupational and physical therapy may be a lifelong process, and parents can be taught techniques to use with the child.

FIGURE 14.2 Hand splint with arthrogryposis.

FIGURE 14.3 Amniotic band constriction ring on the arm of a neonate.

Family involvement is a key factor in the success of therapy for these infants. Creativity on the part of the healthcare professional, as well as on the part of the parents, complements efforts to manipulate the rather rigid infant during feedings, sleeping, holding, and daily care activities. Parents may need referrals to agencies providing respite care or assistance from volunteers to maintain daily care needs.

Prognosis

The long-term prognosis for multiple congenital contractures depends on the extent of involvement. Mortality rates are low for those without CNS involvement (1%–7%). For those with CNS involvement, mortality rates rise to almost 50%. Ventilator dependence at birth is associated with a poor prognosis (Bianchi & Van Marter, 1994).

AMNIOTIC BAND SYNDROME

Amniotic band syndrome (ABS, also referred to as amniotic rupture sequence or constriction band syndrome) is associated with asymmetric fetal deformities due to entanglement of the infant in fibrous amniotic bands. Deformities that have been attributed to the ABS include congenital limb amputation, syndactyly, constriction bands, clubfoot, craniofacial defects such as cleft lip and palate, and visceral defects such as gastroschisis and omphalocele (Baraitser & Winter, 1996). Early fetal evaluation has linked ABS with skull and brain defects (S. H. Lee, Lee, Kim, Son, & Namgung, 2011). **Emergency Alert: ABS can be fatal if organs are involved.**

Pathophysiology

Etiologic factors in ABS are unclear. Part of the difficulty is that some of the same deformities that occur with this syndrome can also occur for other reasons. Thus, the exact cause of the deformities is not always clear, but the primary theory is the association with early amnion rupture and fetal entanglement of the resulting fibrous bands.

Two theories—endogenous and exogenous—explain the cause of ABS. The endogenous theory postulates that the deformities are caused by an innate derangement of the primary embryonic cell layers from which the tissues and organs develop. The presence of amniotic bands, according to the endogenous theory, is a late development with no clinical significance.

The exogenous—and seemingly more popular—theory contends that early amniotic rupture allows the fetus to move into close approximation to the chorion by entering the chorionic cavity. The ruptured amnion then forms fibrous strings or bands. These bands can adhere to the skin, thus altering normal morphogenesis (e.g., cleft lip or palate, omphalocele), or disrupt the vascular integrity, resulting in gastroschisis. Amniotic bands have been found encircling normally developed structures, thus resulting in congenital amputations, constriction rings with lymphedema distal to the ring, and facial clefts in nonanatomic distribution. Postural deformities such as clubfoot are believed to be caused by the fetus's close approximation to the chorion.

Figure 14.3 is an example of an amniotic band constriction ring noted on the arm of an infant with unilateral cleft lip and palate. Evidence of this constriction ring indicates that development of the lip and palate were at one time normal, but development was altered with the presence of amniotic bands.

Diagnosis

Many clinicians believe that amniotic bands must be present for ABS to be diagnosed. Others, however, believe that the presence of fetal deformities in a nonanatomic pattern, without obvious bands, is sufficient to establish the diagnosis of the syndrome. Congenital deformations, such as the visceral and craniofacial types, in the absence of amniotic bands may go undiagnosed as ABS because they could represent a faulty midline developmental pattern during the first trimester of pregnancy instead of the production of amniotic bands that constricted or restricted growth. The true incidence of this syndrome, therefore, may be much higher than it generally appears—not only because of the difficulty in establishing a diagnosis but also because of the high mortality rate that exists during gestation.

ABS has been implicated in fetal deaths secondary to cord compression by the constricting bands. Strauss, Hasbargen, Paek, Bauerfeind, & Hepp (2000) provide a clinical report of fetal demise involving a normal karyotype male secondary to torsion and strangulation of the umbilical cord by an amniotic band. The only significant history in the gestation was an early second-trimester amniocentesis. It has been speculated that amniotic rupture may follow amniocentesis and fetal blood sampling. Strangulation furrows, limb reduction defects, and cleft lip or palate can be late sequelae of invasive prenatal procedures in animal models.

Collaborative Management

Notwithstanding the inherent problems associated with omphaloceles, gastroschisis, encephaloceles, clubfoot, syndactyly, and facial clefts, the clinician must be attuned to the unique complications

of constricting bands. Constricting bands are usually associated with edema distal to the band. The resulting edema and vascular compromise contribute to complications such as skin breakdown, necrosis, thromboembolic formation that results from venostasis, and infection. **Quality and Safety: Care should include frequent vascular checks to assess perfusion. Trauma and tissue breakdown are discouraged through positioning and skin care. Observation for localized areas of necrosis is stressed.**

As with other musculoskeletal disorders, the family may require emotional and psychological support as adjustment to and acceptance of the infant are allowed to occur. Parents may be fearful that an extremity will be lost because of necrotic tissue formation or infection. These fears may be justified, and the parents should be prepared for such a possibility. Complete surgical repair may not be possible during the infant's initial hospitalization, thus necessitating frequent hospitalizations during the early developing years. The delay in repair may necessitate that parents be taught to observe for vascular perfusion of an extremity, to recognize signs of infection, and to change dressings over open or healing areas. Preparation for discharge requires a multidisciplinary approach. The family may need surgical supplies, follow-up visitations by a home-visiting nurse, orthopedic or surgical consultations, pediatrician visits for general well-child care, and support of social or financial services to meet the long-term responsibilities of caring for their infant.

In addition, the nurse, working in collaboration with pediatric occupational therapists and social workers, must attempt to provide opportunities for parent–infant bonding if the parents are to feel somewhat prepared for discharge. While the infant is still in the hospital, the parents must be encouraged to touch and talk to the infant and to participate in the infant's care. They must also be encouraged to verbalize their own feelings about their infant's condition. Every attempt should be made to attend to their fears, concerns, or misconceptions about the cause of their infant's problem.

CLUBFOOT

The classic clubfoot, talipes equinovarus, refers to a dysmorphic-appearing foot with hindfoot equinus (heel is pulled upward as if walking on the toes), forefoot adduction (toes are pointed inward), and midfoot supination. The term *clubfoot* may also be used to describe milder talipes conditions, including talipes calcaneus and talipes varus.

Foot deformities are among the most common birth defects. Clubfoot has an incidence of 1 in 1,000 live births. Males are affected nearly twice as often as females, and, in infants with unilateral presentation, the majority appear on the right.

Pathology

The precise mechanism of development of clubfoot has not been irrefutably established. Some researchers allude to the theory of intrauterine malposition, whereas others, noting a higher incidence of clubfoot in families with a positive history of the disorder, ascribe it to a genetic cause. A popular theory is that clubfoot is a multifactorial disorder involving a genetic predisposition coupled with environmental forces such as oligohydramnios, primiparity, macrosomia, and multiple fetuses.

Clinical Manifestations

Clubfoot deformities are apparent at birth. The skin overlying the lateral aspect of the foot may be taut, whereas the medial aspect may have increased skin folds. The affected foot may be smaller in size than a normal foot. In older children, the calf muscle may be noticeably decreased in size. Milder talipes conditions may be returned to the neutral position by manipulation. The potential for pain also must be addressed.

Collaborative Management

Early diagnosis by orthopedic specialists and treatment referrals to physical and occupational therapists is essential. In the early newborn period, joints, muscles, and ligaments may be more compliant to corrective manipulation without surgical intervention. This may involve serial casting or initiation methods of correction and maintenance such as the Ponseti method (Smythe, Mudariki, Kuper, Lavy, & Foster, 2017). **Emergency Alert: Difficulty with skin closure has been reported as a complication following correction of severe clubfoot.** This is especially true if the affected foot has received prior surgery. Special shoe splints or braces may be used toward the end of any successful treatment.

Parental education includes implementation of routine newborn care for an infant wearing either splints or bilateral casts. Problems and solutions associated with clothing, sleeping, feeding, and bathing should be addressed. Compliance by parents in using splints may vary. Because consistent treatment is necessary for a favorable outcome, healthcare professionals must explore parental feelings and actions while providing anticipatory guidance.

SYNDACTYLY

Fusion, or webbing, between two digits is referred to as *syndactyly*. This condition is the most common anomaly of the hand, with an incidence of 1 in 2,250 live births. Males are affected slightly more than females. Half of the time, both hands are involved in a symmetric presentation. Syndactyly of the fingers may be accompanied by syndactyly of the toes.

Pathology

Although most occurrences of syndactyly appear to be through spontaneous mutation, familial predisposition has been reported, thus indicating an autosomal dominant pattern. Syndactyly may also be associated with a specific syndrome such as Apert syndrome.

There are four classifications of syndactyly. Complete syndactyly occurs when the fusion is from the base to the tip of the digit. Fusion that does not extend to the tip of the digit is termed incomplete. Simple syndactyly refers to digits connected by skin and soft tissue. Fused digits involving an osseous connection are considered complex. Abnormal nerve and vessel configurations may accompany complex syndactyly.

Treatment

The type and timing of treatment of syndactyly depend on its classification. Surgery is directed toward promoting normal function and appearance. Fingers of unequal length should be separated within 6 to 12 months of age to prevent curvature of the longer finger from deviating toward the shorter finger. If more than two adjacent digits are involved, surgery should be performed in stages to prevent vascular compromise of the middle digits.

Prognosis

Prognosis is favorable for normal function and appearance, except in cases of complex syndactyly involving not only bone but also vascular and nervous tissue. These cases may be associated with some postoperative loss of function.

Collaborative Management

Parents of infants with syndactyly are instructed in occupational and physical therapy, specifically in massage of the interconnecting skin. Massaging of the webbed area prior to surgery allows some stretching of the skin, which permits easier repair. Referrals to certified hand therapists or plastic surgeons may also be indicated.

POLYDACTYLY

Polydactyly is any duplication of digits beyond the typical five. It is the second most common hand anomaly, next to syndactyly. Polydactyly is believed to be caused by duplication of a single embryonic bud. African Americans are affected 10 times more often than Caucasians. African Americans more often have postaxial polydactyly (duplication of the little finger), whereas preaxial polydactyly (duplication of the thumb) occurs primarily in Caucasians. In African Americans, postaxial polydactyly is typically an isolated incidence, whereas in Caucasians it is associated with syndromes and chromosomal anomalies. Central axial polydactyly is the duplication of the ring, long, or index finger. Central axial polydactyly is often associated with complex syndactyly. Polydactyly may be further classified into three types: Type I is merely a rudimentary soft tissue mass connected by a piece of tissue, or pedicle. Treatment of this type involves simple excision, which can typically be done prior to discharge from the nursery per the parents' request. To avoid any residual skin tag after excision, infants are often referred to plastic surgery for a more complete removal. Type II is a partial duplication with involvement of the phalanges. Type III, a rare occurrence, involves complete duplication of the metacarpal and phalanges.

Collaborative Management

Treatment of polydactyly types II and III centers around functional capacity first and appearance second. The infant is observed for which duplication is dominant and most functional, and efforts are made to remove the least functional counterpart. If both duplicated digits appear to be equally functional, surgery should then be used to promote aesthetic appearance. Reparative surgery often begins prior to 18 months and should be completed by 3 years of age.

BIRTH TRAUMA

Birth trauma encompasses both mechanical and asphyxial events occurring during delivery. This trauma may be due to pressure and distortion. Mild, transient, or disabling trauma can occur despite exemplary obstetrical care; encouragingly, birth trauma rates are declining but still occur in approximately 2.6% of live births (Chaturvedi, Chaturvedi, Stanescu, Blickman, & Meyers, 2018). A positive association exists between birth trauma and macrosomia, prematurity, breech presentation, shoulder dystocia, cephalopelvic disproportion, and vacuum extraction.

Clinical Manifestations

Birth trauma includes subdural and intracerebral hemorrhage, abrasions, ecchymoses, erythema, cephalohematomas, caput succedaneum, fractures (especially of the clavicle), skeletal and spinal cord injuries, brachial plexus damage, and nerve palsies. Clavicular fractures are the most common fractures diagnosed as birth trauma. Clavicles are at an increased risk for fractures during shoulder dystocia in a vertex presentation or with arms extended during a breech delivery (Liu & Thompson, 2019).

Quality and Safety: Physical examination findings related to birth trauma may appear only as bruising, abrasions, and petechiae that overlie the affected part. Further diagnostic methods should be used when the infant exhibits pain on movement, limited motion, and abnormal passive positioning of an extremity or head movement.

Skull fractures may present as cephalohematomas. Skull fractures are most often linear and typically involve the parietal bones. Symptomatic evidence of a nondepressed skull fracture may resemble signs of increased intracranial pressure secondary to epidural hemorrhage. Clinical presentation may include changes in muscle tone, hypertonicity or hypotonicity, arching of the back with the head in hyperextension, and respiratory compromise. Usually, no treatment is indicated for asymptomatic skull fractures. Depressed skull fractures, however, may require elevation of the depressed area.

Emergency Alert: A rare, but possible, fatal delivery complication is subgaleal hemorrhage. This may present as a cephalohematoma with a small area of swelling on the scalp as early as 4 hours of age. This often progresses and, unlike the cephalohematoma, crosses suture lines and involves the nape of the neck. The volume of blood loss may be high, causing hypovolemic shock.

Vertebral fractures are incurred in difficult breech deliveries in which longitudinal traction in combination with a twisting motion may occur. These features commonly involve the seventh cervical and first thoracic vertebrae. Treatment depends on the extent of resultant nerve damage but often requires traction.

The most common nerve injury attributed to birth trauma is brachial plexus damage and resulting nerve palsy. This injury involves damage to the network of nerve fibers in the neck and shoulders referred to as the *brachial plexus*. The prognosis is variable: Up to 35% of children with brachial plexus palsy may demonstrate lasting functional impairment of the involved limb (O'Berry, Brown, Phillips, & Evans, 2017). Involvement may occur in the upper portion (Erb–Duchenne palsy), lower portion (Klumpke's paralysis), or both portions (complete brachial plexus palsy).

Erb–Duchenne paralysis is the most common form. The affected arm is limp and in a position of elbow extension and internal rotation. The Moro reflex is diminished and the grasp reflex intact. Klumpke's paralysis involves paralysis of the hand and wrist and is uncommon in infants. Complete brachial plexus paralysis results in paralysis of the entire arm. With full nerve-root avulsion injuries, some sensory recover may occur but no motor recovery can be expected (Liu & Thompson, 2019).

Diagnosis

Diagnosis of birth trauma is based on physical assessment findings. These are usually fairly visible at birth or in the immediate postnatal period. Physical findings should be confirmed, when necessary, by radiologic evaluation to establish whether a fracture is present. For significant scalp swelling, evaluation of the skull by x-ray is prudent.

Collaborative Management

Treatment of birth trauma depends on the type and severity of the trauma. Often, supportive measures may be the only intervention required. For instance, brachial plexus injuries may require immobilization in a neutral position using braces or splints. Specialized treatment protocols may, however, be initiated by occupational and physical therapists under the direction of pediatric orthopedic and/or neurology specialists. Surgery may also be indicated in severe cases.

Clavicular fractures also respond to supportive management. Typically, the arm is flexed, and the elbow is held against the chest. This position limits movement, thereby decreasing pain and

preventing additional trauma at the site. Callus formation stabilizes the fracture by 10 days of age. A hard, palpable knot can often be felt with this callus formation. Again, referral to orthopedists and occupational and/or physical therapists is indicated.

Parental Education and Support

Diagnosing a disorder resulting from birth trauma can evoke anxiety in a parent. Birth trauma may connote thoughts of violence. The manner in which such information is taken from and conveyed to the family is important. Nonjudgmental, supportive care by health professionals along with consistent primary care by one individual may diminish some anxiety and allow the parents to establish trust. The mother may especially feel that she is to blame for the neonatal problem. Calm reassurance about the nature of the trauma is important. It also helps to allay fears that something was done incorrectly during the delivery process if parents understand that many of these injuries cannot be avoided or anticipated. Parental education is prerequisite if the parents are to understand the need for continued, long-term treatment, which many of these infants require. Many birth trauma injuries require long-term follow-up care by orthopedists, neurologists, or occupational or physical therapists.

DEVELOPMENTAL DYSPLASIA OF THE HIP

Developmental dysplasia of the hip (DDH) refers to any manifestation of hip instability, ranging from subluxation to complete dislocation. DDH remains a common problem despite almost universal neonatal screening. Although controversy surrounds the usefulness of clinical neonatal screening programs for the diagnosis of DDH, these programs have led to earlier diagnosis and treatment for many infants. Additional studies have noted improved diagnosis of hip dysplasia with the use of ultrasound. It is recognized that up to 88% of unstable hips will normalize without treatment. Early clinical exams and targeted ultrasounds for infants with high-risk factors are the primary screening tools currently used. Infants with high-risk factors include those with a family member with congenital/developmental hip dysplasia, those with breech presentation, and those with feet deformities (Shorter, Hong, & Osborn, 2011).

Incidence and Risk Factors

Reports of the incidence of DDH vary. The incidence of DDH in the United States is approximately 1 to 4 in 1,000 live births. Differences in DDH incidence rates across ethnic groups can be attributed to genetic, ethnic, and environmental influences. Other influential factors include the age of the infant at the time of examination, the expertise of the examiner, and the definition used by the examiner for the diagnosis of DDH.

Incidence of DDH is increased in first-born children. This increase may be due to the unstretched uterine and abdominal muscles, oligohydramnios, and the high association of fetal breech positioning in primigravidas. A definite preponderance toward DDH occurs in female children. The ratio of occurrence of DDH in girls to boys is 6 to 1. Females account for 80% of all cases of DDH. Factors that may contribute to this finding include the fact that twice as many females as males present in the breech position, and females appear to have heightened laxity in response to maternal relaxin hormones.

Breech position remains a major contributory factor to the development of DDH. Specific incidences of DDH in relation to positioning are 0.7% for cephalic, 2% for footling, and 20% for single breech. The incidence of DDH for infants in the breech presentation is not altered by delivery methods. Breech-positioned infants delivered by cesarean section have the same predisposition to hip dislocation as those delivered vaginally. The left hip is involved three times more often than the right hip. Approximately 60% of DDH is on the left side, 20% on the right side, and 20% bilateral. This finding is attributed to the tendency of the fetus to lie with its left thigh against the maternal sacrum. This position forces the left hip into a posture of flexion and adduction. Thus, the femoral head is covered more by the joint capsule than by the acetabulum (Figure 14.4).

For infants born with other musculoskeletal and congenital renal abnormalities, such as torticollis and Potter's association, the incidence of DDH is increased. Congenital renal abnormalities can result in fetal oliguria (abnormally small amounts of urine), thus subsequently producing oligohydramnios. Oligohydramnios can cause postural deformities because of the mechanical pressure on the fetus. Torticollis, arthrogryposis, and metatarsus adductus are thought to result from intrauterine compression, as does DDH.

After 40 weeks gestation, the femoral head in the typically developing infant is firmly seated in the acetabulum and remains positioned there by the surface tension of the synovial fluid. The hips of the infant are difficult to dislocate. Conversely, the infant with a dysplastic hip has a loosely fitting femoral head and acetabulum. Because of this pathophysiologic phenomenon, the femoral head can assume several abnormal positions in an infant with DDH. One such position is termed *subluxation*. Subluxation occurs when the femoral head can be moved to the edge of the acetabulum but not completely out of it. Another position is termed a *dislocatable hip*. A dislocatable hip exists when the femoral head can be displaced from the acetabulum by manipulation but returns to the acetabulum afterward. The femoral head can also be found in a completely dislocated position at birth (Figure 14.5). Dislocated hips may or may not be reduced by manipulation.

DDH is a dynamic disorder that may improve or deteriorate with or without treatment. Thus, the joint may spontaneously dislocate and reduce (return to normal position) with normal neonatal movement. With time, this simple mechanism progresses in complexity secondary to adaptive changes. DDH can eventually progress either to permanent reduction, complete dislocation, or dysplasia (abnormal development). More than 60% of infants with hip instability stabilize within the first week of life, and 88% stabilize postnatally within the second month. Only 12% of infants with initial hip instability are considered to have DDH with potential for progression.

When complete dislocation occurs, pathologic changes occur to the femoral head, acetabulum, and ilium. This complete dislocation is due to the adaptive changes that occur in the

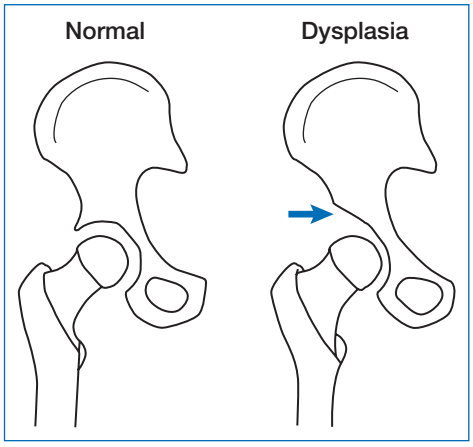

FIGURE 14.4 Acetabular dysplasia of the hip.

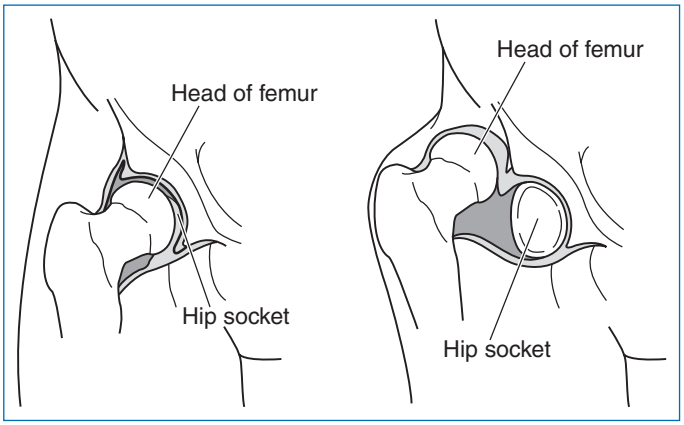

FIGURE 14.5 Normal position of the femoral head and hip socket (left), and hip dislocation (right).

adjacent tissue and bone. **Quality and Safety: The long-term complication of dislocation, when adequate treatment has not occurred, is degenerative changes of both the femoral head and the acetabulum. Once adaptive changes occur, risk for progressive degeneration despite treatment increases.** The subluxated hip, when not diagnosed in the neonatal period, is generally diagnosed at adolescence, when the strain of puberty and rapid growth spurts occur. With subluxation, the femoral head is laterally displaced and pushed upward into the joint; it is not completely out of the acetabulum. As the child grows and increased weight bearing occurs, the femoral head slides around and moves to the joint's edge. Degenerative changes result from this continual sliding. Early arthritis is a common complication in those with DDH, often requiring surgical intervention for improved mobility (Stelzeneder et al., 2012).

Diagnosis and Clinical Manifestations

In the neonatal period, the Ortolani and Barlow maneuvers are useful in diagnosing DDH (Williams, Protopapa, Stohr, Hunter, & Roposch, 2016). The Ortolani test is used to determine dislocation in the hip of a newborn, and the Barlow test is used to determine whether the hip is dislocatable (Barlow, 1962; Ortolani, 1976). In practice, both procedures are done in sequence. For examination, the infant is placed on a firm surface in the supine position.

The infant should be relaxed and quiet. Only one hip should be examined at a time. To perform the Ortolani test, the clinician stabilizes the infant's pelvis with one hand and with the other hand grasps the infant's thigh on the side to be tested. The examiner's middle finger is located over the greater trochanter (lateral aspect of the upper thigh), and the thumb is across the knee. The infant's hip is flexed to 90° while bending the knee. The infant's leg is then gently abducted with an anterior lift. In a positive Ortolani test, a *clunk* is heard with abduction. This clunk occurs as the dislocated femoral head slides over the posterior rim of the acetabulum and into the hip socket. Next, the hip is adducted, and, for the infant with DDH, a second clunk can be heard as the femoral head is displaced out of the acetabulum.

False-positive diagnoses of DDH have occurred when the examiner misinterprets a normal *click* (high-pitched sound) for a clunk. A click is not a sign of DDH. Clicks may be heard as a result of snapping of ligaments or tendons, and the majority are normal.

Barlow's test determines instability of the hip and identifies those hips that can be dislocated upon manipulation. Both hips and knees are flexed, with the hip to be tested in slight adduction. The examiner's middle finger remains positioned as for the Ortolani test, over the greater trochanter. The thumb is, however, located over the medial aspect of the infant's lower thigh. Gentle pressure is exerted by the thumb posteriorly and laterally (down and out). For the infant with DDH, the femoral head can be felt to move out of the acetabulum with the typical clunk. The hip can then be reduced by the Ortolani maneuver or simply by releasing thumb pressure and abducting and flexing the hips.

When the femoral head is subluxated, the examiner may observe a sliding motion in the hip joint during physical examination. This sliding motion can be characteristic of an unstable hip joint. Most cases of unstable hips spontaneously resolve without treatment.

The American Academy of Pediatrics (AAP) committee on quality improvement has issued guidelines to assist in the diagnosis and management of the infant with DDH. All newborns should receive a screening exam. The Barlow and Ortolani maneuvers are not useful after 8 to 12 weeks of age. Ultrasonography is not recommended as a universal screening tool but is useful as a targeted screening tool. If the physical exam of the neonate is equivocal, a repeat exam should be performed at 2 weeks of age. Certain physical signs that would result in an equivocal hip exam for DDH would include a persistent soft click. If the Ortolani/Barlow exam is positive with a hip clunk at 2 weeks of age, a referral to an orthopedic specialist is required. This is not an emergency but should be completed in a timely matter over the next few weeks. The infant presenting at 2 weeks with a persistent soft click should receive ultrasonography of the hip within the next 3 to 4 weeks or referral to an orthopedic specialist at this time. For the infant who exhibits a normal hip exam with resolution of the soft hip click, routine screening with well-baby checks during the first year of life is the recommendation. It is important to note that, according to the AAP recommendations, a newborn who is discharged before 48 hours of age should receive a repeat hip exam 2 to 4 days after discharge.

If the family has a history of DDH, the incidence increases to 9.4/1,000 in males and 44/1,000 in females. Because of this increased risk, even with a negative hip exam, an ultrasound at 6 weeks should be considered, or an x-ray of the hips at 4 months can be an alternative (Morey, 2001).

Collaborative Management

The goal of collaborative management is to achieve and maintain reduction of the unstable hip. The sooner treatment is implemented, the greater the chance for successful outcome. Various splinting devices are used to treat DDH in infants. Examples of splints include the Pavlik harness, von Rosen splint, Denis Browne hip adduction splint, and Frejka pillow splint. The most commonly used splint for neonates is the Pavlik harness.

The Pavlik harness allows for spontaneous hip and lower extremity movement while maintaining reduction of the hip joint. It can be worn comfortably during all aspects of newborn care, including diaper changes. The Pavlik harness can be adjusted for growth. It is indicated for use in newborns and infants up to 6 months of age. Use of the Pavlik harness is contraindicated for infants able to stand and for those infants in whom the hip joint is not reducible by manipulation. A major factor influencing the success of the Pavlik harness is parental compliance with the treatment. With this condition extensive parental education is imperative.

Parent and Family Education and Support

In addition to providing information regarding the pathology and treatment goals of DDH, the nurse should provide the parents with an opportunity to remove and reapply the harness while

under supervision. Referrals to physical therapy and/or occupational therapy may also be indicated. Parental support groups can help parents adjust to the infant's temporary awkward condition. Parents should also be educated in the procedure used to reduce the dislocated hip because complete reduction must be achieved before the harness is applied.

Long-Term Consequences and Complications

As with most therapeutic treatments, the potential for iatrogenic complications exists. Complications observed following DDH treatment include avascular necrosis, redislocation, and acetabular dysplasia. Complications can result from either inadequate or overly aggressive treatment. **Quality and Safety: Delaying surgery is also associated with poorer clinical outcomes, including limited range of motion, gait disturbances, and possible radiologic abnormalities** (Alnamshan, Jawadi, Alshoaibi, & Moukaddem, 2018).

Emergency Alert: An additional complication that has been reported with the use of the Pavlik harness is the development of brachial plexus palsy (Mostert, Tulp, & Castelein, 2000). The tension of the shoulder harness appears related to this complication. The harness may be applied too tightly or may not be modified with the infant's growth, thus causing downward pressure on the brachial plexus nerves and subsequent neuropathy.

Alternatives to harnessing include surgical and nonsurgical reduction of the hip followed by casting. A hip spica cast is most often used with these infants. **Quality and Safety: Care then includes observance for poor pedal pulses, decreased peripheral circulation, pain, skin excoriation or abrasions, and possible development of respiratory infections resulting from decreased mobility.** An adjustment in car seats is required with the harness, and any casting and parental education should be documented prior to discharge of the infant or a specialized car seat may be needed for safe transport of the infant.

HOSPITAL-ACQUIRED POSITIONAL DEFORMITIES: SUPPORTING THE MUSCULOSKELETAL SYSTEM OF THE PREMATURE INFANT IN THE NEONATAL INTENSIVE CARE UNIT

Infants born early are often at a motoric disadvantage. According to Celik, Elbasan, Gucuyener, Kayihan, and Huri (2018), "Disorders in the processing of the signals coming from the proximal sensory systems (vestibular, proprioceptive, tactile) lead to problems in the production of an adaptive response, the development of postural control and movement coordination, and the motor development and the arrangement of the awake-orientation status—all of which affect the development of play, social participation, education, and self-care occupations" (p. 2). Regarding musculoskeletal implications, Sweeney and Gutierrez (2002) state that "alignment and shaping of the musculoskeletal system occur during each body position that infants experience while in neonatal intensive care. Neonatal nurses and physical therapists can play a major role in designing, modeling, and teaching positioning strategies that promote skeletal integrity, postural control, and sensorimotor organization" (p. 58). They continue, describing positioning procedures used by neonatal intensive care unit (NICU)-based healthcare professionals to prevent extremity malalignment, skull deformities, and motor delays.

Infants admitted to the NICU are typically premature and/or medically fragile; therefore, they often demonstrate signs of motoric instability during their hospital stay. Motoric *stability* is indicated by consistent muscle tone appropriate for postconceptual age; controlled activity, including smooth movement of extremities and head; smooth postural changes; demonstration of bright-eyed alertness and visual attention; and attempts to self-regulate through foot clasp (bringing feet together), grasping, bracing, holding on, hand to head or mouth activity, trunk tucking, or sucking. *Instability* is demonstrated through tremors, twitches, startles, coughs, sneezes, yawns, sighs, seizures, flaccidity, hyper/hypotonicity, hyperflexions, frantic activity, fluctuating tone, or eye floating (disorganized eye movements).

Both medical and familial caregivers can support infant musculoskeletal development through recognition of the signs and symptoms of instability and through the use of the following interactions to promote motoric stability: (1) containing the infant's extremities using hands, blankets, positioning aids, and so forth, to promote gentle flexion of the trunk and all extremities; (2) positioning infant with extremities flexed toward midline and hands on face or head; (3) moving the infant slowly to encourage organized position changes; (4) keeping the infant in contact with the bed during movement if possible; (5) allowing opportunities for the infant to use hands and feet to push against surfaces, grasp objects, clasp hands together, and suck; (6) varying infant positions; (7) lifting infant in prone or side lying (as opposed to supine) to promote fetal tuck and calm; (8) providing daily opportunities for tummy time as medically appropriate; (9) performing swaddled bathing; and (10) referring to occupational and physical therapy for specialized evaluation and treatment recommendations.

CRANIOSYNOSTOSIS

The bones that constitute the skull are joined with fibrous joints. These joints are lined with a thin layer of fibrous tissue. Separation of these joints allows for remodeling of the skull at the time of delivery and for rapid growth of the head during the early developmental years. The skull consists of five main sutures: coronal, lambdoidal, squamosal, sagittal, and metopic. The signal for closure of these sutures remains unclear but is believed to be secondary to multiple factors. The various sutures of the skull begin to close clinically in the first year of life, and the process continues into childhood. Complete ossification of these sutures is anticipated in the second or third decade of life. Figures 14.6 and 14.7 illustrate the newborn's cranial sutures.

Premature closure of any suture in the skull results in a clinical condition called *craniosynostosis*. The early closure of a cranial suture typically starts at one point and progresses along the suture line. Premature closure may occur prenatally or postnatally. Only one suture may be prematurely fused, or multiple sutures may be involved. Simple craniosynostosis, which involves one suture, generally occurs as an isolated defect. Complex craniosynostosis describes the premature closure of two or more sutures. This is usually associated with a genetic syndrome such as Apert syndrome or Crouzon syndrome.

Pathology and Clinical Characteristics

Clinical characteristics depend on which suture is affected. The closure of one suture does not allow growth in that area, but generally increases growth in the other areas of the skull. The sagittal suture is the most commonly affected suture. When this suture is involved, the head presents as dolichocephalic, with a long and narrow appearance of the skull and increased length from front to back. Bossing of the frontal and occipital regions is also seen. The coronal suture is the second most common suture involved in premature closure. Bilateral closure of the coronal suture leads to the clinical appearance of a skull that is wide from side to side, but short from front to back (also termed *brachycephaly*). Unilateral

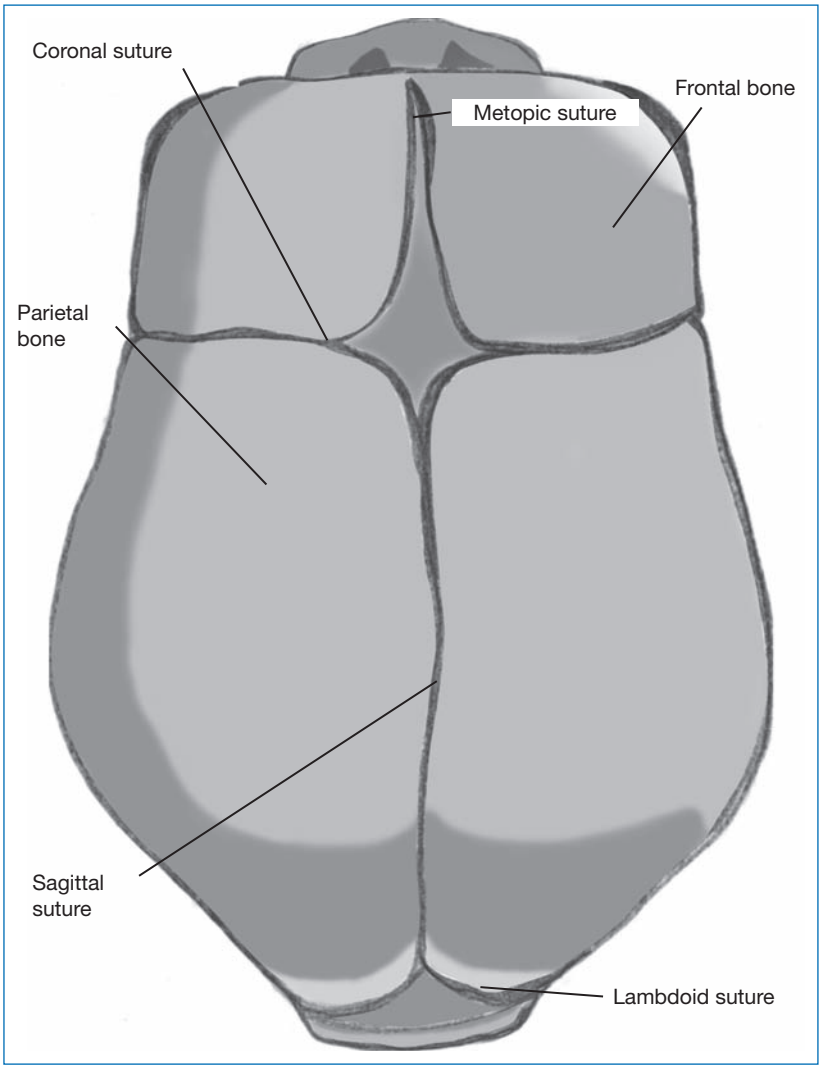

FIGURE 14.6 Superior view of neonatal cranial sutures.

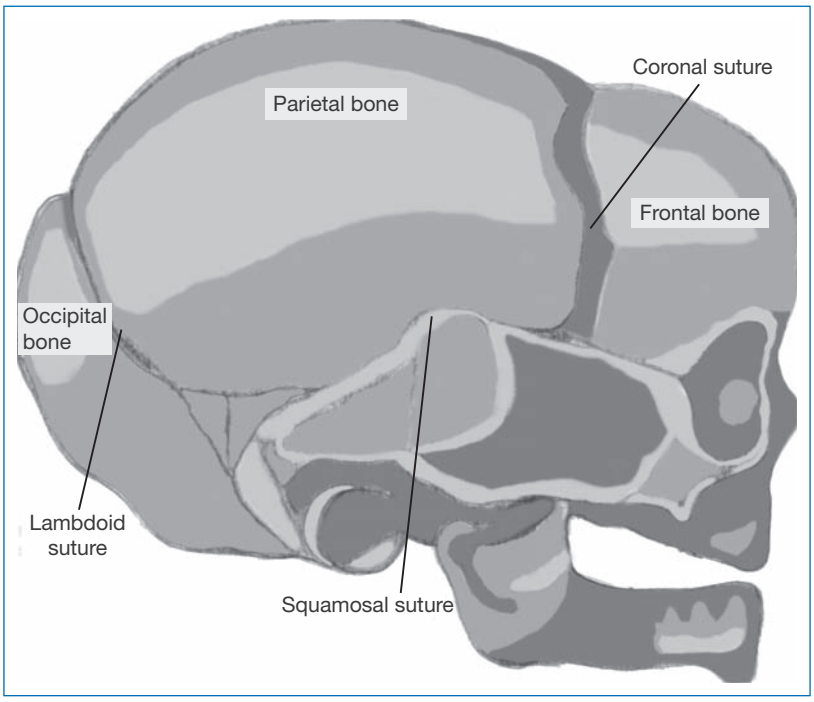

FIGURE 14.7 Lateral view of neonatal cranial sutures.

closure of a coronal suture results in plagiocephaly, or twisted skull, with prominence of the forehead on the unaffected side, as the skull grows in this direction. The forehead is flattened and the eyebrow is raised on the affected side. Bilateral lambdoidal craniosynostosis could be identified with a flattened occipital region, whereas unilateral lambdoidal craniosynostosis has a flattened area on one side of the occiput and appears asymmetrical when compared with the other side. Long-term supine positioning of the infant can also produce this appearance.

Positional asymmetric skull appearance, not related to abnormal suture closure, may be seen in infants with a neuromuscular defect that will not allow the child to move his head from side to side spontaneously. Congenital torticollis can result in an asymmetrically flat occipital region as the infant tilts the head toward the affected side. Isolated metopic craniosynostosis will produce a deformity with a narrow, protruding forehead. Facial development of the skull is affected, and orbital hypotelorism is also noted with this defect.

Diagnosis and Management

Diagnosis is preceded by suspicion of the abnormal physical appearance of the skull, by plagiocephalometry, or by anthropometric measurements with a caliper (Siegenthaler, 2015). There is persistent or progressive abnormal skull growth, often with the head circumference intact for age. Craniosynostosis is usually confirmed with a computed tomography (CT) scan of the skull, with three-dimensional CT required for more detailed preoperative examination. Surgery is required to correct this defect. This will take place in a specialized pediatric hospital with a multidisciplinary team of providers. The complexity of the procedure increases with the number of sutures involved and the cranial remodeling at the time of surgery. The type of repair is dependent on the suture(s) involved. Surgery generally takes place in early infancy (3–9 months of age). The goal is to achieve early correction of the synostosis and avoid extreme cranial deformities as the skull grows rapidly in the first year of life. In recent years, endoscopic procedures have shown good results in reducing the excessive blood loss and extended hospital stays that were previously associated with repair of craniosynostosis.

CONGENITAL MUSCULAR TORTICOLLIS

Congenital muscular torticollis, with an incidence of 0.4% in all live births, is a rare musculoskeletal deformity with unknown pathogenesis. It is known to be primarily a disorder of the sternocleidomastoid muscle.

Pathophysiology

Several theories exist as to the cause of congenital torticollis, including genetics, abnormal uterine positioning, neurogenic disorders, and ischemic injury to the sternocleidomastoid muscle. Whatever the cause, this pathologic disorder consists of a fibrous contraction of the sternocleidomastoid muscle. Typically, the ipsilateral trapezius muscle is atrophied.

Diagnosis

Congenital torticollis can present within the neonatal period. Presentation may include a 1 to 3 cm hard, palpable mass in the neck on the affected side accompanied by an abnormal positioning of the head. Infants with congenital torticollis tilt the head to the affected side, and the chin is pointed upward in the opposite direction. Facial asymmetry may be a later sign. The face and skull on the affected side appear smaller.

In children with untreated congenital torticollis or in cases with torticollis unresponsive to therapy, the shoulder on the affected side is raised to compensate for the abnormal head positioning. This form of compensation may lead to cervical and lumbar scoliosis as well as chronic back pain.

Collaborative Management

Traditionally, occupational and/or physical therapy for congenital torticollis is instituted immediately. Because congenital torticollis may resolve naturally within the first year of life, surgery is typically delayed, pending results of therapy.

Severe fibrosis of the sternocleidomastoid muscle may require surgery (Nilesh & Mukherji, 2013). In one study, however, 98% of infants diagnosed with torticollis responded to physical therapy. Duration of therapy was dependent on severity of the muscular fibrosis (Y. T. Lee et al., 2011).

Occupational therapists, physical therapists, and orthopedic surgeons should be consulted to assist in the management and subsequent follow-up of these infants. Family members should be provided with a functional home exercise program and counseled regarding the possibility of a neck brace to be postoperatively worn by the infant. It is usually the nurse's responsibility to coordinate outpatient consultations and to prepare the family with discharge instructions. In addition, the nurse must determine whether the family lives in an area accessible to follow-up care. If not, a referral to social services, IDEA Part-C Early Intervention services, or financial counseling may be needed so the family can participate in follow-up.

SKELETAL DYSPLASIA

Skeletal dysplasia is a term used to identify a group of clinical disorders that involve abnormal endochondral ossification. It includes achondroplasia, hypochondroplasia, and thanatophoric dysplasia, all of which present with a short-limbed skeletal dysplasia at varying ages of development.

Achondroplasia

Although the word *achondroplasia* was once used to describe any form of dwarfism, it is now recognized as one distinct type of dwarfism having characteristic features. Achondroplasia has an autosomal dominant pattern of inheritance (Wilkin et al., 1998) and is the most common nonlethal skeletal dysplasia. Most cases occur by spontaneous mutation, so many of these children have parents of typical stature. A mutation of the gene encoding fibroblast growth factor receptor-3 (FGFR3) has been implicated in this disorder. In achondroplasia, the infant's body has trouble converting cartilage to bone (ossification). The incidence of achondroplasia has varied in the past as a result of multiple forms of skeletal dysplasia diagnosed as achondroplasia. The current incidence is 1 in 15,000 to 40,000 live births. One risk factor for spontaneous mutation that involves achondroplasia appears to be advanced paternal age.

Infants with achondroplasia can be identified at birth with a rhizomelic shortening of the extremities. In other words, when the arms are viewed, the upper arm (humerus bone) will appear more severely shortened compared with the lower arm (radius and ulnar bones). The same holds for the lower extremities, where the thigh (femur) will appear more severely shortened than the lower leg (tibia and fibular bones). The infant who is affected with achondroplasia also presents with a disproportionately large head with frontal bossing and depressed nasal bridge. The hands are small with a trident configuration that describes the appearance of the fingers and an increased spacing between the long and ring fingers (Horton & Hecht, 2011). Identification of mild hypotonia and limitation of elbow extension with laxity in most other joints are also noted.

These neuromuscular and skeletal anomalies—including mild hypotonia, rhizomelia, joint laxity, and reduced elbow extension—can produce a delay in gross motor milestones but generally progress toward age-appropriate skill over the first few years of life. Commonly associated health problems also include apnea, recurrent ear infections, and obesity. Central intelligence is normal in most cases.

Hypochondroplasia

Hypochondroplasia is similar to achondroplasia but considered milder. It may be rarely noted at birth, as the length of the infant is often age appropriate. The short stature becomes clinically apparent around 24 months of age. This condition is rarely diagnosed in the neonatal period but may present with macrocephaly. Children and adults experience some of the similar orthopedic complications as the individual with achondroplasia. Some of these include joint and lower back pain, limited range of motion at the elbows, and bowing of the lower extremities.

Thanatophoric Dysplasia

Thanatophoric dysplasia is the third in this series of common skeletal dysplasias. The name of this disorder is derived from the Greek word *thanatos*, meaning *death bearing*. It is a lethal defect and is often compared to OI, type II, in terms of its clinical scenario after birth. Death usually occurs within a few hours or days secondary to respiratory failure from severe pulmonary hypoplasia. The clinical presentation of thanatophoric dysplasia describes a fetal environment of reduced fetal movements and polyhydramnios. Hypotonia in the neonate with macrocephaly, often presenting as a cloverleaf-shaped skull, is believed to be secondary to early fusion of the coronal and lambdoidal sutures. The limbs are short and bowed with severe brachydactyly or short digits. The thorax is very narrow and short, reminding the clinician of the abnormal pulmonary development and severe pulmonary hypoplasia. The abdomen has a protuberant appearance (Figures 14.8 and 14.9). Almost all cases of thanatophoric dysplasia result from a new genetic mutation, with a low risk of recurrence in subsequent pregnancies. As with other skeletal dysplasias, there is a defect in the *FGFR3* gene (Miller, Blaser, Shannon, & Widjaja, 2009).

Differential Diagnosis

The differential diagnosis of a neonate with shortened stature includes achondroplasia, OI type II, thanatophoric dwarfism, asphyxiating thoracic dysplasia, lethal short limb–polydactyly syndromes, and achondrogenesis. In achondroplasia, the child has markedly shortened limbs and often bowing of the lower limbs, but radiographic studies do not show evidence of multiple fractures and long-bone crumbling as seen in OI type II. Thanatophoric dwarfism and achondrogenesis, both typically fatal in the neonatal period, are characterized by an extremely narrow chest and marked defective ossification, respectively (Shirley & Ain, 2009). These disorders may be detected prenatally through ultrasound identification of the abnormal skeletal features.

Management

Management of infants with skeletal dysplasias depends on the long-term outcome for the specific type of dysplasia. With nonlethal varieties, complications are primarily neurologic and involve the spinal nerves. Anatomic configuration of the intraspinal canal results in pressure on the cord and spinal nerves. This pressure produces chronic backache and, in the most severe scenario, paraplegia. Referrals to occupational and physical therapists, along with long-term orthopedic follow-up, can reduce some of the complications. **Quality and Safety: If changes in the spinal column do occur, the child is at greatest risk for development of increased respiratory difficulties, mobility problems, daily activity (occupational) challenges, self-concept and self-esteem concerns, physical pain, and central or peripheral nervous system neuropathies.** Other common long-term complications include recurrent otitis media, hearing loss, dental overcrowding, and sleep apnea, which may present in childhood (Sisk, Heatley, Borowski, Leverson, & Pauli, 1999).

Limb-lengthening techniques are sometimes used in management of skeletal dysplasias. This has been done in an attempt to reduce the functional and psychosocial difficulties associated with very short stature. The process of limb lengthening is very arduous and surgically complex, with lengthy rehabilitation periods. Often, the physical outcome does not match the desired result, so the benefit of these procedures remains uncertain (Wright & Irving, 2012).

Because children with achondroplasia have a different appearance than their peers, any exaggeration of the condition can add to a faulty self-concept. As the child grows, continual assessment by healthcare professionals and the parents concerning the personal image that the child is developing is prelude to a positive self-esteem. Positive support of parents during the neonatal period is key.

FIGURE 14.8 Thanatophoric dysplasia: narrow thorax and protuberant abdomen.

FIGURE 14.9 Thanatophoric dysplasia: shortened lower extremities.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI), sometimes called *brittle bone disease*, is a connective tissue disorder causing bone fragility and deformities (Forlino & Marini, 2016). It is caused by a genetic mutation affecting collagen, the major extracellular protein, wherein children suffer from fractures, osteoporosis, and mineral bone loss. The incidence of this disorder is about 1 per 20,000 births. Collagen is found in bone, sclera, ligaments, skin, and teeth. In this disorder, all of these tissues may be affected (Sillence & Danks, 1978).

The clinical presentation of OI varies greatly, depending on the particular type. There is also a wide range of severity and symptoms within each type. The classification system described by Sillence and Danks (1978) outlines four basic types of OI. Additional types described in the literature do not appear to have defects in the collagen genes.

Types of OI and Clinical Presentation

OI type I has an autosomal dominant inheritance pattern. In general, type I is the mildest type of OI, but the clinical appearance of individuals may range from mild to severe, even within the same family. A small number of patients with this type may present with fractures in the neonatal period. An increased rate of fractures may be seen as the child begins to walk. Persons with this type are generally of typical height and stature. Sclerae are blue, and the teeth are also affected. In adults with type I OI, hearing loss may occur (Bishop, 2010). Premature or accelerated bone loss following menopause is also seen.

OI type II is also referred to as the *lethal perinatal type*. This is an autosomal recessive disorder that generally results in death either in utero or in the perinatal/neonatal period. The likelihood of prenatal diagnosis is increased with type II, due to the multiple fractures and bowing of extremities seen in utero. **Emergency Alert: Death can occur secondary to damage of vital organs (brain, liver, and lungs) that are not protected by the fragile bony structures.** Severe respiratory distress is seen secondary to the narrow and shortened ribcage. Infants with type II OI are small for gestational age with shortened body and legs, with the head appearing large for body size. The extremities tend to be shortened and deformed with multiple fractures. X-rays demonstrate multiple fractures, both old and new. Ribs and smaller bones may also appear thin and difficult to discern on x-ray. The trauma of birth takes a further toll on the appearance of these infants and contributes to the maceration of the head and limbs.

OI type III is a severe form with an autosomal recessive inheritance pattern. This is the most severe type for those surviving the neonatal period. Multiple fractures of the long bones may occur both before and after birth. There is significant deformity of the bones over time, with scoliosis and hearing loss. Sclerae may be blue. Infants with type III may have typical height and weight at birth. This deteriorates over time, with very short stature seen in childhood/adulthood. The severe deformities of the spine and thorax seen in type III can restrict breathing, leading to significant respiratory complications in adulthood. Life expectancy may be shortened due to these problems (Marini, 2011).

OI type IV is similar to type I in that it is an autosomal dominant disorder with variable penetrance. OI type IV resembles type I in terms of presentation. Newborns rarely have identified fractures, but a number of fractures occur as the child begins to ambulate, with increased weight bearing. These infants also present with growth that is average for gestational age. The growth pattern can change as the child matures, secondary to increased bowing of extremities and kyphoscoliosis, with a short stature comparable to typical height at maturity with the milder forms of type I. OI type IV can also progress to a more severe form, depending on the degree of kyphoscoliosis and vertebral compression fractures, often resembling type III. Unlike type III, life span in type IV is not affected.

As stated earlier, additional types of OI have been identified since the original classification system was developed. These are described as types V (moderate in severity), VI (extremely rare), and VII, VIII (white sclerae), which do not have defects in the collagen genes. The clinical features and management are, however, similar to the other types of OI.

Diagnosis

OI may be suspected prenatally if there is a positive family history. Fractures and other deformities of the skeleton may be seen on ultrasound prior to birth at around 20 weeks (Van Dijk & Sillence, 2014). After birth, the diagnostic process is based largely on physical exam findings of fractures and deformities of the extremities. While the preferred method of diagnosis involves molecular genetic testing, a skin biopsy may also be used to provide a definitive diagnosis through examination of collagen (Steiner, Adsit, & Basel, 2013).

Collaborative Management

Quality and Safety: Neonates with OI should be handled very gently to avoid causing new fractures and to reduce the pain of existing injuries. During care, they should be lifted by using the hands to gently support the buttocks and head. These patients should never be lifted by pulling the extremities, or with hands under the armpits. With diaper changes, it is important to never lift the baby by the ankles, but to move the diaper by lifting the buttocks. When dressing these infants, the caregiver should gently bring the garments over the arms and legs, while avoiding pulling the extremities through the sleeves and legs of the garments. Simple garments with wide openings for extremities are best. At discharge, a special car bed that allows prone or supine positioning may be required (Osteogenesis Imperfecta Foundation, n.d.).

Feeding ability may be compromised with these infants, due to respiratory compromise and difficulty with positioning and handling. Gentle rubbing should be used for burping to avoid rib fractures. If these infants require prolonged immobilization during healing of fractures, measures to protect the skin and facilitate frequent repositioning may be used, such as gel pads or foam wedges. **Quality and Safety: Pain management is also an important part of the care plan when fractures are present.** IV medications or oral sucrose may be used, as well as other nursing measures to improve comfort and positioning (McLean, 2004). Referrals to occupational therapy, physical therapy, and palliative care may be indicated.

The long-term medical management of patients with OI is focused on avoiding fractures and correcting deformities of bones while maintaining maximal mobility and physical function. Intravenous bisphosphonates have shown some benefit by improving bone volume, though this does not change the essential defect of collagen (Monti et al., 2010). Growth hormone has also been used with the milder types of OI.

THROMBOCYTOPENIA-ABSENT RADIUS SYNDROME

Thrombocytopenia-absent radius (TAR) syndrome is characterized by the bilateral absence of radii and severe thrombocytopenia in the neonatal period. Hypoplasia or absence of the ulna may also be seen. The thumbs are always present in this syndrome (Scott & Montgomery, 2011). Congenital heart defects and renal anomalies

occur in a significant percentage of these patients. Skeletal anomalies of the lower limbs may also be present, although this is highly variable.

Pathology

The inheritance pattern is uncertain in this disorder, although a microdeletion on chromosome 1 is part of the genetic signature. The greatest pathology occurs in the neonatal period and correlates to the severity of thrombocytopenia, which can lead to intracranial and gastrointestinal hemorrhages (Sola, Del Vecchio, & Rimsza, 2000). The thrombocytopenia is quite significant in many patients, with counts as low as 10,000. Hematologic complications improve with age, hence the reduced mortality and morbidity associated with this syndrome after the first year of life. Platelet counts are generally normal by childhood. If no significant intracranial hemorrhage occurs in the neonatal period, intelligence is expected to be typical for age.

Complications occurring from atypical hand and arm development may be encountered as the child matures. These include fine and gross motor developmental delays. Many children who are affected with this syndrome require some type of adaptive device, or they may learn to compensate with their existing limbs. Referrals to occupational and physical therapy are indicated for specialized assessment and treatment.

Management

The primary management in the newborn period centers on the platelet levels. Because of increased risk of bleeding, platelet transfusions may be required. In addition, handling and phlebotomy via heel sticks should be kept to a minimum to reduce bruising. Cow's milk allergy is seen in many patients with TAR syndrome. The introduction of cow's milk may lead to worsening of thrombocytopenia, and this factor should be considered in management (Toriello, 2011).

SUMMARY

The human body is active, responsive, and constantly moving. The development of its functional motor skills is dependent upon the development of the musculoskeletal system. Although the majority of musculoskeletal defects or disorders in the newborn are nonlethal, they may become the focus of the parents' attention. An understanding of the development of the musculoskeletal system and the pathology for various defects can assist the clinician in teaching and supporting the family and the infant. In addition, recognizing subtle abnormalities can prompt the clinician to evaluate for additional, associated defects that could have serious genetic implications. This chapter helps identify the epidemiological and clinical aspects of infant musculoskeletal conditions in order to improve clinician understanding of the defect and to provide guidelines for management based on pathology, complications, and prognosis. Of equal importance, however, is the awareness that musculoskeletal development is best supported in a family-centered environment and in collaboration with parents eager to maximize their child's potential.

CASE STUDY

■ **Identification of the Problem.** Female infant born at term gestation is noted on initial physical exam to have abnormalities of the upper extremities.

■ **Assessment: History and Physical Examination.** The infant was born by vaginal delivery at 37 weeks gestation to a 16-year-old Caucasian female, G1 P0. The mother received late and limited prenatal care, with the pregnancy remaining unacknowledged until the third trimester secondary to young maternal age. Delivery was uncomplicated. The 1-minute Apgar score was 9, and the infant did not require resuscitation or other special care at delivery. The birth weight was 2,850 g. Infant was noted on general inspection to have abnormalities of the upper extremities.

Physical exam on admission to the transition nursery:

- GENERAL: pink, well-developed female infant, vital signs in the normal range, oxygen saturation was 98% on room air
- Head, ears, eyes, nose and throat (HEENT): normocephalic, anterior fontanelle open and flat, eyes normal, ears normally formed, nares patent, palate intact
- LUNGS: bilateral breath sounds clear and equal, good respiratory effort
- Cardiovascular (CV): RRR, soft murmur, good peripheral perfusion, femoral and pedal pulses palpable
- Abdomen (ABD): soft, active bowel sounds, no organomegaly or masses, three-vessel cord
- Genitourinary (GU): normal term female features, patent anus
- Neurologic (NEURO): appropriate tone for gestational age, active and responsive
- NECK: full range of motion, no masses
- SPINE: intact
- EXTREMITIES: bilateral malformed upper extremities with thumbs present, lower extremities appropriate for age
- SKIN: pink, scattered petechiae over the trunk and face

■ **Suspected Diagnosis.** In this patient, the physical exam findings led to a strong suspicion of TAR syndrome. Immediate evaluation would be indicated to assess platelet count, which can be very low with risk of hemorrhage. Cranial ultrasound should be done to rule out intracranial bleeding. Evaluation of the skeletal structure of the upper extremities would also needed. Echocardiogram should be performed to rule out cardiac defects, which are present in a large percentage of patients with this disorder.

■ **Diagnostic Tests**

1. Complete blood count with differential: WBC 12.7, hematocrit 39%, platelet count 28,000/mm^3
2. X-rays of upper extremities: bilateral absence of radii, with hypoplasia of the ulnae bilaterally; the humeri were present and normal bilaterally; x-rays of lower extremities revealed no abnormalities
3. Echocardiogram: patent ductus arteriosus, no significant structural abnormalities
4. Cranial ultrasound: no evidence of intracranial hemorrhage

■ **Development of Management Plan**

- Platelet transfusion
- Gentle handling of infant to avoid bruising and bleeding
- Close monitoring of the platelet count

■ **Implementation of Management Plan.** The infant was transferred to NICU to obtain a peripheral IV and to have the necessary studies completed. The platelet count was repeated 12 hours after the transfusion with a value of 49,000/mm^3. The infant received an additional transfusion of platelets with improvement to 72,000/mm^3. The infant remained hospitalized for an additional week while receiving ad lib breastfeedings. She remained stable. Repeat cranial ultrasound at 7 days of age was again normal.

The infant was discharged home at 10 days of age with platelet count 80,000/mm^3. She returned to the newborn outpatient clinic 3 days later with platelet count 43,000/mm^3. An additional platelet transfusion was given in the outpatient clinic with no complications. The platelet count on a follow-up visit the next day was 85,000/mm^3. The infant continued to receive periodic follow-up visits for complete blood count monitoring over the next 3 months. She required no further platelet transfusion.

■ **Outcome.** Infant was seen at 6 months of age in the newborn follow-up clinic with typical growth and development. Platelet count was normal.

EVIDENCE-BASED PRACTICE BOX

Osteogenesis imperfecta (OI), often called *brittle bone disease*, is a condition caused by a genetic mutation affecting collagen. The complications of OI stem primarily from bone fractures. The treatment of these patients focuses chiefly on preventing fractures, therefore minimizing pain and improving long-term mobility and function. A number of research studies have investigated the use of bisphosphonates to reduce fracture rates in patients with OI. Biphosphonates act by decreasing the activity of osteoclasts, therefore reducing the rate of bone resorption. These drugs are used successfully in adults with osteoporosis to improve bone strength and density.

A review by Bishop (2010) examined the early use of intravenous pamidronate in neonates in the first year of life. The drug was given on a cyclical basis at varying intervals. A reduced rate of fractures was seen in these infants, as well as improved growth. No severe side effects were documented. There are concerns regarding the difficulty of maintaining reliable central venous access in a small infant. Also, the long-term effects of this therapy remain unknown. It should be noted that the drug does not change the process of abnormal collagen formation.

Growth hormone, which is known to stimulate bone growth and collagen synthesis, has also been examined as a potential treatment for OI. A review by Monti et al. (2010) examined the available information. Data from limited studies suggested that growth hormone could improve growth and exert a beneficial effect on muscle mass and strength, therefore improving capacity for exercise; no increased rate of fractures was noted. This increase in physical activity in OI patients may improve skeletal health and overall physical well-being. Growth hormone is considered a promising therapy in patients with moderate forms of OI. Patients with the more severe types of the disorder did not see a benefit.

Research in the arena of genetics is very promising. Investigators hope to identify more specific causative factors at the molecular level, as well as to explore the possibility of manipulating the disorder's genetic expression. Bone marrow transplant is also being examined as a potential treatment. Limited data suggest that bone marrow transplant can be used to introduce stem cells into the body that can produce normal bone. These modalities remain in early stages of development.

CHAPTER 15

Neurologic System

Georgia R. Ditzenberger
and Susan Tucker Blackburn

INTRODUCTION

The central nervous system (CNS) is an extraordinarily complex system. Normal function of the CNS is critical to the function of every organ in the body and for the integration of organ systems that coordinate physiologic and neurobehavioral processes. Neurologic dysfunction during the neonatal period can arise from insults that occur before, during, or after birth. Such insults can affect the infant's ability to survive in the perinatal and neonatal periods and have implications for later developmental and cognitive outcomes. Thus, alterations in neurologic function in the neonate have significant immediate and long-term consequences for the infant and family. Early recognition of infants at risk for neurologic dysfunction and prompt implementation of appropriate interventions are crucial for both the survival and reduction in long-term morbidity.

This chapter examines the structural and functional development of the CNS in the embryo, fetus, and neonate and the basis for common congenital and developmental anomalies. Neurologic assessment of the neonate and related diagnostic techniques are also presented, as are selected pathophysiologic problems that affect the central and peripheral nervous systems. The neurologic problems examined include neonatal seizures, intracranial hemorrhage, brain injury in preterm infants, hypoxic-ischemic encephalopathy (HIE), structural alterations, and birth injuries. Figure 15.1 shows the general structure of the newborn brain.

CNS DEVELOPMENT AND STRUCTURAL ABNORMALITIES

Many disorders of the neurologic system are related to defects in the development of the CNS. The development of the CNS can be divided into six stages: (a) neurulation, (b) prosencephalic development, (c) neuronal proliferation, (d) neuronal migration, (e) organization, and (f) myelination. These stages overlap, and development progresses at different rates in various sections of the CNS. Embryologic development of the CNS begins shortly after fertilization, and maturation continues after birth until adulthood. The CNS therefore is one of the earliest systems to begin development and one of the last to reach maturity. The stages of CNS development are summarized in Table 15.1. CNS development is controlled by developmental genes in a complex cascade of signaling molecules, neurotropic growth factors, and vitamins (such as vitamin A and folic acid) mediating gene expression along the anterior–posterior axis of the embryo (Gressens & Hüppi, 2015; Yuskaitis & Pomeroy, 2017).

Neurulation

Neurulation is the process by which the formation of the central neuroaxis, that is, the brain and spinal cord, occurs as a result of inductive events within the dorsal aspect of the embryo (Table 15.1). The inductive events are separated into two stages: primary neurulation, the events related to the formation of the brain and spinal cord excluding the caudal segments of the lumbar region; and secondary neurulation, the events related to caudal neural tube formation (du Plessis & Volpe, 2018).

Primary neurulation occurs during the first 3 to 4 weeks of gestation and involves the formation of the primitive brain and spinal cord except the lower sacral and coccygeal segments. The CNS arises as a thickening of the ectoderm on the dorsal portion of the embryo at about 18 days' gestation. The brain and spinal cord develop from this thickening, which is called the neural plate. The neural plate invaginates, forming the midline neural groove along the dorsal surface of the embryo. The parallel folds of tissue on either side of this groove are called the neural folds. The neural folds eventually form the forebrain, midbrain, hindbrain, and spinal cord. By the end of the third postconceptional week, the neural folds fuse to form the neural tube. The cranial portion of the lumen of the neural tube forms the ventricles; the caudal portion forms the central canal of the spinal cord. The tissues of the neural tube interact with surrounding mesoderm tissues (somites) to stimulate development of the bony structures, the skull and vertebrae, of the CNS (du Plessis & Volpe, 2018; Moore, Persaud, & Torchia, 2015).

In the fusion of the neural folds, some of the neuroectodermal cells on the upper margins are not incorporated into the neural tube. These cells form the neural crest, which lies between the neural tube and the surface ectodermal layer. The neural crest tissue forms the peripheral nervous system, which includes the cranial, spinal, and autonomic system ganglia and nerves, Schwann cells, melanocyte (pigment) cells, meninges, and skeletal and muscular components of the head (du Plessis & Volpe, 2018; Moore et al., 2015).

Closure of the neural tube begins in the occipitocervical region (at the level of the future hindbrain and cervical junction) at about 22 days' gestation (du Plessis & Volpe, 2018). The neural folds do

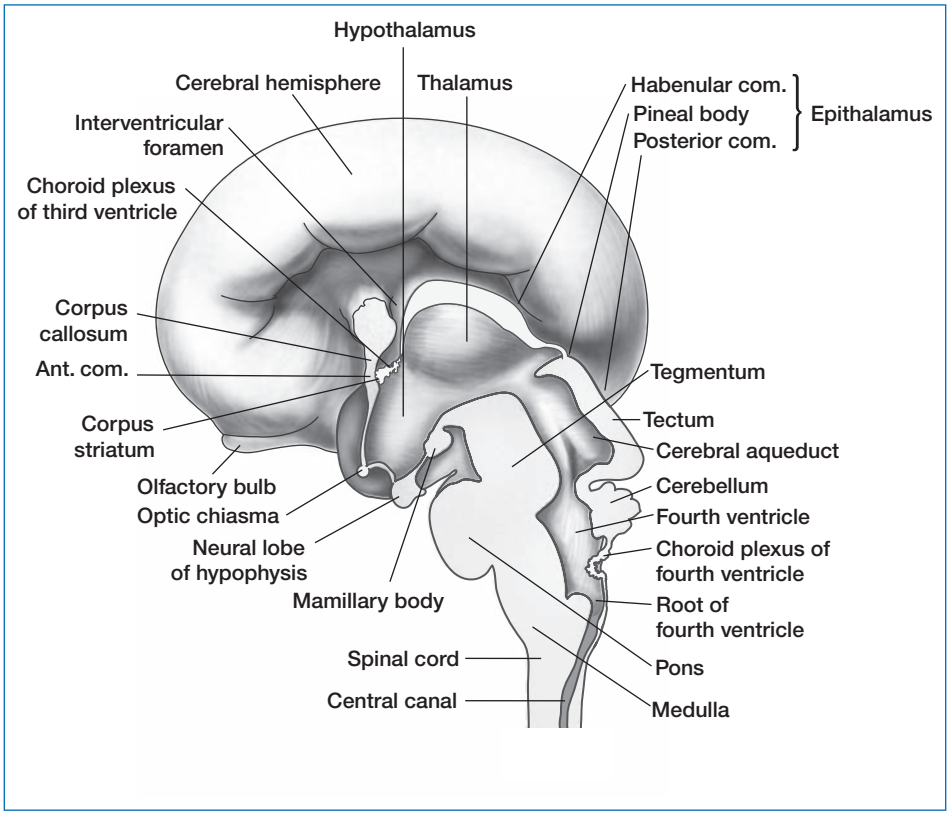

FIGURE 15.1 Cerebral anatomy.

TABLE 15.1

STAGES IN THE DEVELOPMENT OF THE CNS AND RELATED DEVELOPMENTAL DEFECTS

Stage	Peak Period of Occurrence	Examples of Developmental Defects
Primary neurulation	3–4 weeks' gestation	Neural tube defects, anencephaly, encephalocele, spina bifida cystica (meningocele, myelomeningocele, myeloschisis), dermal sinus
Prosencephalic development	2–3 months' gestation	Holoprosencephaly, holotelencephaly
Neuronal proliferation	Cerebrum: 3–4 months' gestation (may continue to term for interneurons) Cerebellum: 2–10 months postnatally	Microcephaly vera, macrencephaly, neurofibromatosis, other neurocutaneous disorders
Neuronal migration	Cerebrum: 3–5 months' gestation (may continue to term for interneurons) Cerebellum: 4–10 months postnatally	Hypoplasia or agenesis of the corpus callosum, schizencephaly, lissencephaly, pachygyria, polymicrogyria
Organization	6 months' gestation—first years postnatal (continues for many years postbirth)	Alterations in brain development secondary to the effects of Down syndrome and trisomy 13, 14, and 15; behavioral alterations; intellectual disabilities
Myelination	8 months' gestation—first years postnatal (continues for many years postbirth)	Brain hypoplasia, neurologic deficits

Fox (Eds.), *Fetal and neonatal physiology* (5th ed., pp. 1294–1313). Philadelphia, PA: Elsevier Saunders.

not fuse simultaneously; fusion proceeds in cephalic and caudal directions from this site. For several days the neural tube is fused toward the central area but is open at both ends. The end areas are known as the rostral (anterior) and the caudal (posterior) neuropores. The cranial end of the neural tube closes at approximately 24 days' gestation. Fusion of the cranial portion contributes to the formation of the forebrain. The caudal neuropore, which is in the future lumbosacral area, closes in a rostrocaudal direction at approximately 26 days' gestation (du Plessis & Volpe, 2018). Once both neuropores are closed, the neural tube is a closed, fluid-filled system that has no further connection to the amniotic cavity unless a defect is present. Alterations in neural tube development and closure give rise to neural tube defects (NTDs). Because differentiation of the surrounding mesodermal tissue (somites) into vertebrae, cranium, and dura depends on interaction with the neural tube, NTDs involve not only the neural elements but also the bony structures and meninges (Blackburn, 2018; du Plessis & Volpe, 2018; Moore et al., 2015).

Secondary neurulation consists of two sequential phases: canalization and regressive differentiation. These phases form the spinal cord of the sacral and coccygeal segments. Canalization begins at 28 to 32 days' gestation and continues through the seventh week of gestation and involves the development of the lower lumbar, sacral, and coccygeal areas from an undifferentiated cell mass at the caudal end of the neural tube. Vacuoles develop that gradually coalesce, enlarge, and contact the caudal end of the neural tube. The second phase, regressive differentiation, begins about the seventh week and continues until sometime after birth. Regressive differentiation is characterized by regression of much of the caudal cell mass, leaving behind the ventriculus terminalis, which is located in the conus medullaris, and the filum terminale (Blackburn, 2018; du Plessis & Volpe, 2018).

Disorders of Neurulation. Congenital anomalies that arise during the period of neurulation result from alterations in neural tube closure, of which 80% occur at either the cranial or caudal end, or alterations in surrounding tissues under development during this period (du Plessis & Volpe, 2018; Moore et al., 2015). Alterations in neurulation are often accompanied by alterations in vertebral, meningeal, vascular, and dermal structures, and include craniorachischisis totalis, anencephaly, encephalocele, spina bifida occulta and cystica (meningocele, myelomeningocele [MMC], and myeloschisis), and Chiari type II malformations (Blackburn, 2018; du Plessis & Volpe, 2018). NTDs are one of the most common CNS malformations. Incidence varies with ethnicity, diet, geographic area, and socioeconomic status; prevalence has decreased with increased folic acid intake by childbearing women (Danzer, Rintoul, & Adzick, 2017).

Disorders of neurulation arise from genetic, nutritional, and/or environmental influences (Blackburn, 2018; du Plessis & Volpe, 2018; Gressens & Hüppi, 2015; Yuskaitis & Pomeroy, 2017). A familial incidence and an increased genetic susceptibility within immediate families is seen. The risk for an NTD increases three- to fivefold for subsequent offspring after one affected child; the risk increases to 10-fold with two or more affected family members (Danzer et al., 2017). In addition, the risk of NTD is greater if the previously affected family member had a lesion at T11 or higher. In the general population, increased risk of NTD is associated with maternal diabetes, maternal obesity, prior miscarriages, maternal folate deficiency, and maternal exposure to drugs such as valproic acid and folic acid antagonists such as trimethoprim and carbamazepine (Au, Ashley-Koch, & Northrup, 2010; Chitayat et al., 2015; du Plessis & Volpe, 2018).

Folic acid supplementation at conception reduces the rate of NTDs (Balashova et al., 2018; Breimer & Nilsson, 2012; Chitayat et al., 2015). Up to 50% to 72% of NTDs may be preventable with adequate folate supplementation (du Plessis & Volpe, 2018). Folate is a cofactor for enzymes needed in DNA and RNA synthesis and is important to a cell's ability to methylate proteins, lipids, and myelin, for cell proliferation and growth, and for the actions of other B vitamins (Balashova, Visina, & Borodinsky, 2018; Czeizel, Dudás, Paput, & Bánhidy, 2011). Women of childbearing age are recommended to consume 0.4 mg of folate daily; for women who previously have had an infant with NTD, the recommendation is 4 to 5 mg daily (American Academy of Pediatrics Committee on Genetics, 1999; Czeizel et al., 2011).

Antenatal screening for NTDs involves maternal serum alpha-fetoprotein screening (MSAFP) and ultrasound examination, or, more commonly, just second trimester ultrasound (American College of Obstetricians and Gynecologists [ACOG], 2017). Analysis of MSAFP is performed between 15 and 20 weeks' gestation, with the optimal time between 16 and 18 weeks' gestation. AFP is a major fetal glycoprotein, similar to the albumin produced in the fetal liver from 6 weeks' gestation; concentrations of AFP peak at 13 to 15 weeks' gestation. Normally, the AFP concentration of the cerebrospinal fluid (CSF) is significantly higher than that of the amniotic fluid; therefore, when CSF leaks into the amniotic fluid, as occurs with an open NTD, the AFP level of the amniotic fluid and maternal serum is elevated. MSAFP is done much less frequently currently due to improvements in ultrasonography and increased use of second trimester fetal anatomic assessment; the detection rate is 96% (ACOG, 2017; Sepulveda et al., 2017). Fetal ultrasound can be used for detection by the end of the first trimester, although the detection rate is lower (ACOG, 2017; Orlandi, Rossi, Perino, Cucinella, & Orlandi, 2016). MRI has also been used to complement use of ultrasound (Cavalheiro, da Costa, Moron, & Leonard, 2017). If MSAFP screening is used, elevated AFP levels are followed up with examination by fetal ultrasound to determine if the elevated AFP levels are the result of open NTD or other causes, such as open abdominal wall defects (gastroschisis and omphalocele), congenital nephrosis, or fetal demise (ACOG, 2017; Sepulveda et al., 2017).

Anencephaly. Anencephaly is associated with failure of the anterior neural tube to fuse in the cranial area. The primary defect may involve failure of normal mesenchyme and cutaneous (i.e., skin, bone, and dorsal coverings) development (du Plessis & Volpe, 2018). Since the advent of antenatal diagnosis and folic acid therapy, the incidence of infants born with anencephaly has markedly declined. Because fusion of the anterior neural tube contributes to the forebrain, anencephalic infants have minimal development of the brain. The brain tissue that does develop is poorly differentiated and becomes necrotic with exposure to amniotic fluid; this results in a mass of vascular tissue with neuronal and glial elements and a choroid plexus marked by partial absence of the skull bones. Anencephaly is thought to occur before about 24 days' gestation, around the period of closure of the rostral neuropore (du Plessis & Volpe, 2018).

Anencephalic infants often have other anomalies. Three-fourths are stillborn; live born infants usually die within the first postnatal month, generally by the end of the first week (du Plessis & Volpe, 2018; Huang & Doherty, 2018). Management of infants with anencephaly is supportive, involving provision of warmth and comfort until the infant dies. Families require emotional support and assistance in coping with their grief over the birth of an infant with a defect and the death of their infant.

Encephalocele. Encephaloceles are "developmental disorders of cranial mesoderm . . . associated with a cystic extracranial extension of meninges, neural tissues and cerebrospinal fluid"

(du Plessis & Volpe, 2018, p. 9). Thus, encephalocele is thought to be a postneurulation disorder involving a skull defect through which neural tissue protrudes (Huang & Doherty, 2018). Although this defect can occur in any region, approximately 70% to 80% occur in the occipital region (du Plessis & Volpe, 2018; Huang & Doherty, 2018). The sac protrudes from the back of the head or the base of the neck. The next most common area is the frontal region, with involvement of the orbit, nose, and/or nasopharynx. Encephaloceles can also occur, although uncommonly, in the temporal or parietal areas (Gressens & Hüppi, 2015). Hydrocephalus, which may be present at birth or develop after surgical repair, occurs with 50% of occipital encephaloceles because of alterations in the posterior fossa (Gressens & Hüppi, 2015). Encephalocele may occur in association with chromosomal abnormalities, such as trisomy 13, 18, and 21, Meckel–Gruber syndrome, or Walker–Warburg syndrome (du Plessis & Volpe, 2018).

The protruding sac varies considerably in size; however, the size of the external sac does not necessarily correlate with the presence of neural elements. For example, a large occipital sac may contain minimal neural tissue, whereas a small sac may contain parts of the cerebellum or accessory lobes; some occipital lesions have no neural elements in the sac. Neural tissue generally displays normal gyration and white matter and is connected to the brain by a slender necklike structure (du Plessis & Volpe, 2018; Gressens & Hüppi, 2015). If the sac is leaking CSF at birth, immediate repair is necessary. If the defect is covered by skin, surgery may be delayed until a complete workup, including skull radiography, CT or cranial ultrasonography, MRI, and electroencephalography (EEG), can be performed. Surgical closure helps prevent infection and facilitates feeding and other care. A ventriculoperitoneal shunt is inserted if hydrocephalus is present. Other management includes prevention of infection and trauma and positioning to avoid pressure on the defect. Maintenance of normal body temperature is essential, especially in infants with CSF leakage, because these infants are at risk for thermoregulatory problems caused by evaporative losses. Postoperative management includes assessment of ventilation and perfusion, comfort measures, monitoring of neurologic and motor function, promotion of normothermia, prevention of infection, positioning to prevent pressure on the operative site, and monitoring of the site for CSF leakage. The mortality rate and later outcome are significantly better for infants with anterior defects than for those with posterior defects. The prognosis is poor if significant brain tissue is contained within the sac (Huang & Doherty, 2018).

Families of infants with an encephalocele need initial and continuing support and counseling. Initial parental care involves assisting parents with the shock of the defect and its appearance and with their grief over having an infant with an anomaly, as well as helping the parents deal with the outcome implications of this defect. Nursing care also involves enhancing parent–infant interaction and involving the parents in the infant's care when they are ready. Teaching before discharge includes skin care, positioning, exercises, handling and feeding techniques, and activities to promote growth and development.

Spina Bifida. Spina bifida is a general term used to describe defects in closure of the caudal neural tube that are associated with malformations of the spinal cord and vertebrae. Spina bifida arises from defects in closure of the caudal neuropore during primary neurulation (open defects) or during secondary neurulation (closed defects). Defects range from minor malformations of minimal clinical significance to major disorders that result in paraplegia or quadriplegia and loss of bladder and bowel control. The two major forms of spina bifida are spina bifida occulta and spina bifida cystica.

Spina bifida occulta is a vertebral defect at L5 or S1 that arises from failure of the vertebral arch to grow and fuse between 5 weeks' gestation and the early fetal period. Frequently, only one vertebra is involved in the defect and the spinal cord and nerves are not involved, so there usually are no neurologic symptoms. The dermal layer is intact over the vertebral defect; occasionally, the defect is indicated by a dimple or tuft of hair. Incidence is difficult to determine as many are unrecognized due to minimal/no physical problems arising from the presence of this defect. Spina bifida occulta is often discovered in radiographs of the lumbar and sacral regions. A few individuals have underlying abnormalities of the spinal cord or the nerve roots, or both, such as diastematomyelia or dermal sinus (dermoids; Moore et al., 2015). Diastematomyelia results from the division of the spinal cord or nerve roots in an anteroposterior direction by a bony spicule or cartilaginous band. A dermal sinus is a tract of squamous epithelium that connects to the dura mater and is found in the midline, usually in the lumbosacral area corresponding to the location of the caudal neuropore. A dermal sinus occasionally is recognized at birth, but more often it is diagnosed later, after repeated episodes of meningitis (Danzer et al., 2017; du Plessis & Volpe, 2018).

Spina bifida cystica is a generic term for NTDs characterized by a cystic sac containing meninges or spinal cord elements, or both, along with vertebral defects. Epithelium or a thin membrane covers the sac. As with anencephaly, the incidence has declined in recent years (ACOG, 2017; Moore et al., 2015). Spina bifida cystica can occur anywhere along the spinal column but is seen most often in the lumbar or lumbosacral area. The three main forms of spina bifida cystica are meningocele, MMC, and myeloschisis.

A meningocele involves a sac that contains meninges and CSF, but the spinal cord and nerve roots are in their normal position. Neurologic deficits are not typically associated with meningocele. Meningoceles account for about 5% of spina bifida cystica (Moore et al., 2015).

MMC refers to a sac containing spinal cord or nerve roots, or both, in addition to meninges and CSF and accounts for 80% of spina bifida cystica. The incidence of MMC is 0.3 to 0.72 per 1,000 births (Cavalheiro et al., 2017). This defect occurs around 26 days' gestation, around the time of closure of the caudal neuropore (du Plessis & Volpe, 2018). During development, the nerve tissues become incorporated into the wall of the sac, impairing differentiation of nerve fibers. The spinal cord and/or nerve roots are displaced dorsally, and defects of the muscle and bony structures are present. These lesions are covered with skin or meninges, or both, and are usually located in the lumbosacral area. The level of the impairment of the spinal cord dictates the severity of the neurologic deficit as the nerve tissues below the sac are impaired. The sensory level generally tends to approximate the motor level but may be several segments lower because of differences in the pattern of innervation between sensory and motor fibers (Blackburn, 2018). Approximately 80% of these malformations occur in the lumbar area, which is the final area of neural tube fusion (du Plessis & Volpe, 2018). If the sac is covered with meninges, there is a risk of rupture during delivery, along with leakage of CSF and the risk of infection and dehydration. Individuals with MMC may have motor and sensory impairments of the lower extremities, bowel and bladder dysfunction, hydrocephalus, and spinal/leg alterations such as scoliosis and hip, ankle and foot issues (Cavalheiro et al., 2017). Infants with MMC have altered tone and activity of the lower extremities and may assume a froglike posture. With bowel and bladder involvement, dribbling of urine and feces may be noted. Many infants also have associated Chiari type II malformations with a noncommunicating form of hydrocephalus (Gressens & Hüppi, 2015; Moore et al., 2015). Hydrocephalus

is seen in up to 82% of infants repaired after birth (Cavalheiro et al., 2017).

Chiari type II malformations are defects in neural tube closure involving several anomalies, including displacement of the medulla, fourth ventricle, and lower cerebellum into the cervical canal; bony defects of the occiput, foramen magnum, and cervical vertebrae; and obstruction of the foramen magnum, leading to hydrocephalus (du Plessis & Volpe, 2018; Gressens & Hüppi, 2015). The resulting hydrocephalus is caused primarily by one, or both, of two defects—either a hindbrain malformation blocking normal flow of the spinal fluid from fourth ventricular outflow and/or through the posterior fossa, or there may be aqueductal stenosis causing disruption of normal spinal fluid flow. Chiari type II malformation occurs with most MMCs located at the thoracolumbar, lumbar, and lumbosacral levels.

Management

Immediate management for all NTDs includes stabilization and prevention of trauma to or infection of the sac, if present, and its contents. The infant is monitored for signs of infection, including signs of sepsis or meningitis and localized infection, including redness or discharge from the sac. Warmth and hydration are provided, and fluid and electrolyte status are monitored. **Emergency Alert: These infants are at greater risk of hypothermia and dehydration because of the open lesion, which lacks the normal protective skin covering.** Infants with NTDs may have evidence of hydrocephalus at birth. Ultrasonography, CT, or MRI can be used to determine the size of the ventricular system, to rule out Chiari type II malformation, and to monitor ventricular status and the development of hydrocephalus. Renal dysfunction may develop as a result of recurring urinary tract infections. Infants with NTDs may also have cardiac, intestinal, orthopedic, and other neurologic anomalies (Blackburn, 2018; du Plessis & Volpe, 2018; Gressens & Hüppi, 2015; Hockley & Salanki, 2009).

The infant with NTD is positioned prone or on the side to reduce tension on the sac. A roll between the legs at hip level assists in maintaining abduction of the legs; a foot roll is used to maintain the feet in a neutral position. Change of position from prone to side lying or side to side, as well as range-of-motion exercises, helps prevent skin breakdown and contractures. If the infant must be temporarily placed in a supine position for a procedure, a donut roll can be used to prevent pressure on the sac. Postoperative positioning also involves use of the prone or sidelying position, maintenance of body alignment, prevention of hip abduction, and prevention of pressure on the operative site with holding. Lumbar/sacral defects must be kept free of fecal or urine contamination. Meticulous skin care, with attention to keeping the skin clean and dry and removing urine and stool, helps prevent skin breakdown and infection. The timing and characteristics of urination and stool excretion are observed to help determine the degree of deficit.

For most infants with MMC, immediate closure and aggressive care constitute appropriate management (Cavalheiro et al., 2017; Hockley & Salanki, 2009; Huang & Doherty, 2018; Piatt, 2010). Less infection and better outcomes are reported with MMC repair within 48 hours of birth (Cavalheiro et al., 2017). Unless the defect is severe or is associated with multiple life-threatening anomalies, more than 90% of infants with MMC survive the neonatal period. Immediate closure reduces the risk of infection and improves the prognosis by reducing further deterioration of the spinal cord and nerve tracts. Early closure also facilitates caregiving. A large defect may require several surgical procedures for complete closure. If the defect is completely covered by epithelium, surgery may be delayed for a short period so that function can be evaluated further. All infants with NTDs are evaluated and monitored for hydrocephalus. Urologic function and renal function also are assessed continually. All infants with involvement of the spinal cord or nerve roots, or both, require multidisciplinary follow-up and continuing care to deal with neurologic, urologic, orthopedic, and psychologic problems (Hockley & Salanki, 2009; Huang & Doherty, 2018; Piatt, 2010).

Families of infants with NTDs need initial and continuing support and counseling. Initial parental care involves assisting parents with the shock of having an infant with a defect and its appearance and with their grief over having an infant with an anomaly. Nursing care also involves enhancing parent–infant interaction and involving the parents in the infant's care when they are ready. Teaching before discharge includes skin care, positioning, exercises, handling and feeding techniques, and provision of activities to promote development. Many areas have spina bifida associations and parent-to-parent support programs to which parents can be referred for peer support.

In utero repair of MMC is performed before 26 weeks in some centers to reduce postnatal complications such as hindbrain herniation, hydrocephalus, and urologic dysfunction. In utero intervention is based on the hypothesis that long-term outcomes are related to both the primary defect (MMC) and secondary complications such as damage to exposed neural tissue along with development of Chiari II and hydrocephalus, and that in utero surgery may reduce this secondary damage (du Plessis & Volpe, 2018). Significant improvement in sensorimotor function has not been reported and an increase in obstetrical complications, such as preterm labor, oligohydramnios, premature rupture of the membranes, and surgical risks involved, were reported in several small studies (Adzick et al., 2011; Bebbington, Danzer, Johnson, & Adzick, 2011; Czeizel et al., 2011; Danzer, Johnson, & Adzick, 2012; Hockley & Salanki, 2009). In an effort to determine whether prenatal repair of MMC improved outcomes over postnatal surgical repair, a large, prospective randomized clinical trial, the Management of Myelomeningocele Study, was done at three maternal–fetal surgery centers (Adzick et al., 2011; Danzer et al., 2012). The results of this study showed that in utero repair of MMC reduced the need for postnatal shunting and improved motor outcomes at 30 months but was associated with maternal and fetal risks. Maternal risks included oligohydramnios, chorioamniotic separation, placental abruption, and spontaneous membrane rupture. Fetal complications included premature delivery, with an average gestational age of 34.1 versus 37.1 weeks in postnatal surgical group, and nearly 13% delivered before 30 weeks' gestation (vs. none in postnatal surgical group), and respiratory distress syndrome, which was likely primarily attributable to prematurity. No other significant fetal/neonatal complications were reported for the in utero surgical group.

In utero surgery was associated with a decreased need for ventriculoperitoneal shunt, less risk of moderate-to-severe brain herniation, improved motor function and ambulatory status, and improved mental development (Adzick et al., 2011; Cavalheiro et al., 2017; Danzer et al., 2012). The prenatal surgical group required more procedures for delayed spinal cord tethering than did the postnatal surgical group. Parent-reported self-care and mobility were also significantly better in the prenatal surgical group than in the postnatal group. There were no differences in later cognitive scores between groups (Adzick et al., 2011; Danzer et al., 2012). Long-term follow-up of infants with fetal surgery at 10 years of age found that 79% were community ambulators, 14% wheelchair dependent, and 26% had normal bladder function (Danzer et al., 2016). Since fetal surgery requires a specialized, multidisciplinary team, it is only available in a limited number of centers, and, as previously noted, is associated with increased maternal and fetal complications (Cavalheiro et al., 2017). Work is ongoing on

improving surgery techniques such as examination of less invasive endoscopic techniques and use of a biocellulose patch to reduce maternal and perinatal complications (Cavalheiro et al., 2017; du Plessis & Volpe, 2018).

The prognosis associated with NTDs varies with the level and severity of the defect. However, these limitations are changing as a result of improved perinatal management and new technologies, and more children are ambulatory now than they were previously. The prognosis has also improved with the current early and aggressive treatment of infants, especially in those without major cerebral lesions, hemorrhage, infection, high spinal cord lesions, or advanced hydrocephalus (du Plessis & Volpe, 2018; Huang & Doherty, 2018).

Prosencephalic Development

Prosencephalic development, or ventral induction, involves early development of the brain and ventricular system, which occurs during the second to third month of gestation (peaking at 5–6 weeks). The brain develops from the cranial end of the neural tube, beginning at the end of the fourth week. During this period, the three primary brain bulges (or vesicles) and cavities are formed, after fusion of the neural folds in the cranial area.

The primary brain bulges are the forebrain (prosencephalon), the midbrain (mesencephalon), and the hindbrain (rhombencephalon). During the fifth week, the forebrain divides into two secondary vesicles, the telencephalon and the diencephalon, and the hindbrain divides into the metencephalon and the myelencephalon. The derivatives of each of these structures form the structures of the definitive brain. The third and fourth ventricles are formed from cavities within the rhombencephalon and diencephalon; the aqueduct of Sylvius links these two ventricles. The lateral ventricles arise from cavities in the cerebral hemispheres and are connected to the third ventricle by the foramen of Monro (see Figure 15.1). Early growth of the neural tube is most rapid in the forebrain region. To give these structures space to grow, the neural tube bends at several points, forming the mesencephalic (midbrain area), cervical (junction of the hindbrain and spinal cord), and pontine flexures (Huang & Doherty, 2018; Moore et al., 2015). The cerebellum arises from the rhombencephalon.

Disorders of Prosencephalic Development. Malformations that occur during this period generally are thought to arise around the fifth to sixth weeks of gestation. Infants with these anomalies have a poor prognosis, and many are lost in early pregnancy or are stillborn. Malformations of the forebrain include holoprosencephaly and holotelencephaly. Holoprosencephaly is an abnormality in cleavage of the hemispheres that arises from genetic or possibly environmental alterations. Failure of horizontal, transverse, and sagittal cleavage of the prosencephalon disrupts formation of the telencephalon and the diencephalon and their derivatives. The resultant brain has a single monoventricular cerebral mass enclosed by a membrane; aplasia of the optic tract with absence of the olfactory tracts and bulbs, and agenesis of the corpus callosum, also is characteristic. Microcephaly, hydrocephaly, and facial anomalies also may be seen (Huang & Doherty, 2018; Moore et al., 2015). With holotelencephaly, the parts of the brain that develop from the telencephalon form a single spheroid structure; the diencephalon and its derivatives are less affected. Congenital hydrocephalus and agenesis of the corpus callosum can also arise during this period. Development of the face is associated with prosencephalic development of the CNS; consequently, alterations in brain development often result in facial malformations (Huang & Doherty, 2018; Kanekar, Shively, & Kaneda, 2011).

Neuronal Proliferation

The development of neurons and glial cells involves proliferation in the germinal matrix; migration (to their final destination) in the next stage of CNS development; differentiation of glial cells (during the period of organization) into specific cell types; alignment of neurons; and the development of interneuron and glial–neuron relationships. Cerebellar neurons arise within the cerebellar germinal matrix. The peak period of neuronal proliferation in the cerebral area lasts from 2 to 4 months' gestation, followed by glial proliferation beginning at 15 weeks' gestation, and in the cerebellum from 2 months' gestation to 10 months postnatal age (Yuskaitis & Pomeroy, 2017). During this stage, further development occurs in the cerebral subventricular and ventricular zones, where neurons and glial cells are derived from stem cells in the cerebral germinal matrix. Initial proliferation involves primarily neurons and radial glia, which are needed for neuron migration. Proliferation of other glia and their derivatives (astrocytes and oligodendrocytes) occurs intensively during the stage of organization, at 5 to 8 months' gestation. During the most intense period of proliferation, before 32 to 34 weeks' gestation, the periventricular area receives a large proportion of the cerebral blood flow. This area is vulnerable to hemorrhage (see section on Germinal Matrix-Intraventricular Hemorrhage) in preterm infants (Blackburn, 2018; Fleiss, Stolp, Mezger, & Gressens, 2018; Poduri & Volpe, 2018a).

Disorders of Neuronal Proliferation. Disorders of proliferation arise from inadequate or excessive proliferation of neuronal derivatives, glial derivatives, or glial cell derivatives. Insults may alter the neuronal-glial stem cells, which reduces the number of neurons or glial cells, or may alter cell growth, which results in smaller cells. The resulting disorders include micrencephaly, macrencephaly, and neurofibromatosis (Huang & Doherty, 2018; Poduri & Volpe, 2018a). Micrencephaly may be due to a reduction in either the size or number of stem cells (Huang & Doherty, 2018; Poduri & Volpe, 2018a). Micrencephaly vera is associated with a small brain caused by a decrease in the size of the proliferating units as a result of genetic or environmental factors and occurs at 2 to 4 months' gestation. These infants often do not have marked neurologic deficits or seizures during the neonatal period, and in general the brain is well formed; however, the infants later manifest mental delays. Genetic factors associated with micrencephaly vera include autosomal recessive or dominant trait, X-linked recessive trait, or translocation. Micrencephaly vera is associated with environmental factors such as irradiation, metabolic alteration, maternal rubella, fetal alcohol syndrome, maternal cocaine use, and maternal phenylketonuria with elevated phenylalanine levels during pregnancy.

Macrencephaly results in a large brain size because of excessive proliferation of neuronal elements or nonneuronal elements, or a combination of both. Macrencephaly is associated with genetic disorders including Beckwith–Wiedemann syndrome, Sturge–Weber syndrome, Weaver syndrome, and achondroplasia; chromosomal disorders such as Klinefelter and fragile X syndromes, and partial trisomy of chromosome 7; and neurocutaneous disorders, such as neurofibromatosis. Neurofibromatosis is an autosomal dominant genetic disorder involving excessive proliferation of nonneuronal elements in the CNS and mesodermal structures of the body, with cutaneous stigmata (Blackburn, 2018; Huang & Doherty, 2018; Kanekar, Kaneda, & Shively, 2011; Poduri & Volpe, 2018a). Neurofibromatosis often presents with alterations to skin pigmentation (café-au-lait macules), Lisch nodules of the iris, buphthalmos (enlarged eyeball), skin nodules, and multiple benign neurofibromas. Infants with more than five café-au-lait macules larger than 5 mm in diameter at birth should be further evaluated for neurofibromatosis. Neurofibromatosis is associated

with learning disabilities and, later in life, possible development of skeletal abnormalities, vascular disease, CNS tumors, or malignant peripheral nerve sheath tumors (Blackburn, 2018; Jett & Friedman, 2010; Poduri & Volpe, 2018a).

Neuronal Migration

The peak period for the neuronal migration stage is 3 to 5 months' gestation in the cerebrum and 4 months' gestation to 10 months postnatally in the cerebellum (Yuskaitis & Pomeroy, 2017). This stage is characterized by the movement of millions of cells from their point of origin in the subependymal germinal matrix of the periventricular region to their eventual loci in the cerebral cortex (see Figure 15.1) and similar movements of neurons within the cerebellum from their point of origin to their final location. The process of neuronal migration is critical to the formation of the neocortex, gyri, and deep nuclear structures. Development of the gyri and sulci follows a predictable pattern that is linked to gestational age. At 21 to 25 weeks' gestation, the central ventricles are large and the brain agyric; gyral development begins by the end of this period (Blackburn, 2018; Poduri & Volpe, 2018b).

The mechanisms that guide neuronal migration are not completely understood, but they are mediated by signaling proteins, surface molecules, and receptors on both the neurons and the radial glia (Poduri & Volpe, 2018b; Valiente & Marin, 2010). The migration of the neurons to both the cortex and within the cerebellum is assisted by the radial glia (Poduri & Volpe, 2018b). Radial glia act as guides for migrating cells and then later transform into astrocytes (Poduri & Volpe, 2018b; Valiente & Marin, 2010). The cerebral cortex has essentially achieved its full complement of neurons by 24 weeks' gestation; however, GABAergic neuron migration continues to near term (Fleiss et al., 2018; Poduri & Volpe, 2018b). Later migration predominantly involves glial cells.

Disorders of Neuronal Migration. Errors or exogenous insults before or after birth can alter migration of neurons and glial cells. Alterations in migration can result in hypoplasia or agenesis of the corpus callosum, agenesis of a part of the cerebral wall (schizencephaly), or gyral anomalies (pachygyria, lissencephaly, and polymicrogyria). The preterm infant may be especially vulnerable to gyral alterations. Rapid development of the gyri begins at 26 to 28 weeks' gestation and continues through the third trimester into the postbirth period. Development of gyri results in a marked increase in cerebral surface area (Fleiss et al., 2018; Poduri & Volpe, 2018b; Valiente & Marin, 2010).

Organization

The peak period for organization is about the fifth month of gestation to a few years after birth. However, organizational processes continue throughout childhood, particularly in the cerebellum. Some processes, such as synaptogenesis, continue until death. Organizational processes allow the nervous system to act as an integrated whole. These processes include (a) establishment of subplate neurons; (b) attainment of the proper alignment, orientation, and layering of cortical neurons; (c) arborization or differentiation and branching of axons and dendrites; (d) differentiation of glial cells; (e) development of synaptic connections ("wiring" of the brain) with balancing of excitatory and inhibitory synapses; (f) gyral development; and (g) cell death and selective elimination of neuronal processes (Blackburn, 2018; Fleiss et al., 2018; Kinney & Volpe, 2018c).

Subplate neurons are critical structures in the development of the neocortex, with maximal size and vulnerability reached by 24 to 32 weeks (Fleiss et al., 2018; Kinney & Volpe, 2018c). Thus, subplate neurons are vulnerable to perinatal injury. Subplate neurons serve as transient "way stations" by providing a place of synaptic contact for axons that ascend from the thalamus and other areas in which connecting cortical neurons are not yet in place, are a site of initial synaptogenesis between areas within the cortex, produce axons for the corpus callosum, and are critical in guiding axons to their final loci and in establishing functional connections between different areas of the brain (Fleiss et al., 2018; Kinney & Volpe, 2018c; Volpe, Kinney, Jensen, & Rosenberg, 2011). Subplate neurons may be damaged in preterm infants with periventricular leukomalacia (PVL; Fleiss et al., 2018).

Glial cells serve as supportive structures with the CNS. The three forms of glia are (a) myelin-producing glia (oligodendrocytes in the CNS; Schwann cells in the peripheral nervous system); (b) guiding glia (radial glia for neuron migration during CNS development; Schwann cells for guiding peripheral nerves); and (c) "clean-up" glia (astroglia and microglia), which remove waste and dead tissue. Astroglia also provide support for neurons, assist in integration of information within the CNS, and are important in the structure and function of the blood–brain barrier. Astrocyte proliferation peaks at 26 to 28 weeks (Fleiss et al., 2018). Microglias are capable of phagocytosis and function as brain macrophages and may be involved in developmental apoptosis (Blackburn, 2018; Kinney & Volpe, 2018c; Volpe et al., 2011). When activated by inflammation or ischemia, as occurs with white matter injury (WMI), microglia can lead to further cellular injury. During the premyelinating period, oligodendrocytes are especially vulnerable to hypoxic-ischemic injury (see section on White Matter Injury in Preterm Infants; Back & Volpe, 2018; Fleiss et al., 2018; Volpe et al., 2011).

The process of cell death and selective elimination of neuronal processes is important in adjusting the size of individual neurons to their anticipated need. It is also an important component of brain plasticity in infants. In the developing brain, neuronal processes targeted for elimination can be saved if they are needed because of damage to other processes; by this means, functional ability is preserved. Excitatory neurotransmitters, such as glutamate, mediate neural development and organization by acting on *N*-methyl-D-aspartate (NMDA) receptors, and also likely, on GluR2-deficient alpha-amino-3-hydroxyl-5-methyl-4-isoxazolenpropionic acid (AMPA) receptors and by opening voltage-dependent calcium channels (Kinney & Volpe, 2018c).

A striking increase in the cerebral cortical volume and gyral changes occurs during this period of development and with organization of cortical neurons, especially from around 28 to 40 weeks' gestation. During this time there is a fourfold increase in cortical gray matter volume (Kinney & Volpe, 2018c).

Disorders of Organization. Organization of the brain is susceptible to insults from errors of metabolism, abnormal chromosomes, and perinatal insults. Organizational processes are particularly vulnerable in the preterm infant being cared for in an intensive care unit during this period. Alterations in arborization and wiring of the brain can lead to hypersensitivity, poorly modulated behavior, and all-or-nothing responses. Alterations in organization are seen in infants with Down syndrome-Trisomy 21, who have abnormal development of the axons and dendrites and altered synaptic formation, fragile X syndrome, Angelman syndrome (microdeletion on the long arm of maternal chromosome 15), Duchenne muscular dystrophy, intellectual disabilities (with or without seizures), and Rett syndrome.

Myelination

The myelination stage involves development of myelin sheaths around nerve fibers in the nervous system. Oligodendrocytes myelinate the nerve fibers of the CNS and Schwann cells myelinate

the nerve fibers of the peripheral nerves. The lipoprotein plasma membranes of these cells wrap themselves around the nerve fibers for several layers. Myelination of fiber tracts tends to occur before maturation of functional ability (Moore et al., 2015; Kinney & Volpe, 2018b).

Myelination begins early in pregnancy and continues into adulthood. Myelination predominates between 8 months' gestation and 2 years of age, with the peak period thought to be occurring within the first 8 postnatal months of life. However, myelination continues into adolescence and early adulthood (Kinney & Volpe, 2018b). This process begins before birth in the peripheral areas, first in the peripheral motor nerves and then in the peripheral sensory nerves. Myelination also begins before birth in the CNS, moving upward from the brainstem and cerebellum. In the CNS, myelination occurs first in the sensory areas and then in the motor areas. Myelination of ascending pathways in the spinal cord, brainstem, and thalamus is completed by about 30 weeks' gestation, and myelination from the thalamus to the cortex is completed by 37 weeks (Kinney & Volpe, 2018b). From birth to adulthood, myelination proceeds within the cerebral hemispheres in conjunction with the development of higher associative and sensory functions. Myelination is important in most nerve tracts in the CNS because it insulates individual fibers to enhance specificity of connections, increases the number of alternative pathways, and markedly increases the speed of transmission (Blackburn, 2018; Kinney & Volpe, 2018b). This has implications for neonatal pain management, particularly for preterm infants.

Disorders of Myelination. Myelination is susceptible to damage from diverse exogenous influences, particularly malnutrition, which can lead to a range of neurologic deficits in which hypoplasia of the cerebral white matter occurs. Primary hypoplasia of the white matter with vacuolization of the myelin occurs in inadequate postnatal nutrition, congenital hypothyroidism, 18q-syndrome, and amino and organic acidopathies such as maple syrup urine disease, homocystinuria, and phenylketonuria. This defect in myelination can lead to severe neurologic deficits in these infants (Kinney & Volpe, 2018b).

Neurologic Assessment

Assessment of neurologic function is an initial step in evaluating an infant's response to the transition to extrauterine life and the impact of perinatal events and pathophysiologic problems on the central and peripheral nervous systems. Assessment of neurologic function and identification of dysfunction encompass several components, including the history, physical examination, neurologic examination, laboratory tests, and other diagnostic techniques.

History

Risk factors noted in the maternal, obstetrical, and neonatal histories can be useful in identifying infants at risk for neurologic dysfunction and specific pathophysiologic factors. Specific risk factors for each problem discussed here are identified later in individual sections. General maternal or family historical factors that must be examined include a family history of NTDs; chromosomal or genetic abnormalities or other malformations; maternal substance abuse; chronic maternal health problems; maternal age, nutritional status, and exposure to teratogens; and the outcome of previous pregnancies (Heaberlin, 2019).

Obstetrical risk factors include prematurity, postmaturity, placental problems (e.g., abruptio placentae and placenta previa), use of analgesia or anesthesia, and maternal problems (e.g., infection, hypertension, and substance abuse). A large for gestational age (LGA) infant, prolonged or precipitate labor, forceps delivery, and abnormal presentation increase the risk of birth trauma and hemorrhage. Alterations in intrauterine growth and polyhydramnios may be present with an infant who has a CNS malformation. Fetal distress, hypoxia, ischemia, and low Apgar scores are associated with intracranial hemorrhage and HIE (Back & Miller, 2018; Blackburn, 2018; Inder & Volpe, 2018a, b).

Because neurologic dysfunction also can arise from postnatal problems, the infant's postnatal history is evaluated for status at birth, whether resuscitation was required, ischemic or hypoxic episodes, shock, hypoperfusion with or without, hemorrhage, infection, and metabolic or electrolyte aberrations. The infant's record is also reviewed for clinical signs, such as seizures or alterations in activity, tone, and state, which are associated with neurologic dysfunction (Heaberlin, 2019; Walker, 2018).

Physical Examination

A comprehensive physical examination is an important component of the assessment of any infant at risk for, or showing evidence of, neurologic dysfunction. Infants are examined especially for evidence of infection and birth trauma, such as ecchymosis, edema, lacerations, and fractures. Temperature, blood pressure, color, and respiratory patterns are also assessed. The infant is examined for signs of vascular alterations, such as a port-wine stain along trigeminal nerve branches, which may indicate Sturge–Weber syndrome. The characteristics of the infant's cry (e.g., robustness, presence in response to aversive stimuli, and pitch) may also be useful. Funduscopic examination may be performed to assess for chorioretinitis (associated with intrauterine viral infection), papilledema (seen with cerebral edema, although less reliably in neonates), and congenital anomalies (Amiel-Tison & Gosselin, 2009; Walker, 2018).

Specific parameters that are particularly important for the nurse to assess in infants with neurologic problems are (a) the head size, shape, and rate of growth; (b) the sutures and fontanelles; (c) whether major and minor anomalies are present; and (d) the vertebral column. Because CNS anomalies often are associated with other anomalies and syndromes, the infant is also examined for major anomalies of body systems and for isolated or clustered minor malformations, such as low-set or abnormally shaped ears, micrognathia, and hypertelorism of the eyes. The vertebral column is inspected and palpated for evidence of NTDs. Signs that may indicate an underlying defect include hair tufts, dimples, and fistulae (Amiel-Tison & Gosselin, 2009; Walker, 2018).

Head Size, Shape, and Rate of Growth. The monitoring and plotting of head circumference are basic components of healthcare for all infants, regardless of gestation or health status. The largest circumference is measured, which usually is the occipitofrontal circumference, about 1 cm above the eyes. The measurement is plotted on the appropriate growth grid for the infant's gender and gestation. The most accurate measurements are made with a metal or plastic tape marked in centimeters. Paper tapes tend to stretch and are less accurate but can be used for initial screening and for infants whose head size raises no concern. The occipitofrontal circumference generally ranges from 32.6 to 37.2 cm in term infants. Infants with caput succedaneum or overriding sutures may need to be remeasured after 3 days to obtain a more accurate measurement (Amiel-Tison & Gosselin, 2009). The head usually grows 0.1 to 0.6 cm/week in infants 24 to 40 weeks' gestation (Ditzenberger, 2015).

Serial measurements must be made to identify changes in the rate of growth as well as in size. Changes in the growth rate are important because an infant may have a significant increase or decrease in head growth but remain within the 10th to 90th

percentiles on standard head growth grids. The occipitofrontal circumference should be measured several times over the first days after birth to obtain an accurate baseline after molding and edema from birth have resolved. Head circumference is measured weekly on preterm or ill infants. More frequent measurements may be made if the infant is at risk of developing progressive ventricular dilatation. Head shape can also reflect perinatal events and specific anomalies. The forces of labor and delivery may deform the head, but these changes are transient and disappear within a few days. Infants with craniosynostosis (premature closure of one or more sutures) and hydrocephalus have abnormal head configurations (Evans, Hing, & Cunningham, 2018; Johnson, 2019).

Sutures and Fontanelles. The entire head is inspected and palpated, and each suture and fontanelle is assessed. The anterior fontanelle is assessed while the infant is in a quiet state and in a semi-upright or sitting position. The fontanelle should be open, soft, and flat. Pulsation may be felt normally in a newborn but can be associated with elevated blood pressure. **Emergency Alert: A sunken or depressed fontanelle is seen with dehydration, and a bulging fontanelle is noted with increased intracranial pressure (ICP).** The anterior fontanelle usually is diamond shaped and may be small at birth if molding and overriding of the sutures are present; the size increases within a few days to the usual dimensions seen in term infants (i.e., 3–4 cm long by 1–3 cm wide). The anterior fontanelle closes at 8 to 16 months of age. The anterior fontanelle may bulge slightly with increased tension when the infant cries and may be slightly depressed when the infant is placed in an upright position. The posterior fontanelle closes any time from 8 months' gestation to 2 months after birth. If open at birth, it is 1 to 3 cm wide and has a triangular shape. In rare cases, a "third fontanelle" may be palpated along the sagittal suture between the anterior and posterior fontanelles; this is not a true fontanelle but a defect in the parietal bone. It can be palpated in normal infants, but it is also seen in infants with Down syndrome or hypothyroidism (Heaberlin, 2019). A 4- to 5-mm separation (up to 1 cm) of all the sutures except the squamosal (temporoparietal) suture is normal in the newborn. The squamosal suture should not be separated more than 2 to 3 mm, especially in the term or near-term (late preterm) infant. Overriding of the bones and molding from delivery may modify this finding in the first few days after birth. Abnormal findings include persistence of suture separation over time, increased separation of the sutures, and separation of the squamosal suture by more than 2 to 3 mm. With increased ICP, separation of the sutures occurs in a specific order: sagittal, coronal, metopic, lambdoidal, and squamosal; therefore, separation of the squamosal suture is the most clinically significant (Amiel-Tison & Gosselin, 2009). The cranial bones are inspected and palpated so that fractures, extradural hemorrhage, edema, and areas of uneven ossification of the cranial bones or craniotabes can be identified.

Neurologic Examination

The neurologic examination is useful for evaluating for the presence and determining the extent of neurologic dysfunction in the neonate, for monitoring recovery, and as a prognostic indicator. Factors such as gestational age, health status, the infant's state, medications, and timing of feedings must be considered in the interpretation of neurologic findings. Parameters examined in the assessment of neurologic status include level of consciousness, activity, tone, posture, reflexes, and evaluation of selected cranial nerves (Amiel-Tison & Gosselin, 2009; Heaberlin, 2019; Walker, 2018). The optimum state of the infant during a neurologic examination is quiet and alert, after awakening naturally from a sleep state. It may be difficult to find such a perfect moment, and often the infant must be aroused from a sleep state or quieted from a state of heightened arousal. It is important to determine the state of the infant prior to a neurologic examination, since the infant's level of alertness has an effect on the interpretation of the infant's neurologic status (Amiel-Tison & Gosselin, 2009; Heaberlin, 2019; Walker, 2018).

Observation of State: Level of Consciousness. Neurologic insults frequently alter the infant's level of consciousness. The level of consciousness may range from normal states of consciousness for gestation to hyperexcitability, irritability, lethargy, hyperalertness, and stupor or coma. The three clinical levels of consciousness that best correlate with outcome are hyperalertness, lethargy, and stupor or coma. In the hyperalert state, the infant has an increased sensitivity to sensory stimulation, with wide-open eyes but with a diminished blink response and ability to fixate and follow. A lethargic infant responds to tactile and noxious stimuli, but the responses are delayed. A stuporous or obtunded infant's response is limited to noxious stimuli, and a comatose infant shows no response to tactile or noxious stimuli (Amiel-Tison & Gosselin, 2009; Walker, 2018). Hyperexcitability and irritability can be assessed by noting an infant's response to caregiving actions and medical procedures, as well as the baby's state between caregiving intervals to assess the infant's ability to use self-consoling measures.

Posture, Tone, and Activity. Because normal tone requires integrated functioning of the entire nervous system, disturbances in either the central or peripheral nervous system may manifest in alterations in neonatal position, tone, and activity (Walker, 2018). The infant first is assessed while lying in a resting position. A frog-leg position while supine is seen in immature infants, after breech delivery, and in infants who have experienced severe asphyxia or who have major health problems or neuromuscular disorders (Amiel-Tison & Gosselin, 2009; Walker, 2018). The quality and symmetry of activity with spontaneous and elicited movement are assessed. Alterations in symmetry of the trunk, face, and extremities at rest or with spontaneous movement suggest congenital anomalies, birth injury, or neurologic insult. Tight fisting is an abnormal sign. A cortical thumb (inside thumb on closure of the hand) may be normal, but it is abnormal if persistent. Opisthotonos and decerebrate or decorticate posturing may also occur (Amiel-Tison & Gosselin, 2009; Heaberlin, 2019; Johnson, 2019; McAdams & Traudt, 2018).

Abnormal movements include seizure activity, jitteriness, and tremors, although the last two findings often are normal. Tremors and jitteriness must be differentiated from seizures. The characteristic movements seen with tremors in the neonate vary with the underlying disorder. Tremors associated with metabolic abnormalities usually are low-amplitude, high-frequency movements, whereas tremors associated with CNS complications usually are high-amplitude, low-frequency movements. Jitteriness is a common finding in infants because of the lack of myelination of the pyramidal tracts. A major function of these tracts is to inhibit spinal reflexes. In the neonate, these unmyelinated respond to central arousal with generalized peripheral hyperexcitability. Jitteriness is stimulus sensitive and is not marked by gaze or eye deviations. The predominant movement in jitteriness is tremulousness, rather than the clonic movement seen in seizures, which ceases with passive flexion. Spontaneous or elicited movement can set off tremors. Tremors can also be associated with metabolic abnormalities, asphyxia, or drug withdrawal (Heaberlin, 2019; Natarajan & Gospe, 2018).

Resting, passive, and active tone are assessed. Resting tone is evaluated by observing the infant at rest in a supine position. Passive tone is evaluated by examining extensibility, which involves maneuvers used in the neuromuscular component of the

assessment of gestational age. Assessment of active tone involves altering the infant's posture to obtain directed motor responses (Amiel-Tison & Gosselin, 2009; Volpe, 2018a).

Common maneuvers are righting reactions of the legs and trunk and examination of neck flexors and extensors. Righting reactions are elicited by holding the infant upright with the feet on a firm surface. The infant's ability to straighten the legs and trunk is assessed. Neck flexors and extensors are assessed using the pull-to-sit maneuver (Amiel-Tison & Gosselin, 2009; Heaberlin, 2019; Volpe, 2018a; Walker, 2018). Infants with peripheral nerve injuries, neuromuscular disorders, alterations at the neuromuscular junction, and spinal cord injuries tend to be hypotonic and have muscle weakness. Infants with CNS disturbances secondary to asphyxia, intracranial hemorrhage, chromosomal disorders or other genetic defects, or metabolic disturbances tend to be hypotonic without muscle weakness (Amiel-Tison & Gosselin, 2009; Dastgir, Chan, & Darras, 2012; Volpe, 2018a; Walker, 2018). Hypertonia is seen less often than hypotonia in neonates with neurologic problems. Marked extensor hypertonia with arching of the back (opisthotonos) may be seen in association with severe hypoxic-ischemic injury, bacterial meningitis, or massive intraventricular hemorrhage (IVH; Amiel-Tison & Gosselin, 2009; Heaberlin, 2019; Johnson, 2019; Volpe, 2018a; Walker, 2018).

Reflexes. In infants with neurologic dysfunction, primary and tendon reflexes may be diminished, absent, or accentuated. Primary reflexes are affected by gestational age, but all are present to some degree by 28 to 32 weeks' gestation and include sucking, grasping, crossed extension, automatic walking (stepping), and the Moro reflex. These reflexes should be present, symmetric, and reproducible in the neonatal period and should gradually disappear during infancy (Amiel-Tison & Gosselin, 2009). The tendon reflexes assessed in the neonate are the biceps, knee, and ankle jerk. All should be present after about 33 weeks' gestation, but are not very helpful beyond confirming symmetry in the neonatal period (Amiel-Tison & Gosselin, 2009; Hoppe & Benedetti, 2018; Volpe, 2018a; Walker, 2018).

Examination of Selected Cranial Nerves. Full cranial nerve assessment generally is not performed on the neonate. However, the function of these nerves can be evaluated using several relatively simple maneuvers: fixation and following, pupillary responses, doll's eye response, hearing, vestibular response, and suck and swallow (Table 15.2; Amiel-Tison & Gosselin, 2009; Evans et al., 2018; Heaberlin, 2019; Johnson, 2019; Volpe, 2018a; Walker, 2018).

Clinical Signs Associated With Neurologic Dysfunction. Clinical manifestations of neurologic dysfunction can be specific or nonspecific. Five types of clinical signs are commonly seen in infants with neurologic problems: (a) CNS depression, (b) hyperirritability, (c) increased ICP, (d) seizures, and (e) movement alterations. Seizures are discussed later. Signs and symptoms of CNS depression, hyperirritability, increased ICP, and movement alterations are listed in Table 15.3.

Diagnostic Techniques

Diagnostic techniques that may be used with infants suspected of neurologic problems include neurophysiologic studies, structural brain imaging and assessment of cerebral blood flow, and laboratory tests. Neurophysiologic studies used in the neurologic assessment of the newborn include brainstem auditory evoked responses, visual evoked responses, somatosensory evoked responses, and EEG and amplitude-integrated EEG (aEEG; Neil & Inder, 2018; Trollmann, Nüsken, & Wenzel, 2010). The brainstem auditory evoked response test is the reflection of the electrical events generated in the auditory pathways detected via small external sensors and indicates the response of the infant to auditory stimulus. This test is easily performed and is currently the most often used technique for routine hearing screening in newborn nurseries. Visual evoked and somatosensory evoked responses are part of a more extensive neurologic examination to aid in determining the extent of the disturbance in the vision and peripheral sensation (Neil & Inder, 2018; Trollmann et al., 2010; Volpe, 2018a). EEG and aEEG will be discussed in the section on neonatal seizures.

The three types of brain structural imaging most often used are ultrasonography, CT, and MRI. Head, or cranial, ultrasound examination is used most often to evaluate intracranial structures and is most frequently the imaging modality of choice to evaluate germinal and IVH in the premature infant, with an estimated 90% accuracy level (Neil & Inder, 2018; Ramenghi & Hüppi, 2009). Ultrasonography is portable, safe, convenient, and readily available at the bedside, utilizing nonionizing radiation with minimal/no need for sedation. Cranial and sagittal images can be evaluated by means of the anterior fontanelle and PVL by means of the posterior fontanelle. Doppler sonography, which is done as part of a complete head ultrasound, can be used to evaluate cerebral blood flow. Head ultrasonography is not generally useful for evaluating the posterior fossa and intraparenchymal and meningeal areas (Koufman, Zanelli, Cantey, & Sanchez, 2012; Neil & Inder, 2018; Neil & Volpe, 2018; Ramenghi & Hüppi, 2009). CT uses ionizing radiation coupled with computerized image reconstruction to provide high-resolution images within a few minutes of scanning. A CT of the newborn brain provides information regarding calcifications and cranial bony abnormalities, most parenchymal disorders, hemorrhage or fluid in the subdural and subarachnoid spaces, and most posterior fossa lesions. The MRI, which uses nonionizing radiation, is useful for diagnosing many abnormalities, some of which may be missed by sonography or CT, such as partial agenesis of the corpus callosum, arteriovenous malformations, acute or chronic focal cerebral ischemic lesions (infarcts), venous thrombosis, PVL, hemorrhagic lesions, and virtually all lesions in the posterior fossa and spinal cord (Girard & Raybaud, 2011; Koufman et al., 2012; Neil & Inder, 2018; Neil & Volpe, 2018). Both CT and MRI require transportation and sedation, however, which may prove to be detrimental to the critically ill infant. Using these modalities often necessitates waiting until the infant has recovered from the initial critical condition to be performed (Neil & Inder, 2018; Neil & Volpe, 2018).

Laboratory tests are performed to assist in the diagnosis of specific neurologic disorders and to identify underlying causes. The CSF is examined for signs of hemorrhage (increased red blood cells, increased protein, decreased glucose, and xanthochromia) and to rule out infection (culture, turbidity of the fluid, and increased or decreased white cells, protein and/or glucose; Gomella, Cunningham, & Eyal, 2009). Xanthochromia often is a late sign and may reflect an elevated protein level rather than the presence of blood. Other laboratory evaluations include complete blood count with differential (e.g., white and red blood cell counts, hemoglobin, hematocrit [Hct], neutrophils, bands, and platelet count), serum glucose and calcium levels, electrolyte levels, blood gases, and acid–base status. A sepsis workup or screening for toxoplasmosis, rubella, cytomegalovirus, herpes simplex, and syphilis is performed if intrauterine infection or neonatal sepsis and meningitis are suspected. A genetic workup and other metabolic studies are performed if errors of metabolism or other inherited disorders are thought to be present (Merritt & Gallagher, 2018; Neil & Volpe, 2018).

TABLE 15.2

NURSING ASSESSMENT OF SELECTED CRANIAL NERVES IN THE NEWBORN

Nerve	Assessment	Implications
Optic (II)	Blink in response to light (consistent by 28 weeks' gestation) Fixation on object placed approximately 19 cm in front of infant's face (consistent by 32 weeks' gestation) Follows object with eyes and by turning head (consistent by 37 weeks' gestation) Examination of external eye	Visual system intact to the level of the superior colliculi (does not indicate visual cortex function) Presence of vision
Oculomotor (III), trochlear (IV), and abducens (VI)	Funduscopic examination (ophthalmoscope set at 2–4 diopters) Pupillary reactivity (equal and responsive to light; appears by 28 weeks' gestation and consistent by 32 weeks) Doll's eye maneuver (vestibular response; present by 25 weeks' gestation): hold infant in an upright position at arm's length and rotate in both directions	Evaluation of abnormalities (e.g., cataracts, irregularities of size or shape, microphthalmos, or scleral hemangiomas) Normal newborn optic disc is pale or grayish-white; observe for abnormalities (e.g., retinal hemorrhage or lesion) Intact cranial nerve III; unequal or nonresponsive pupils in infants over 32 weeks' gestation are associated with increased ICP or hemorrhage Stimulation of semicircular canals with impulses sent to the brainstem via nerves III, VI, and VII. Normal response is isotonic deviation of the eyes away from the direction of movement; lack of response is associated with brainstem dysfunction or excessive administration of sedatives such as phenobarbital; disconjugate eye movements and some nystagmoid movements occasionally are seen normally during the first 3 weeks
Trigeminal (V)	Elicit the corneal reflex (may not be reliable in newborn) or observe for a grimace on pinprick Elicit sucking and ability of infant to bite down on examiner's finger	Facial sensation (not usually done routinely but may be useful with an infant with facial paralysis) Masticatory power
Facial (VII)	Observe appearance and symmetry of face at rest and during spontaneous and elicited movement	Abnormalities associated with birth injury and cerebral insults
Acoustic (VIII)	Evaluate auditory function by noting response (blink or startle) to sudden loud noise (seen by 28 weeks' gestation) or (in more mature infants) by cessation of movement and turning to sound while in a quiet, alert state	A gross assessment of auditory function; failure of the infant to respond while in a quiet, alert state in a quiet environment on repeated examinations indicates the need for examination of auditory function
Trigeminal (V), facial (VII), glossopharyngeal (IX), vagus (X), and hypoglossal (XII)	Evaluate sucking (V, VII, XII), swallowing (IX and X), and gag reflex (IX and X)	Impairment interferes with feeding and may indicate or be associated with cerebral insult

ICP, intracranial pressure.

TABLE 15.3

CLINICAL MANIFESTATIONS OF CNS DYSFUNCTION

Alteration	Clinical Manifestations
CNS depression	Altered level of consciousness
	Weak, absent cry
	Weak, absent primary reflexes
	Poor feeding
	Decreased activity
	Decreased passive tone
	Decreased active tone
	Altered respirations
Hyperirritability	Sharp, excessive crying
	Hyperactivity
	Exaggerated passive tone
	Hypertonia
	Difficult to console
	Low sensory threshold
Increased ICP	Irritability
	Lethargy
	Increased head circumference
	Palpable sutures, especially squamous
	Bulging, tense fontanelle
	Increased extensor tone of neck
	Downward deviation of eyes
	Vomiting (late)
	Dilated head veins (late)
Seizures	See Table 15.5
Movement alterations	Jitteriness, tremors
	Decerebrate posturing
	Decorticate posturing
	Opisthotonos

GENERAL MANAGEMENT

Management specific to each type of neurologic dysfunction is described in later sections. However, in the nursing care of infants with neurologic dysfunction, common nursing diagnoses and management techniques that must be considered with all infants and their families are included in the following list. Those marked with an asterisk (*) are discussed in other chapters.

1. Alteration in level of consciousness
   - Monitor infant's state, activity level, responsiveness, eye movements, head circumference, and vital signs; also monitor for seizure activity and signs of increased ICP
   - Position infant so as to promote skin integrity, prevent contractures, and reduce ICP (i.e., head in midline and slightly elevated)
   - Monitor fluid and electrolyte status
   - Maintain adequate ventilation and perfusion
   - Implement comfort measures
   - Maintain an appropriate thermal environment
   - Reduce environmental stressors
   - Promote neurobehavioral stability
2. Potential for injury related to trauma or infection
   - Use sterile technique
   - Position infant to prevent contamination of defects or operative sites
   - Monitor for signs of localized infection or neonatal sepsis
   - Handle infant gently
   - Position infant to reduce potential of trauma or contamination
3. Impairment of skin integrity
   - Position infant in alignment and change position regularly
   - Use foam, sheepskin, lambskin, or waterbeds
   - Massage skin gently to stimulate circulation
   - Use appropriate skin care measures
4. Alteration in comfort*

5. Impaired mobility
   - Position infant in alignment and change position regularly
   - Promote skin integrity
   - Use gentle range-of-motion exercises
6. Alteration in thermoregulation*
7. Alteration in nutrition*
8. Promote neurobehavioral organization and development*
9. Altered family processes*
10. Grieving (family)*

NEONATAL SEIZURES

Seizures are the most common neurologic sign during the neonatal period and are more common in the newborn stage than at any other time in childhood. The reported incidence of neonatal seizures is approximately 2 to 4 per 1,000 live term births and 30 to 130 per 1,000 live preterm births (Abend, Jensen, Inder, & Volpe, 2018; Natarajan & Gospe, 2018). Neonatal seizures usually are acute, with a third occurring on the first day and another third on the second day of life, then disappearing within the first few weeks after birth. Perinatal hypoxia-ischemia is generally reported to account for 50% to 60% of all neonatal seizures and is the most common cause of seizures for term newborns; IVH is the most common cause of seizures for preterm newborns (Natarajan & Gospe, 2018; Rennie & Boylan, 2009; Scher, 2012).

Seizures were described by the American Clinical Neurophysiology Society in 2013 as a rhythmic activity lasting 10 seconds with a minimum of 2 μV peak-to-peak (pp) voltage that evolves in quality and subsequently resolves. Events that last less than 10 seconds but have similar characteristics are called brief rhythmic discharges (BRDs). Although BRDs are not considered true seizures, the risk of developing seizures increases when BRDs are observed (Natarajan & Gospe, 2018).

Seizures are not a disease in themselves but a sign of underlying disease processes that have resulted in an acute disturbance within the brain. There is increasing evidence suggesting that these seizures exacerbate brain injury, which increases the necessity for prompt recognition, efficient observation and monitoring methods, and effective therapeutic interventions (Abend et al., 2018; Jensen, 2009; Natarajan & Gospe, 2018; Scher, 2012; Shah, Boylan, & Rennie, 2012). If left untreated, these disorders can lead to permanent damage of the CNS or other tissues. Disease processes associated with seizures in the neonate include primary CNS disorders, hypoxic-ischemic events, systemic diseases, and metabolic insults. Seizure activity may be an acute, recurrent, or chronic phenomenon. Recurrent or continuous seizures increase the risk of neurologic damage from the seizure activity itself (Natarajan & Gospe, 2018; Rennie & Boylan, 2009; Scher, 2012; Shah et al., 2012).

Pathophysiology

Seizures are the result of excessive, synchronous electrical discharge or depolarization in the brain that produces stereotypic, repetitive behaviors. Depolarization and repolarization of the nerves are caused by the movement of sodium and potassium across the cell membrane. The inward migration of sodium ions (Na^+) results in depolarization; repolarization is produced by the outward migration of potassium ions (K^+). These processes require an energy-dependent pump and energy in the form of adenosine triphosphate (ATP). The specific mechanism that causes neonatal seizures is unknown but might be the result of one or more of these mechanisms: (a) disturbances in energy production and the Na^+-K^+ pump, (b) altered neuronal membrane permeability to sodium, and (c) imbalances in excitatory and inhibitory neurotransmitters (Abend et al., 2018; Rennie & Boylan, 2009; Scher, 2012). A disturbance in energy production, with changes in the movement of Na^+ and K^+ across the neuronal membrane, may lead to an imbalance between depolarization and repolarization. The movement of K^+ (repolarization) unbalances the movement of Na^+ (depolarization). Changes in energy production may result from hypoxemia, ischemia, and/or hypoglycemia. Alterations in the permeability of the neuronal membrane to sodium can occur with hypocalcemia. Calcium normally binds with proteins in the cell membrane to inhibit Na^+ movement. A decrease in the availability of calcium would increase inward movement of Na^+ and lead to depolarization. Hypomagnesemia also increases membrane permeability to Na^+, and alkalosis or hyponatremia also leads to seizures through this mechanism. Imbalances in neurotransmitters lead to a relative excess of excitatory neurotransmitter (glutamate or acetylcholine) over inhibitory neurotransmitter (gamma-aminobutyric acid [GABA]) and increases the rate of depolarization. This can occur as a result of an excess of excitatory substance (associated with hypoxemia, ischemia, and hypoglycemia) or a deficiency of inhibitory substance. Pyridoxine deficiency leads to an inhibitory neurotransmitter deficiency by depressing the activity of the enzyme responsible for the synthesis of GABA. Elevated levels of excitatory inhibitors derived from ammonia are seen in infants who have liver dysfunction after severe hypoxic-ischemic events (Abend et al., 2018; Jensen, 2009; Rennie & Boylan, 2009; Scher, 2012).

Biochemical Effects of Seizures

Seizures result in increased energy expenditure, which leads to the following sequence of biochemical events: (a) breakdown of ATP to adenosine diphosphate with release of energy; (b) increased glycolysis, stimulated by adenosine diphosphate, with conversion of glycogen to glucose; (c) increased production of pyruvate, which is used by the mitochondria in ATP production; (d) increased oxygen and glucose consumption; (e) increased production of lactate from pyruvate, stimulated by increased adenosine diphosphate; and (f) lactate/H^+-stimulated local vasodilation, which increases local blood flow and substrate availability (Abend et al., 2018; Rennie & Boylan, 2009; Scher, 2012). The rise in blood pressure associated with seizures also increases cerebral blood flow and substrate availability. Seizures result in a marked decrease in brain glucose concentrations because the cells to replenish ATP supplies use much of the available glucose. Repetitive seizures in the neonate eventually alter brain lipid and protein metabolism and energy metabolism, resulting in a reduction in total brain DNA, RNA, protein, and cholesterol. In animal models, these deficiencies lead to impairment of cellular proliferation, differentiation, and myelination. The effects in the human neonate are unclear but of concern. Brain damage caused by seizure activity could be the result of alterations in protein metabolism or the energy supply, or it could be the result of damage from asphyxia or edema. The extent to which these changes occur in the human newborn with recurrent seizures is controversial; mounting evidence suggests that seizures are associated with less favorable neurobehavioral outcomes (Abend et al., 2018; Scher, 2012).

Seizures in Neonates Compared With Those in Older Children and Adults

Seizures are expressed differently in the neonate than in older individuals because of structural and functional differences in the neonatal brain (Abend et al., 2018; Blackburn, 2018). The peak time

for organizational processes in the brain is from the sixth month of gestation to 1 year after birth; therefore, term and especially preterm infants have relatively immature brain organization. This lack of organization results in an inability to propagate and sustain generalized seizures. For example, the neonate's brain lacks the arborization and synaptic connections (wiring) necessary for a firing neuron to recruit adjacent neurons to fire synchronously. Inadequate organization also leads to a slower response to stimuli (Blackburn, 2009a, 2009b; Volpe, 2008). The lower rate of nerve conduction, limited myelination, and smaller number of connections between neurons alter the threshold for neuron firing and ability to propagate seizures (Abend et al., 2018; Blackburn, 2018; Scher, 2012).

The neonate has increased inhibitory synapses compared with excitatory synapses which may actually be a protective mechanism because it reduces the chance that a generalized seizure will be propagated in the cerebral cortex. As a result, cortical seizures are rare in neonates (Abend et al., 2018; Blackburn, 2018). The newborn has more excitatory (glutamate) than inhibitory neurotransmitters. In addition, GABA, the main inhibitory neurotransmitter in adults, is excitatory in the newborn. The glutamate level is increased (it is needed by the brain for neuronal development and organization); maturation of the inhibitory system is delayed; and the number of NMDA receptors that respond to glutamate is increased (Blackburn, 2018; Rennie & Boylan, 2009). Seizure activity in these infants is more likely to be generated in areas of the brain that are more mature, such as the temporal lobe and subcortical structures, especially in the limbic area. The limbic area, located above the corpus callosum, is one of the oldest parts of the brain in terms of embryologic development. This area is involved with behaviors such as sucking, drooling, chewing, swallowing, oculomotor deviations, and apneic episodes, behaviors typical of those seen with subtle seizures in the neonate (Abend et al., 2018; Blackburn, 2018).

Assessment

Seizures are a clinical manifestation associated with various underlying pathologic processes (Table 15.4), including hypoxia, ischemia, hypoglycemia, hypocalcemia, intracranial hemorrhage, infection (meningitis, congenital viral infections, viral encephalopathy), congenital anomalies of the CNS, and other metabolic disturbances, such as alkalosis, hypomagnesemia, hypernatremia, and hyponatremia. Less common causes of seizures are drug withdrawal from opiates or barbiturates, genetic disorders of amino and organic acid metabolism, kernicterus, hyperviscosity, and local anesthetic intoxication (Abend et al., 2018; Natarajan & Gospe, 2018; Rennie & Boylan, 2009; Scher, 2012).

Seizures can be difficult to recognize in neonates because the clinical manifestations often are subtle and can be associated with other disorders or can involve individual behaviors such as grimacing, startle, sucking, and twitching. Seizures can also occur with minimal or no outward signs, leading to an increasing reliance on EEG or aEEG. Recognition of seizures in the neonatal period requires careful, continuous assessment by the nurse of all infants at risk. Clinical manifestations may include abnormal movements or alterations in tone of the trunk or extremities; abnormal and repetitive facial, oral, tongue, or ocular movements such as blinking, lip smacking, or chewing motions; and increases in blood pressure and apneic events (Abend et al., 2018; Natarajan & Gospe, 2018; Pisani & Pavlidis, 2018; Rennie & Boylan, 2009). Specific examples of each of these are listed in Table 15.5.

Types of Seizures

Various classifications of neonatal seizures are used, some focusing primarily on clinical and behavioral manifestations, others on the presence or absence of echocardiogram correlates (Rennie & Boylan, 2009; Scher, 2012). Increasing evidence supports a combination of clinical categories with electrographical confirmation, especially with the recent advances in digital technology that make it possible to archive and review huge amounts of data generated by bedside video-EEG monitoring (Abend et al., 2018; Pisani & Pavlidis, 2018; Rennie & Boylan, 2009; Scher, 2012). The addition of simultaneous, continuous video-EEG and aEEG (method of displaying one or two channels of compressed and filtered EEG readings) monitoring may refine the diagnosis and management of newborns, with seizure activity categorized within traditional classifications. The aEEG monitoring technique is a relatively easy method of detection of seizure activity and is in use with increasing regularity and reliability for monitoring the neurologic status of infants with HIE (Abend et al., 2018; Bonifacio, Glass, Peloquin, & Ferriero, 2011; Pisani & Pavlidis, 2018; Rennie & Boylan, 2009; Toet & de Vries, 2012).

Determining the etiology of the seizure is important as it will provide the opportunity to administer specific treatment and for prognostic information. Many etiologies may cause neonatal seizures but relatively few etiologies account for the majority of neonatal diagnoses. Seven tertiary care pediatric centers in the United States comprising the Neonatal Seizure Registry consortium collected prospective data related to etiology for 426 newborns with seizures who underwent continuous EEG (cEEG). This study found that 38% of the newborns experiencing seizures related to HIE, 18% with ischemic stroke, 13% with neonatal onset epilepsy, 11% with intracranial hemorrhage, 6% with neonatal genetic epilepsy syndrome, 4% with congenital cerebral malformation, and 3% with benign familial neonatal epilepsy (BFNE). In addition, 59% of the newborn subjects experienced greater than seven electrographic seizures, and 16% developed status epilepticus. There was no significant difference in the number of seizures between preterm and full-term newborns or among the three most common causes of seizure (HIE, ischemic stroke, and intracerebral hemorrhage; Abend et al., 2018).

Traditional clinical seizure classification identifies the following seizure types: subtle, tonic, clonic (multifocal or migratory, and focal), and myoclonic (Abend et al., 2018; Natarajan & Gospe, 2018; Rennie & Boylan, 2009). Subtle seizures are the most common type of seizure seen in neonates, particularly among preterm infants. This type of seizure often is missed because the clinical manifestations may be difficult to recognize and distinguish from other events. The behaviors most commonly seen with subtle seizures are (a) tonic, horizontal deviations of the eyes with or without nystagmoid jerking; (b) repetitive blinking or fluttering of the eyelids; (c) drooling, sucking, or tongue thrusting; and (d) swimming or rowing movements of the arms with occasional bicycling movements of the legs. Apnea may occur but usually is the result of the underlying cause of the seizure in the preterm, rather than of the seizure, and rarely occurs as an isolated seizure event (Abend et al., 2018; Natarajan & Gospe, 2018; Rennie & Boylan, 2009; Scher, 2012).

The most common form of tonic seizure is the generalized tonic seizure, which usually involves tonic extension of all the extremities but sometimes is limited to a single extremity or is manifested by tonic flexion of all limbs. Generalized tonic seizures can be confused with decorticate or decerebrate posturing. Other signs may include eye deviations, apnea, and occasional clonic movements. This type of seizure is the one seen most frequently in preterm infants, especially those with IVH and hypoxic-ischemic insults. Generalized tonic seizures often are accompanied by apnea or decerebrate-type postures, or both. Occasionally, focal tonic seizures may occur, which are characterized by sustained asymmetric posturing of the limbs, trunk, or neck. Focal tonic seizure activity may be difficult to differentiate from voluntary movement

TABLE 15.4

MAJOR CAUSES OF NEONATAL SEIZURES

Cause and Frequency (% of Total)	Usual Age at Onset (Days)	Predominant Type of Seizure
Hypoxic-ischemic injury (38% [Abend et al., 2018]; others 50%–60%)	After 1 or more (often 6–18) hours following birth; 90% in the first 72 hours	Subtle (all), generalized tonic, multifocal clonic
Perinatal stroke (18%); arterial ischemic strokes most frequent; cerebral sinovenous thrombosis		
Hypocalcemia (15%)	Early: 1–3 days; late 4–7 days	Usually focal or multifocal
Neonatal onset epilepsy (13%)		
Neonatal genetic epilepsy syndrome (6%)		
Intracranial hemorrhage (11%)		
IVH	Most within first 3 days; later with late-onset IVH	Subtle progressing to generalized tonic with severe IVH
SAH	2–3	Any type
SDH	1–2	May be focal
Hypoglycemia (10%)	1–3	Usually focal or multifocal
Infections (5%–10%)		
Bacterial meningitis	4–7	Any type; may be tonic
Viral encephalopathy	2–15	Any type
Congenital viral infection	3–7	Tonic, myoclonic
CNS malformations (<5%–10%)	2–10 (often not until several months of age)	Tonic, myoclonic
Drug withdrawal (rare)	3–34	Tonic or myoclonic
Local anesthetic intoxication[a] (uncommon)	Before 1 (1–6 hours after birth)	Tonic

CNS, central nervous system; IVH, intraventricular hemorrhage; SAH, subarachnoid hemorrhage; SDH, subdural hemorrhage.

[a] Caused by accidental injection of local anesthetic into the scalp during placement of paracervical, pudendal, or epidural blocks or during injection of local anesthetics at delivery.

(Abend et al., 2018; Heaberlin, 2019; Natarajan & Gospe, 2018; Rennie & Boylan, 2009; Scher, 2012).

Clonic seizures may be multifocal or focal. Because multifocal or migratory clonic seizures involve the cortex, they are more characteristic of term infants but occasionally may be seen in older preterm infants. This type of seizure involves rhythmic, jerky clonic movements of one or more limbs that migrate to other parts of the body in a random fashion. Multifocal clonic seizures can be confused with jitteriness. These seizures are associated with diffuse hyperexcitability of the cortex, such as occurs with metabolic derangements (Abend et al., 2018; Natarajan & Gospe, 2018).

Focal clonic seizures are also seen more frequently in term than in preterm infants. This form of seizure is characterized by localized clonic jerking that is usually present in one limb or the face. Focal clonic seizures may be associated with focal traumatic CNS injuries, such as cerebral contusions and infarcts, or may be

TABLE 15.5

CLINICAL MANIFESTATIONS OF SEIZURES IN THE NEONATE

Type of Manifestation	Specific Alterations
Abnormal movement or alterations of tone in the trunk and extremities	Clonic (generalized or multifocal, migratory)
	Altering hemiclonic tonic (single extremity), extension of arms and legs ("decerebrate-like"), extension of legs and flexion of arms ("decorticate-like"), or generalized
	Myoclonic (isolated or general)
	Bicycling movements of legs
	Swimming or rowing arm movements
	Loss of tone with general flaccidity
Facial, oral, and tongue movements	Sucking
	Grimacing
	Twitching
	Chewing, swallowing, yawning
Ocular movements	Tonic horizontal eye deviation
	Staring, blinking
	Nystagmoid jerks
Respiratory manifestations	Apnea (usually preceded or accompanied by one or more subtle manifestations)
	Hyperpneic or stertorous breathing

a response to a severe metabolic disturbance or asphyxia and occur in combination with other seizure types (Abend et al., 2018; Heaberlin, 2019; Natarajan & Gospe, 2018; Scher, 2012).

Myoclonic seizures are uncommon in term infants and are rarely seen in preterm infants. These seizures are characterized by single or multiple sudden jerks with flexion of the upper (most common) or lower extremities and occasionally the trunk and neck. Myoclonic seizures are most often seen with inborn errors of metabolism or other metabolic problems (Heaberlin, 2019; Natarajan & Gospe, 2018; Rennie & Boylan, 2009).

Management

Management of neonatal seizures has two goals: (a) to determine and treat the underlying cause of the seizures and (b) to protect the infant from injury during and after the seizure. Determining the cause involves assessment of the perinatal and neonatal history, a physical examination, laboratory evaluation, and other diagnostic studies. Previous events that may indicate the underlying cause include the delivery history, bleeding, birth trauma, hypoxic-ischemic events, exposure to infectious agents and other teratogens, maternal substance abuse, and postbirth illnesses.

The physical examination includes evaluation of the infant's general health and neurologic status. Routine laboratory studies include electrolyte levels; glucose, calcium, magnesium, and blood urea nitrogen (BUN) levels; Hct value; blood gases; and pH. A blood culture and lumbar puncture are also often performed. A lumbar puncture helps to rule out both infection and CNS bleeding. Other laboratory and diagnostic studies may include screening for congenital viral infections, amino acid screening (for inborn errors of metabolism), CT, ultrasonography, MRI, skull radiography, or EEG. The results of a continuous video-EEG can provide information for the prognosis, more so in a term than a preterm infant (Abend et al., 2018; Heaberlin, 2019; Scher, 2012).

Quality and Safety: Seizures must be recognized, seizure activity documented, and the infant protected and supported during and after the seizure. Observing and documenting seizure activity involves noting and recording (a) the time the seizure begins and ends; (b) the body parts involved (e.g., extremities, eyes, head); (c) a description of motor movement, eye deviations, and pupillary reactions; and (d) the infant's respiratory status, color, state, level of consciousness, and postictal status. **Emergency Alert: During the seizure, the infant's airway must be maintained, vital signs monitored, and the infant assessed for adequacy of respiration and heart rate to maintain ventilation and perfusion.** To protect the infant from injury during the seizure, the nurse should not force anything into the infant's mouth or try to restrain the infant's extremities. The nurse should try to turn the infant's head to the side, if possible. After the seizure, the infant's condition should be monitored, and supportive care should be provided so that ventilation, oxygenation, adequate fluids, glucose, and warmth are maintained. The nurse also should assess the infant for signs related to the events that can cause seizure activity in the neonate to help determine the cause of the seizure and prevent additional seizures (Heaberlin, 2019; Scher, 2012).

The overall goal of treatment of neonatal seizures is to prevent long-term brain damage through management of the underlying cause of the seizures and cessation of the clinical and electrical seizure activity (Abend et al., 2018; Natarajan & Gospe, 2018). Treatment of the underlying cause of the seizure is a priority for preventing more seizures and neurologic damage. Continual monitoring of blood gases, acid–base status, serum glucose, and fluid and electrolyte status is important for any infant with seizures. Infants who have seizures, regardless of the cause, require intravenous administration of glucose because seizure activity depletes brain glucose and energy supplies (Abend et al., 2018; Blackburn, 2018; Natarajan & Gospe, 2018). Alterations in oxygenation and acid–base status can occur as a complication of the apnea associated with a seizure or the physiologic consequences of seizure activity. Fluid and electrolyte management should be appropriate to the underlying cause of the seizures. For example, fluids are restricted initially in infants with cerebral edema and perinatal hypoxic-ischemic injury (Abend et al., 2018; Natarajan & Gospe, 2018). Management of intracranial hemorrhage and CNS anomalies is discussed later in this chapter. Management of other conditions, such as hypoxic-ischemic events, metabolic and electrolyte disorders, infections, and drug withdrawal, are discussed in detail in other chapters.

The issues of when to treat with anticonvulsant drugs, which drug or combination of drugs to use, and duration of treatment are controversial (Scher, 2012; Shetty, 2015). Some clinicians favor early, aggressive therapy, whereas others do not because neonatal seizures often abate spontaneously (Shetty, 2015). Recurrent or prolonged seizures require treatment with anticonvulsants to reduce the risk of brain injury. Controversy over what medications to use to provide control of neonatal seizures persists due to the diversity of etiology, complexities of diagnosis, and the limited efficacy of the known anticonvulsants available in treating neonatal seizures (Shetty, 2015). In general, however, the current consensus is that the first-line anticonvulsant used for seizure control in the newborn continues to be phenobarbital; phenytoin (Dilantin) is second-line if seizures persist (Scher, 2012; Shetty, 2015). Other drugs used include fosphenytoin (recommended for IV use over phenytoin) and benzodiazepines such as lorazepam and midazolam (Abend et al., 2018; Natarajan & Gospe, 2018; Rennie & Boylan, 2009; Scher, 2012; Shetty, 2015). Phenobarbital, phenytoin, and fosphenytoin doses may be given incrementally to reach therapeutic blood levels, which then must be monitored carefully to maintain therapeutic effect and prevent toxicity. Refractory seizure may require alternative agents such as clonazepam, lidocaine, carbamazepine, diazepam, valproate, or primidone (Abend et al., 2018; Natarajan & Gospe, 2018; Rennie & Boylan, 2009; Scher, 2012). Recent studies on the use of bumetanide for neonatal seizures have been promising; further research is necessary to provide evidence for efficacy (Pressler et al., 2015).

Length of treatment after seizure activity has been controlled and after the infant has recovered is undefined at this point. Often the duration of treatment is clinically determined by etiology of the seizures, the time taken, and amount of medications required to control the seizure activity. It may range from length of hospitalization to 2 years post discharge, provided there is no further seizure activity or perceived neurologic indication for extending treatment (Abend et al., 2018; Natarajan & Gospe, 2018; Scher, 2012).

Because anticonvulsants can be respiratory or myocardial, and CNS depressants can compete with bilirubin for albumin binding, the infant's cardiorespiratory status, color, and neurologic status are monitored in addition to drug effectiveness. Parent teaching includes helping the family to understand the cause and significance of the seizure or seizures and any diagnostic tests that are planned. Discharge teaching of parents includes recognition of seizure manifestations, care of the infant during and after a seizure, and administration of anticonvulsants (dosage and side effects) if administration of these drugs is to be continued after discharge.

Outcomes

The mortality rate for infants with seizures has declined in recent years, from approximately 33% in the 1990s to 10% reported (range: 7%–16%; Natarajan & Gospe, 2018; Uria-Avellanal, Marlow, & Rennie, 2013). Two-thirds of infants with seizures, especially premature infants and/or those with repeated seizures, have adverse neurologic sequelae, including epilepsy (20%–25%), motor deficits, intellectual disabilities, and subtle deficits, such as learning disabilities or poor social adjustment in teen years. Benign seizures in otherwise healthy infants during the first week have a good prognosis (Natarajan & Gospe, 2018; Uria-Avellanal et al., 2013). Preterm infants tend to recover more rapidly from a seizure than do term infants; however, mortality and later morbidity are higher in preterm infants. The prognosis for infants who have seizures during the neonatal period is influenced by (a) the time of onset, (b) the cause of the seizure, (c) continuous video-EEG results, (d) responsivity to treatment, and (e) the frequency and duration of the seizures (Abend et al., 2018; Inder & Volpe, 2018a; Natarajan & Gospe, 2018; Rennie & Boylan, 2009; Scher, 2012; Uria-Avellanal et al., 2013). Seizure onset less than 48 hours after birth has a poor prognosis, whereas onset after 4 days generally has a good prognosis. Clonic seizures have a better prognosis than the other types. The EEG results appear to be a better prognostic sign in term than in preterm infants (Abend et al., 2018; Natarajan & Gospe, 2018; Scher, 2012).

The poorest prognosis is seen with seizures associated with severe hypoxic-ischemic injury, grade III or grade IV IVH, herpes infection, some bacterial meningitis, and CNS malformations. The best prognosis is seen in infants with seizures secondary to late hypocalcemia, hyponatremia, and uncomplicated subarachnoid hemorrhage (SAH). Other causes have a mixed prognosis. Repeated or prolonged seizures can lead to brain injury by altering cerebral blood flow and delivery of oxygen and nutrients, by depleting brain glucose and energy stores, and by interfering with ventilation (Abend et al., 2018; Inder, Perlman, & Volpe, 2018a; Natarajan & Gospe, 2018).

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

HIE is an injury to the brain caused by oxygen deficit resulting from either systemic hypoxemia (decreased oxygen in blood supply) or ischemia (diminished cerebral blood perfusion) or a combination of the two conditions. The hypoxemia and ischemia may occur simultaneously or sequentially, and it appears from recent evidence that ischemia is the more important of the two oxygen deprivation states in causing the brain injury. In addition, the subsequent reperfusion of the affected brain area has been shown to be the time at which the majority of the injury to the brain occurs. Glucose deprivation also plays a part in the severity of the brain injury (Inder & Volpe, 2018a; McAdams & Traudt, 2018). HIE may occur secondary to prenatal, intrapartum, or postnatal insults in both preterm and term infants. The site of injury varies with maturational changes in the vascular anatomy and metabolic activity of the brain. In the preterm infant younger than 32 to 34 weeks' gestation, hypoxic-ischemic damage usually is associated with germinal matrix hemorrhage/IVH. The incidence of severe forms of HIE has declined markedly as a result of advances in perinatal care. Most perinatal hypoxic-ischemic events are mild with minimal effects. The insult is significant enough to cause transient organ dysfunction in 2 to 5 per 1,000 live births and result in death or significant neurologic sequelae in 1 per 1,000 (Dickey, Long, & Hunt, 2011; Inder & Volpe, 2018a; McAdams & Traudt, 2018; Wachtel & Hendricks-Muñoz, 2011).

Pathophysiology

After 33 to 34 weeks' gestation, blood flow and brain metabolic activity become less prominent in the germinal matrix and periventricular area and shift to the cortical area. Hypoxia and ischemia in older preterm and term infants, therefore, are more likely to damage areas of the peripheral and dorsal cerebral cortex. Five types of lesions have been identified in infants with HIE: (a) selective neuronal necrosis; (b) status marmoratus of the neurons of the basal ganglia and thalamus, with loss of neurons in these areas; (c) parasagittal cerebral injury; (d) PVL (primarily in preterm infants); and (e) focal or multifocal ischemic brain necrosis (Inder & Volpe, 2018a; McAdams & Traudt, 2018).

The primary lesion for the hypoxic injury is neuronal necrosis in the cortices of the cerebrum and cerebellum, with damage to the gray matter at the depths of the sulci. Neurons of the brainstem may also be injured. Areas of necrosis may extend into the white matter and into the gray matter of the basal ganglia. The primary ischemic injury occurs in the posterior portion of the parasagittal region secondary to watershed or border zone infarcts. The border zone is at the junctions of the anterior, middle, and posterior cerebral arteries and the superior and inferior cerebellar arteries. This area is farthest from the major cerebral vessels, which are the source of the blood supply for the brain. Thus, with localized ischemia, such as occurs when the infant has systemic hypotension or hypoperfusion, this area receives the least amount of blood. With hypoxia and systemic hypotension, cerebral perfusion is maintained at first by cerebral vasodilation and redistribution of blood flow to the brain from other organs. If the hypoxia continues, cerebral blood flow is altered; energy is depleted; ischemia and edema develop; and neurophysiologic activity is disrupted. At the cellular level, neurologic injury is caused by energy depletion, accumulation of extracellular glutamate, and activation of glutamate NMDA receptors. This process occurs in two phases. The initial insult and effects of hypoxia lead to hyperpolarization with an influx of sodium, potassium, and water into the cell. This interferes with the cell's ability to produce an action potential, leading to failure of the sodium-potassium pump and cell edema. Calcium moves into the cell via voltage-dependent ion channels opened by the changes in the sodium-potassium pump. This reduces calcium currents and release of neurotransmitters. These events may be protective mechanisms to reduce neuronal excitability and conserve oxygen. However, reperfusion and reoxygenation may lead to buildup of free oxygen radicals and primary neuronal death. If the hypoxia and ischemia persist, NMDA receptors are activated, which further increases intracellular calcium (entering the cell via glutamate-controlled ion channels). More glutamate is released and accumulates to toxic levels. Nitric oxide (NO) is also released and accumulates. NO, which at normal levels promotes vasodilation and increased blood flow, reaches toxic levels, leading to the production of excess free oxygen radicals and further activation of NMDA receptors. NO combines with superoxide free radicals to produce the toxic peroxynitrates, causing further cell damage. This late reperfusion phase (usually beginning 6–12 or more hours after the initial insult) is characterized by hyperexcitability and cytotoxic edema and damage caused by the release of free oxygen radicals and NO, inflammatory changes, and imbalances in inhibitory and excitatory neurotransmitters with secondary neuronal death due to necrosis or apoptosis (Dickey et al., 2011; Inder & Volpe, 2018a; Johnston, Fatemi, Wilson, & Northington, 2011; Sorem, Smith, & Druzin, 2009; Stola & Perlman, 2008). After a hypoxic-ischemic insult, the entire cortex initially may be edematous, and further ischemic damage may occur as a result of compression of the cortex against the skull.

Assessment

Most term infants with HIE demonstrate a characteristic pattern of neurologic findings over the first 72 hours of life, including seizures, altered levels of consciousness, altered tone, altered activity, irregular respirations, apnea, poor or absent Moro reflex, abnormal cry, poor suck, and altered pupillary responses and eye movements. Clinical signs categorizing the severity of HIE have been classified in three stages first by Sarnat and Sarnat (1976) and are summarized in Table 15.6. Stage 1, mild HIE, is characterized by mild depression or hyperalertness, irritability, and sympathetic nervous system excitation (tachycardia, dilated pupils). These infants have a good Moro reflex and deep tendon reflexes and generally are symptomatic for less than 24 hours or so. Infants in Stage 2, moderate HIE, demonstrate lethargy interspersed with brief arousal, decreased tone, altered primary reflexes, and increased parasympathetic tone (bradycardia, decreased pupil size and blood pressure) and may develop seizures. Infants in Stage 3, severe HIE, have varying levels of consciousness initially but then become stuporous or comatose. These infants have depressed deep tendon and Moro reflexes, as well as hypotonia, and most develop seizures. Seizures occur in up to 60% of infants with HIE, with a usual onset at 12 to 14 hours of age. The types of seizures most often seen are multifocal clonic seizures in term infants, although myoclonic clonic and/or subtle seizures may also be seen (Inder & Volpe, 2018a; Johnston et al., 2011; McAdams & Traudt, 2018).

Management

Infants with HIE have multiorgan and multisystem problems that arise from the original hypoxic-ischemic insult (McAdams & Traudt, 2018; Sarkar, Barks, Bhagat, & Donn, 2009; Tagin, Woolcott, Vincer, Whyte, & Stinson, 2012; Zanelli, Buck, & Fairchild, 2011). As a result, management of these infants is complex and requires a coordinated team effort. Acute management of infants with HIE focuses on delivery room resuscitation and stabilization and management of the primary problem and related alterations in the

TABLE 15.6

STAGES OF HYPOXIC-ISCHEMIC ENCEPHALOPATHY

	Stage 1: Mild	Stage 2: Moderate	Stage 3: Severe
Level of consciousness	Hyperalert	Lethargic; obtunded	Stuporous
Pupils	Dilated	Constricted	Variable; unequal
Heart rate	Tachycardic	Bradycardic	Variable
Muscle tone	Normal	Mildly hypotonic	Flaccid
Myoclonus	Present	Present	Absent
Sucking reflex	Weak	Weak; absent	Absent
Salivary secretions	Sparse	Profuse	Absent
Moro embrace reflex	Strong	Weak; incomplete	Absent
Seizures	None	Common; focal or multifocal	Uncommon
Duration of symptoms and recovery	<24 hours	2–14 days	Hours to weeks

cardiovascular, pulmonary, gastrointestinal, and renal systems. Prompt identification and treatment of seizures are needed to prevent further alterations in ICP and cerebral blood flow. Management of these infants in relation to neurologic problems focuses on elimination of the cause of the original hypoxia, alleviation of tissue hypoxia, and promotion of adequate cerebral perfusion and brain oxygenation with maintenance of an adequate glucose supply. Inotropic support may be necessary to provide adequate perfusion (Kelen & Robertson, 2010; McAdams & Traudt, 2018; Stola & Perlman, 2008; Wachtel & Hendricks-Muñoz, 2011).

Interventions are directed toward establishing ventilation and adequate perfusion and preventing or minimizing hypotension, hypoxia, acidosis, rapid alterations in cerebral blood flow and systemic blood pressure, and severe apneic and bradycardic episodes. Hyperoxia is also avoided because this state can result in cerebral vasoconstriction and diminished perfusion. The infant's neurologic status is continually monitored and documented, as are oxygenation, temperature, and blood pressure (Stola & Perlman, 2008; Wachtel & Hendricks-Muñoz, 2011). HIE must be differentiated from other neurologic dysfunctions caused by trauma, infection, or CNS anomalies. An extensive workup to define the type, extent, and location of the injury may include cranial ultrasonography, brainstem auditory evoked potentials, MRI, EEG, and measurements of cerebral blood flow, ICP, and the creatinine kinase level (Gunny & Lin, 2012; Stola & Perlman, 2008; Tao & Mathur, 2010; Toet & de Vries, 2012; Wachtel & Hendricks-Muñoz, 2011; Walsh, Murray, & Boylan, 2011).

Other parameters that are monitored are the serum and urinary electrolyte levels and osmolality; BUN, serum creatinine, and glucose levels; and fluid and electrolyte balance. These infants are at risk for hypocalcemia secondary to release of excessive phosphorus from the breakdown of ATP that occurred to produce energy; the need for energy arises in response to the stress induced by perinatal hypoxic-ischemic injury. The excess phosphorus is also related to the use of bicarbonate to correct acidosis induced by these events. After hypoxic-ischemic events, an infant is at risk for hypoglycemia as a result of depletion of stores from high energy; therefore, provision of adequate glucose for energy and interventions to reduce energy expenditure are important. Fluid status and intake and output are monitored to prevent fluid overload and to reduce localized increases in pressure; fluids are restricted, although the effectiveness of this intervention has not been evaluated with clinical trials. Fluid management is critical not only for treating the cerebral edema but also for managing the alterations in renal function and problems such as acute tubular necrosis that frequently accompany moderate to severe stages of HIE (Liao, Xu, Ding, & Huang, 2018; Stola & Perlman, 2008; Wachtel & Hendricks-Muñoz, 2011).

Induced mild hypothermia has been shown to provide neuroprotection and reduce the extent of tissue injury and is increasingly the treatment of choice for infants greater than or equal to 36 weeks' gestation with moderate-to-severe HIE (Bonifacio, Gonzalez, & Ferriero, 2012; Inder & Volpe, 2018a; Laptook, 2012; McAdams & Traudt, 2018; Pfister & Soll, 2010; Rutherford et al., 2010; Stola & Perlman, 2008). Potential mechanisms for these effects with

hypothermic therapy include inhibition of glutamate release, reduction in cerebral metabolism, and preservation of high-energy phosphates. Additional neuroprotective mechanisms include decreases in intracellular acidosis and lactic acid accumulation, preservation of endogenous antioxidants, reduction in NO production, decrease in protein kinase inhibition, improved protein synthesis, reduction in leukotriene production, minimization of blood–brain barrier disruption, reduced brain edema, and apoptosis inhibition (Hoehn et al., 2008; Inder & Volpe, 2018a; Liao et al., 2018; Pfister & Soll, 2010; Stola & Perlman, 2008). Techniques studied include either selective head cooling or whole-body cooling to attain mild systemic hypothermia of 32°C to 34°C core body temperature (Barks, 2008; Hoehn et al., 2008; Inder & Volpe, 2018a; Kelen & Robertson, 2010; Laptook, 2012; McAdams & Traudt, 2018; Stola & Perlman, 2008). Infants are assessed to determine whether hypothermia criteria are met before the cooling regimen is initiated. Current criteria used to determine if a newborn is a candidate for hypothermia are (a) term infants ≥36 weeks' gestation without major congenital anomalies, intrauterine growth restriction (IUGR; ≤1,800 g), or known chromosomal anomaly; (b) admitted at less than or equal to 6 hours of age to the neonatal intensive care unit (NICU); (c) assessed to be in Stage 2 moderate HIE, or Stage 3, severe HIE by neonatologist and/or pediatric neurologist (Gancia & Pomero, 2011; Hoehn et al., 2008; Inder & Volpe, 2018a). The cooling regimen continues for 72 hours and is begun as soon as possible after birth, by 5.5 to 6 hours postbirth and optimally before seizure activity is noted (Bonifacio et al., 2011, 2012; Hoehn et al., 2008; Inder & Volpe, 2018a; Laptook, 2012; Liao et al., 2018; McAdams & Traudt, 2018; Stola & Perlman, 2008). Within 6 hours of birth is a therapeutic window demonstrated in sheep between insult and further cell death for neuroprotective interventions; early hypothermia studies indicate that cooling may be less effective if started after onset of seizures or in infants with most severe EEG changes before therapy (Gancia & Pomero, 2011; Gluckman et al., 2005; Gunn et al., 2008; Inder & Volpe, 2018a; Liao et al., 2018; McAdams & Traudt, 2018).

Hypothermia therapy has multisystem effects in addition to the effects resulting from HIE (Table 15.7; Battin et al., 2009;

TABLE 15.7

POTENTIAL PHYSIOLOGIC EFFECTS OF HYPOTHERMIA BY SYSTEMS WITH MEDICAL AND NURSING INTERVENTIONS

System	Potential Physiologic Effects	Medical and Nursing Interventions
Neurologic	Decreased cerebral blood flow	Observe for seizure activity
	Decreased cerebral metabolic rate	Monitor infant's state of arousal
	Amplitude and frequency	EEG, cEEG with video; aEEG
Respiratory	Decreased respiratory drive	Monitor respiratory rate, effort; may need intubation, ventilation
	Increased pulmonary vascular resistance	Monitor systemic blood pressure
	Increased CO_2 and O_2 solubility	Monitor blood gases (preferably arterial)
	Decreased CO_2 production and O_2 consumption	Adjust assisted ventilation as needed to prevent hypercarbia, hypoxia
	Increased pH by 0.0016 for every 1°C decrease in temperature	Monitor saturations with pulse oximetry to prevent hypoxia
	Decreased minute ventilation to preserve normal $Paco_2$	
Cardiovascular	Decreased heart rate by 14–60 bpm	Monitor continuous cardiorespiratory monitoring
	Increased systemic vascular resistance	Monitor invasive arterial blood pressure
	Decreased cardiac output	Observe changes in perfusion status, urine output
	Decreased intravascular volume	Maintain blood pressure within parameters with vasopressors, boluses
	Potential for ECG changes: prolonged PR, QRS, QT	Monitor cardiac strips; obtain ECG as needed

(*continued*)

TABLE 15.7

POTENTIAL PHYSIOLOGIC EFFECTS OF HYPOTHERMIA BY SYSTEMS WITH MEDICAL AND NURSING INTERVENTIONS (*continued*)

System	Potential Physiologic Effects	Medical and Nursing Interventions
Renal	Decreased renal perfusion and glomerular filtration rate	Monitor fluid intake, urine output
	Impaired salt and water reabsorption	Obtain electrolytes every 4–8 hours as needed
	Diuresis	
	Potential for hypokalemia with increased intracellular uptake	Maintain normal potassium level
	Potential for hyperkalemia during rewarming	
	Potential for decreased calcium, magnesium, phosphorus	
Gastrointestinal	Decreased intestinal blood flow	Provide parenteral nutrition
*		Begin enteral nutrition cautiously after rewarming; monitor for intolerance
Hematologic	Decreased platelet count; thrombocytopenia	Monitor platelet count every 6–12 hours as indicated
	Increased activation and aggregation (clumping)	
	Increased PT, PTT	Monitor PT, PTT every 12–24 hours as indicated
Immunologic	Impaired neutrophil release and function	Monitor CBC with differential at least every 24 hours
	Decreased leukocyte chemotaxis	
	Decreased phagocytosis and killing	

aEEG, amplitude-integrated EEG; CBC, complete blood count; cEEG, continuous EEG; PT, prothrombin time; PTT, partial thromboplastin time.

Glass, 2010; Liao et al., 2018; Lista et al., 2011; Reynolds & Talmage, 2011; Selway, 2010; Vandertak, 2009; Verklan, 2009). The infants undergoing a cooling regimen, either selective head cooling or whole-body cooling, require optimal care and attention at the bedside; this intervention is only being done in tertiary NICU settings (Barks, 2008; Liao et al., 2018; Reynolds & Talmage, 2011; Selway, 2010; Zanelli et al., 2011). Delays in transport are critical and should be avoided. Induced hypothermia is not recommended either prior to or during transport. Care should be taken that the infants not become hyperthermic with core temperatures greater than 37°C (Glass, 2010; Hoehn et al., 2008; Pfister & Soll, 2010).

Fluctuations in systemic blood pressure with increased ICP and altered cerebral hemodynamics can occur as a result of caregiving or environmental stress; therefore, developmentally supportive care of these infants to reduce stress is essential. As the infant recovers, opportunities for sensory experiences are an important part of care. These experiences can be introduced

slowly, as the infant can tolerate them without becoming stressed and overloaded. Physiologic and neurologic status is monitored and documented at regular intervals. The infant is observed for changes in level of consciousness, tone, and activity and for evidence of seizures. Seizures are recognized and treated promptly to prevent further injury. Positioning and skin care are important, especially for hypoactive, obtunded, or comatose infants. Physiologic and clinical effects and supportive measures for infants treated with hypothermia are summarized in Table 15.7.

Parents need initial and continuing support in dealing with their infant's critical illness; the lack of infant responsiveness if the infant is hypoactive, stuporous, or comatose; the possibility of death; and the implications for later neurologic deficits. Parent teaching focuses on promoting an understanding of the infant's health status and care and providing anticipatory guidance regarding changes in the infant's state, as well as the outcome (Long & Brandon, 2007; Selway, 2010). The parents need to be shown how to interact with and care for their infant in a developmentally appropriate manner, with the goal of promoting opportunities for interaction while minimizing stressful events. The nurse can model this type of care for the parents and provide anticipatory guidance in the ways the infant's needs and care will change as the baby matures. Parents can also be involved in devising and implementing a developmental plan of care for their infant (Gudsnuk & Champagne, 2011; Sullivan, Perry, Sloan, Kleinhaus, & Burtchen, 2011).

Outcomes

The prognosis, which varies with the extent and severity of the insult and the resulting brain injury, ranges from perinatal death to severe neurologic impairment to minimal or no sequelae. Specific sequelae may not be apparent for several months or longer. Some infants make a significant recovery, although the rate and degree of recovery vary. MRI or CT can be used to assess the location, degree, and extent of the injury (Epelman, Daneman, Chauvin, & Hirsch, 2012; Gunn et al., 2008; Gunny & Lin, 2012; Inder & Volpe, 2018a; Liao et al., 2018; Lodygensky, Menache, & Hüppi, 2012; Lori et al., 2011; McAdams & Traudt, 2018). Sequelae of HIE in term infants are related to the site of injury (e.g., the cortex) and include intellectual disabilities, microcephaly, cortical blindness, hearing deficits, and epilepsy. Generally, infants with mild HIE do well. Infants with moderate HIE or severe HIE have a higher mortality rate and later cognitive and motor problems (de Vries & Jongmans, 2010; Gunn et al., 2008; Inder & Volpe, 2018a; McAdams & Traudt, 2018; Wyatt et al., 2007).

The advent of hypothermia therapy as a treatment modality appears to have improved the general outcome, especially for infants with Stage 2 moderate HIE. Most human studies report beneficial effects of hypothermia therapy in terms of improved survival and outcome with no significant adverse effects for infants with Stage 2 moderate HIE (Bonifacio et al., 2012; Gunn et al., 2008; Inder & Volpe, 2018a; Liao et al., 2018; McAdams & Traudt, 2018; Rutherford et al., 2010; Volpe, 2008). A recent meta-analysis comparing head cooling with total body cooling technique showed both to be effective treatments for moderate-to-severe HIE, resulting in reduction in the risk of death or major neurodevelopmental disability at 18 months, particularly for infants with moderate HIE (Tagin et al., 2012). Guillet et al. (2012) reported subtle cognitive and motor neurological disabilities at school age (7–8 years) follow-up of the CoolCap study. The authors also reported support for long-term predictive value of a favorable outcome at 18 months of age.

BRAIN INJURY IN PRETERM INFANTS

Preterm infants are particularly vulnerable to brain injury, with the greatest prevalence of neurologic alterations seen in very low birth weight infants. These infants are at increased risk for cognitive, behavioral, motoric, vision, hearing, attentional, and socialization problems (Blackburn, 2016; Neil & Volpe, 2018; Symes, 2016). Major disabilities (cognitive, motor, vision, hearing) are seen in 6% to 8% of infants from 1,501 to 2,000 g birth weight, increasing to 14% to 17% at 1,001 to 1,500 g and 20% to 30% in infants weighing less than 1,000 g at birth (Symes, 2016). Cognitive dysfunction continues into school age and adulthood (15%–25% in those born at <1,500 g and over 50% in those <750 g; Back, 2015; Back & Miller, 2018; Symes, 2016). Reductions in cerebral white and gray matter growth are seen in these infants (Back & Miller, 2018; Penn, Gressens, Fleiss, Back, & Gallo, 2016; Symes, 2016).

The major etiologic events leading to brain injury in preterm infants are a combination of pathophysiologic events leading to specific injuries and an increased susceptibility to injury due to their stage of brain development leading to interruption or disruption of brain development. The relative contributions of altered or delayed maturation versus specific injury are unclear (Penn et al., 2016). Developmentally, preterm infants are vulnerable to alterations in brain maturation and injury because they are born "at a time of peak brain growth, synaptogenesis, developmental regulation of specific receptor populations, and central nervous system organization and differentiation" (Symes, 2016, p. 1157). Exposure to pain and stress, opioids and other pharmacologic agents, and the NICU environment may also influence brain development and maturation in preterm infants (Blackburn, 2018; Penn et al., 2016).

The main pathophysiologic events leading to brain injury in preterm infants are hypoxia-ischemia and inflammation/infection (Inder, Perlman, & Volpe, 2018b). The primary lesions seen in these infants are germinal matrix hemorrhage–IVH, which may include periventricular hemorrhagic infarction (PVHI) and posthemorrhagic hydrocephalus, WMI (including PVL, often accompanied by gray matter damage with neuronal and axonal damage), and cerebellar injury (Back & Miller, 2018; Juul, Fleiss, McAdams, & Gressens, 2018; Kinney & Volpe, 2018a; Volpe et al., 2011). PVL accompanied by neuronal and axonal abnormalities has been referred to as the encephalopathy of prematurity and is the most common brain injury currently seen in preterm infants (Kinney & Volpe, 2018a; Volpe et al., 2011).

Prevention of brain injury in preterm infants is a complex process that begins in the perinatal period with prevention of preterm birth, perinatal asphyxia, and birth trauma (Blackburn, 2016; Juul et al., 2018). Neuroprotective strategies for preterm infants include use of antenatal glucocorticoids, antenatal magnesium sulfate to reduce the risk of cerebral palsy, delayed cord clamping, and neonatal skin to skin contact (kangaroo care; Doyle, Crowther, Middleton, Marret, & Rouse, 2009; Hirtz et al., 2015; Juul et al., 2018; Silva, Barros, Pessoa, & Guinsburg, 2016). Currently under investigation are the use of melatonin and erythropoietin (Juul et al., 2018). Nursing management after birth involves recognition of factors that increase the risk of brain injury, implementation of strategies to reduce these risks, and supportive care (Blackburn, 2016).

Germinal Matrix-Intraventricular Hemorrhage

Germinal matrix-intraventricular hemorrhage (GMH/IVH, or, most commonly, IVH) is the most common type of intracranial hemorrhage seen in the neonatal period (Back & Miller, 2018; Inder et al., 2018b; Takenouchi & Perlman, 2012). IVH is seen

almost exclusively in preterm infants, particularly those weighing less than 1,500 g. Decreasing gestational age increases the risk and severity of IVH. Incidence of IVH in premature infants less than 1,500 g has remained fairly stable for the past decade at 15% to 25% (Back & Miller, 2018; Ballabh, 2014; Inder et al., 2018b; Takenouchi & Perlman, 2012). However, the risk of IVH and severe IVH is higher in more immature infants, especially those with birth weights less than 750 g (Inder et al., 2018b). The major risk factors for IVH in the neonate are prematurity and hypoxic events interrelated with the anatomic and physiologic processes that make the periventricular site particularly vulnerable. IVH occurs but is uncommon after 35 to 36 weeks' gestation because of the involution of the subependymal GM and alterations in cerebral blood flow patterns that occur after this time. Any perinatal or neonatal event that results in hypoxia or alters cerebral blood flow or intravascular pressure increases the risk of IVH (Inder et al., 2018b). IVH is classified by the location and severity of the hemorrhage. Several classifications are available (Back & Miller, 2018). Using Volpe's system, a grade I or slight hemorrhage is characterized by isolated GM hemorrhage; a grade II or small hemorrhage by IVH with normal ventricular size; and a grade III or moderate hemorrhage IVH with ventricular dilation and hemorrhage in greater than 50% of the ventricle (Inder et al., 2018b). PVHI or severe hemorrhage (also referred to as grade IV) involves both intraventricular and brain parenchyma hemorrhage IVH (Back & Miller, 2018; Inder et al., 2018b).

Pathophysiology. The neuropathophysiology of IVH involves a complex interaction of intravascular, vascular, and extravascular factors. In infants of less than 28 to 32 weeks' gestation, the hemorrhage generally arises from the subependymal GM at the head of the caudate nucleus near the foramen of Monro. On those rare occasions when IVH occurs in term infants, bleeding usually arises from the choroid plexus rather than from the GM (Inder et al., 2018b). The GM includes the tissue underlying the ependymal wall of the lateral ventricles. In many preterm infants, the hemorrhage begins as a microvascular event in the GM and is confined to the subependymal area. In the rest, the original hemorrhage ruptures into the lateral ventricles and then into the third and fourth ventricles. The blood eventually collects in the subarachnoid space of the posterior fossa, often extending into the basal cistern (see Figure 15.1; Back & Miller, 2018; Ballabh, 2014). Rupture of the hemorrhage from the GM into the ventricles may serve a protective function by decompressing the hemorrhagic area and reducing further tissue destruction. Progressive ventricular dilation may occur as the result of obstruction of CSF flow by an obliterative arachnoiditis or as the result of blood clots at the level of the aqueduct of Sylvius or the foramen of Monro. With severe hemorrhages (PVHI), blood may also be found in the periventricular white matter, with parenchymal lesions seen in 10% to 15% of very low birth weight infants with an increased risk of adverse neurodevelopmental outcomes (Inder et al., 2018b). These parenchymal lesions are differentiated from PVL in that the circulatory disturbance is venous (vs. arterial in PVL), hemorrhagic (uncommon in PVL), and asymmetric with a single large cyst (vs. more symmetrical findings with multiple small cysts with PVL; Inder et al., 2018b).

The neuropathological consequences of IVH include (a) destruction of the GM and its glial precursor cells, including oligodendrocytes and late migrating GABAergic neurons; (b) infarction and necrosis of periventricular white matter; and (c) posthemorrhagic hydrocephalus (Back & Miller, 2018; Inder et al., 2018b) that alters cerebral brain development, myelination, and axonal maturation (Inder et al., 2018b). Infants with IVH may also have PVL. However, PVL is usually a consequence of hypoxic-ischemic injury and thus may not be a result of the IVH (Inder et al., 2018b).

Intravascular Factors. Intravascular hemodynamic factors play a prominent role in the pathogenesis of IVH. These factors include distribution of blood to the periventricular region, pressure-passive cerebral blood flow, and venous hemodynamics. The stages of CNS development characteristic of preterm infants born at less than 32 to 33 weeks' gestation increase the risk of hemorrhage in the periventricular area (Blackburn, 2018).

Periventricular Blood Flow. The subependymal GM is a transient structure that begins to thin after 14 weeks, then increases to become the site of neuron and glia proliferation, and then involutes during the third trimester (Inder et al., 2018b). This is the site where neuroectodermal cells that serve as precursors for neurons (primarily before about 24 weeks' gestation) and glial cells develop. These cells subsequently migrate to their eventual locus in the cerebral cortex. Processes involved in the proliferation, differentiation, and migration of these cells result in an area that is highly vascularized and metabolically active. Before 32 weeks' gestation, a significant portion of the total cerebral blood flow goes to the periventricular GM, primarily to support neuroblast and glioblast mitotic activity and migration. Any factor that increases cerebral blood flow can result in overperfusion of the periventricular region. After 32 to 34 weeks' gestation, cell proliferation and migration decline; the GM becomes less prominent and receives a smaller proportion of the cerebral blood supply. After this time, the greater proportion of blood flow is to the rapidly differentiating cerebral cortex (Back & Miller, 2018; Blackburn, 2016; Inder et al., 2018b).

Cerebral Autoregulation. The blood vessels of the brain normally are protected from marked alterations in flow by autoregulatory processes. If cerebral autoregulation is intact, the arterioles constrict or dilate to maintain a constant cerebral blood flow despite fluctuations in systemic blood pressure. Hypoxia and hypoxemia in the neonate alter cerebral autoregulation. This can lead to a pressure-passive system in which cerebral blood flow varies directly with arterial pressure. Subsequent alterations in systemic blood pressure or cerebral blood flow, or both, are transmitted directly to the brain and, in particular, to the area receiving the greatest proportion of cerebral blood flow, that is, the fragile, thin-walled vessels of the GM in preterm infants. Thus, rapid fluctuations in systemic blood pressure or cerebral blood flow (i.e., moving from increased to decreased flow and vice versa) may increase the risk of vessel rupture (Back & Miller, 2018; Fyfe, Yiallourou, Wong, & Horne, 2014; Inder et al., 2018b). Altered hemodynamics with fluctuations in blood flow can occur with positive pressure ventilation, rapid volume expansion, hypercapnia, and possibly reduced Hct and blood glucose values. Increased systemic blood pressure and, potentially, cerebral blood flow also can occur with caregiving events, such as handling, suctioning, and chest physical therapy (Blackburn, 2016; Inder et al., 2018b; Takenouchi & Perlman, 2012).

Venous Hemodynamics. Increased venous pressure, arising from events such as myocardial failure or positive pressure ventilation, can also be transmitted directly to the capillaries of the GM. These events can impede cerebral venous return, leading to stasis and venous congestion, which then lead to increased venous pressure and vessel rupture. The point of vulnerability in the venous drainage system of the brain is at the level of the foramen of Monro and the caudate nucleus (the usual site of IVH). At this location, a U-shaped turn occurs in the venous drainage system where the confluence of the thalamostriate, terminal, and choroidal veins forms the internal cerebral vein, which empties into the great vein

of Galen. This results in a sharp change in the direction of blood flow and predisposes to turbulent venous flow with stasis and thrombus formation and an area vulnerable to increased intravascular pressure (Inder et al., 2018b). In addition, the pliable skull of the preterm infant can easily be deformed, obstructing the major venous sinuses and increasing venous pressure.

Vascular Factors. The capillary bed of the GM is immature and has large, irregular, thin-walled vessels, a feature that increases its vulnerability to rupture. The capillary walls thicken with increasing gestational age. The fragility of these vessels is due partly to the lack of thickness and strength of the basement membrane, limitations in pericytes that provide basement membrane support, and the lack of collagen and smooth muscle (Ballabh, 2014; Blackburn, 2016; Walsh, Inder, & Volpe, 2017). With migration of the neuronal and glial cells and their derivatives, the GM undergoes involution. The immature capillary bed is remodeled into the definitive, mature capillary. The epithelial cells of these capillaries are dependent on oxidative metabolism and thus are easily injured by hypoxic events. This characteristic increases the likelihood of leakage or rupture if transmural pressure increases. Because these vessels require an adequate supply of oxygen to maintain their functional integrity, decreased cerebral blood flow can lead to hypoxic-ischemic injury. These vessels are also susceptible to ischemia because they tend to lie in the vascular border zone, or "watershed" area. Both increased and decreased cerebral blood flow, therefore, can be involved in the pathogenesis of IVH (Ballabh, 2014; Blackburn, 2018; Inder et al., 2018b).

Extravascular Factors. The capillary bed of the highly vascularized GM is embedded in gelatinous material deficient in supportive mesenchymal elements, thus providing poor support for the fragile blood vessels. In addition, excessive fibrinolytic activity occurs in the periventricular area. As a result, a small initial bleed may not clot off and be localized, but rather may continue to enlarge and rupture into the ventricles, or the cerebral parenchyma, or both (Ballabh, 2014; Inder et al., 2018b; Walsh et al., 2017).

Assessment. Perinatal events associated with fetal and neonatal hypoxia include maternal bleeding, fetal distress, perinatal hypoxic-ischemic injury, prolonged labor, maternal infection, preterm labor, and abnormal presentation. Neonatal hypoxic events, such as respiratory distress, apnea, and hypotension, further increase the risk of IVH. Events associated with impairment of venous return, increased venous pressure, or both, include assisted ventilation, high positive inspiratory pressure, prolonged duration of inspiration, continuous positive airway pressure (CPAP), and air leak. Venous pressure can also be increased by compression of the infant's skull during vaginal delivery, application of forceps, and use of constricting head bands. Rapid administration of hypertonic solutions (e.g., sodium bicarbonate and glucose), rapid volume expansion, hypernatremia, hypercarbia, caregiving interventions, and environmental stress can increase cerebral blood flow. Hypercarbia causes cerebral vasodilation, thus increasing blood flow. Hypertonic solutions given rapidly or in a large bolus alter osmotic gradients between the brain and the blood. Repeated or prolonged seizures raise the blood pressure and can lead to hypoxia (Blackburn, 2018; Inder et al., 2018b; Walsh et al., 2017).

The clinical manifestations of this disorder often are nonspecific and are not well correlated with later sonographic evidence of bleeding. Therefore, a high index of suspicion, along with careful monitoring, is important for infants at risk. The diagnosis is generally made by cranial ultrasound to determine the presence and severity of IVH and the progression of the hemorrhage, as well as to monitor later complications such as PVL, progressive ventricular dilation, and posthemorrhagic hydrocephalus (Back & Miller, 2018; Takenouchi & Perlman, 2012; Walsh et al., 2017). Although CT scans and MRI can also be used, cranial ultrasound is preferred since it does not involve ionizing radiation and is easily done at the bedside (Inder et al., 2018b).

More than 90% of infants with IVH bleed within the first 72 hours after birth; less than 5% develop after 4 to 5 days. Extension of the hemorrhage may be seen during the first few days (Back & Miller, 2018; Ballabh, 2014). Late hemorrhages after a few days or weeks are seen primarily in preterm infants with severe, prolonged respiratory problems. A new hemorrhage or an extension of a previous one may develop in these infants. IVH may also develop before birth in some infants (Inder et al., 2018b).

The signs and symptoms of IVH are often nonspecific and subtle. Clinical signs may include a full anterior fontanelle, changes in activity level, and decreased tone. Other clinical signs associated with IVH are impaired visual tracking, increased tone of the lower limbs, hypotonia of the neck, and brisk tendon reflexes (Back & Miller, 2018; Inder et al., 2018b).

Besides a declining Hct or failure of the Hct to increase after transfusion, laboratory evidence suggestive of IVH involves CSF findings indicative of hemorrhage: increased red blood cell levels, increased protein levels, decreased glucose levels, and xanthochromia (often a later finding and caused by increased protein). Extremely low CSF glucose levels, or hypoglycorrhachia, can be found several days to a week (usually 5–15 days) after the hemorrhage in some infants.

The patterns of clinical manifestations seen in individual infants vary widely and range from silent or subtle to catastrophic. At one end of the continuum are infants with IVH who have only silent, subependymal bleeding with no or minimal clinical signs. This is the most common and often discovered during routine ultrasound screening. Other infants may demonstrate clinical manifestations, including alterations in level of consciousness or stupor, hypotonia, abnormal eye movements or positions, and altered mobility. These infants generally survive. Later developmental outcome varies, depending on the severity of the hemorrhage (Back & Miller, 2018; Inder et al., 2018b).

Catastrophic deterioration usually involves major hemorrhages that evolve rapidly over several minutes or hours. **Emergency Alert: Clinical findings include stupor progressing to coma, respiratory distress progressing to apnea, generalized tonic seizures, decerebrate posturing, fixation of pupils to light, and flaccid quadriparesis.** This clinical presentation is associated with a declining Hct value, bulging fontanelle, hypotension, bradycardia, temperature alterations, hypoglycemia, and syndrome of inappropriate antidiuretic hormone. Infants with catastrophic hemorrhages have a high mortality rate and, if they survive, a poor prognosis for later development (Back & Miller, 2018; Inder et al., 2018b).

Management of GM/IVH. Management of IVH involves prevention of hemorrhage in infants at risk, acute care of infants with current bleeding, pharmacologic therapies, and management of posthemorrhagic ventricular dilation. Routine ultrasound screening of infants at risk for IVH can identify infants with silent bleeding or bleeding associated with nonspecific, subtle symptoms. Prevention or risk reduction begins in the perinatal period, with the prevention of preterm birth, perinatal hypoxic-ischemic injury, and birth trauma. Administration of antenatal glucocorticoids to enhance fetal lung maturation is associated with a decreased incidence of IVH, perhaps due to improved cardiovascular stability (Back & Miller, 2018; Blackburn, 2018; Inder et al., 2018b).

Postbirth prevention and risk reduction must begin immediately at birth. Activities include resuscitation by a trained NICU team and interventions to prevent or reduce hypoxic or ischemic events; to prevent rapid changes in cerebral blood flow, to avoid both hypocarbia and hypercarbia fluctuations in systemic blood pressure, and hyperosmolarity; and to prevent or minimize

fluctuations in ICP. By identifying these vulnerable infants, interventions can be instituted to prevent new bleeding or extensions of existing hemorrhage. Continual assessment of fetal and neonatal oxygenation and perfusion is important so that subtle alterations can be recognized and clinicians can intervene early to prevent cerebral hyperperfusion and stabilize cerebral blood flow and pressures. Prompt resuscitation at birth minimizes hypoxemia and hypercarbia, which can alter cerebral autoregulation. Hypertonic solutions and volume expanders are administered slowly, with careful monitoring of vital signs and color. Activities that can increase ICP or cause wide swings in arterial or venous pressure are avoided or minimized when possible, especially during the first 72 hours of life. Because seizures can alter cerebral blood flow and ICP, they must be recognized promptly and treated (Back & Miller, 2018; Inder et al., 2018b; Takenouchi & Perlman, 2012).

Acute treatment of infants with IVH involves providing physiologic support by maintaining oxygenation, perfusion, normothermia, and normoglycemia. Physical manipulations, handling, and environmental stressors are minimized to reduce the risk of hypoxia and of fluctuations in arterial blood pressure and cerebral blood flow. The infant's position is also important. The head is positioned in a neutral position in the midline or to the side, without flexing the neck. The head of the bed can be elevated slightly. The Trendelenburg position is avoided. Vital signs, blood pressure, tone, activity, and level of consciousness are monitored frequently. The care of infants with progressive ventricular dilation is discussed in the section on hydrocephalus. Developmental interventions, such as containment or swaddling during aversive procedures such as endotracheal suctioning, may promote greater physiologic stability during these procedures and a more rapid return to baseline (Bissinger & Annibale, 2014; Blackburn, 2016, 2018; Kling, 1989; Owens, 2005; Pitcher, Schneider, Drysdale, Ridding, & Owens, 2011). Specific interventions are listed in Table 15.8.

Since IVH generally occurs in the first few days after birth, IVH prevention bundles have been developed and implemented for the first 48 to 72 hours in many units to minimize activities that increase intracranial pressure or lead to alterations in venous and arterial pressure or to hypoxemia and promote neutral head positioning (Christ et al., 2015; de Bijl-Marcus, Brouwer, de Vries, & van Wezel-Meijler, 2017; Malusky & Donze, 2011).

TABLE 15.8

NURSING CARE TO REDUCE THE RISK OF GERMINAL MATRIX HEMORRHAGE/INTRAVENTRICULAR HEMORRHAGE AND OTHER BRAIN INJURY IN PRETERM INFANTS

Intervention	Rationale
Position the infant with the head in the midline (neutral alignment) and the head of the bed slightly elevated.	ICP is lower with the head in the midline and the head of the bed elevated 30°.
	Turning the head sharply to the side causes obstruction of the ipsilateral jugular vein and can increase ICP.
Avoid tight, encircling phototherapy masks.	Pressure on the occiput can increase ICP by impeding venous drainage.
Avoid rapid fluid infusions for volume expansion and rapid infusion of hypertonic solutions such as glucose. (a) Know the normal BP for the infant's weight and age. (b) If the infant is not hypovolemic, suggest dopamine therapy to maintain BP.	Rapid increases in intravascular volume can rupture the capillaries in the germinal matrix, and this risk may be even greater with a history of hypoxia and hypotension. Even modest, abrupt increases in BP may cause IVH.
Monitor BP diligently. Inform physician if with a fluctuating pattern in the arterial pressure tracing.	The blood flow velocity in the anterior cerebral artery is reflected by the pattern of the simultaneously recorded arterial BP.
Monitor closely for signs of pneumothorax, including: (a) Increase in mean BP, especially increases in diastolic BP (early) (b) Tachycardia (early) (c) Hypotension and bradycardia (late) (d) Changes in breath sounds (e) Diminished arterial oxygen pressure (Pao_2) (f) Increased arterial carbon dioxide pressure ($Paco_2$) (g) Shift in cardiac point of maximum impulse	Pneumothorax may precede IVH. The sum of hemodynamic changes caused by pneumothorax is flow under increased pressure in the germinal matrix capillaries. Changes in vital signs can be early indicators of pneumothorax.
Maintain temperature in neutral thermal range.	Hypothermia has been associated with IVH.
Suction only as needed.	Even brief suctioning episodes (20 seconds) can increase cerebral blood flow velocity, BP, and ICP and reduce oxygenation.

(*continued*)

TABLE 15.8

NURSING CARE TO REDUCE THE RISK OF GERMINAL MATRIX HEMORRHAGE/INTRAVENTRICULAR HEMORRHAGE AND OTHER BRAIN INJURY IN PRETERM INFANTS (*continued*)

Intervention	Rationale
Avoid interventions that cause crying. (a) Consider long-term methods of achieving venous access to avoid frequent venipuncture. (b) Critically evaluate all manipulations and handling. (c) Use analgesics for stressful procedures.	Crying can impede venous return and increase cerebral blood volume.
Reduce pain and stress (a) Regular assessment and monitoring of pain (b) Minimize numbers of painful procedures (c) Implement pharmacologic and nonpharmacological pain reduction therapies (d) Monitor the NICU physical and caregiving environment and reduce stressors	Pain and stress may alter neurodevelopment and impair cortical and white matter development. Exposure to repeated pain may alter pain circuitry and responsivity.
Maintain blood gas values within a normal range. (a) Use continuous noninvasive monitoring of oxygenation. (b) Adjust the fractional concentration of oxygen in inspired gas (Fio_2) as needed to maintain the transcutaneous oxygen pressure ($Tcpo_2$) or pulse oximeter values within desired range. (c) Avoid interventions that cause hypoxia.	Hypoxia and excessive hypercapnia are associated with the development of IVH. These events increase cerebral blood flow and may impair the neonate's already limited ability to autoregulate the cerebral blood flow. Hypoxia can injure the germinal matrix capillary endothelium.

BP, blood pressure; ICP, intracranial pressure; IVH, intraventricular hemorrhage; NICU, neonatal intensive care unit.

Few randomized controlled trials of the effects of neutral head positioning on the incidence of IVH and data are inconclusive (de Bijl-Marcus et al., 2017; Malusky & Donze, 2011; Romantsik, Calevo, & Bruschettini, 2017).

Pharmacologic therapies have been tried prophylactically to reduce the incidence of hemorrhage, to prevent more severe bleeding and/or neurologic damage, or both. Research findings have been inconsistent for most of these therapies (Inder et al., 2018b). For example, prophylactic indomethacin has been reported to reduce the risk of IVH in some, but not all, studies (Inder et al., 2018b).

Parent care involves recognition and discussion of parental concerns about their infant's immediate and long-term prognosis and teaching regarding IVH, as well as its implications and management. The parents need to be shown how to interact with and care for the infant at risk for IVH in a developmentally appropriate manner, with the goal of promoting opportunities for interaction while minimizing stressful events. The nurse can model this type of care for parents and provide anticipatory guidance in ways in which the infant's needs and care will change as the baby matures. Parents can also be involved in devising and implementing a developmental plan of care for their infant to reduce pain and environmental stressors.

Management of Progressive Ventricular Dilation. Because progressive posthemorrhagic ventricular dilation can develop, infants with a history of IVH are followed with serial cranial ultrasonography. Approximately 25% develop a slow, progressive ventricular dilation; 25% develop a nonprogressive dilation; 50% do not develop ventricular dilation (Inder et al., 2018b). Posthemorrhagic hydrocephalus develops after birth at varying times after the initial insult, usually in the first 4 to 8 weeks (Back & Miller, 2018). Head size can increase without increases in ICP (normopressive hydrocephalus) because of the neonate's soft, malleable skull and open sutures and fontanelle. A tense fontanelle may be noted when the infant is placed in an upright position when the fontanelle is typically soft. Progressive ventricular dilation initially may cause compression and damage to the cortex without causing any change in head size and may be apparent only on ultrasound. Signs of increased ICP (e.g., bulging anterior fontanelle, setting-sun sign, dilated scalp veins, and widely separated sutures) tend to be later findings. In most infants, the ventricular dilation occurs slowly, without increased ICP. Ventricular growth spontaneously arrests in approximately 65% (Inder et al., 2018b). The remaining infants continue to demonstrate ventricular dilation and increased ICP.

The initial treatment for normopressive hydrocephalus may be observation because in many infants, ventricular growth arrests spontaneously without therapy. Progressive ventricular dilation with increasing ICP is managed with a ventriculoperitoneal shunt or, if the infant is too ill or too small for surgery, with temporary ventricular drainage (Back & Miller, 2018). A ventriculoperitoneal shunt is the shunt of choice in infants and children because this type is easy to insert, revise, and uncoil as the infant grows. One

end of a radiopaque catheter is placed in the lateral ventricle, usually on the right side, and the other end is placed in the peritoneal cavity. The catheter contains a one-way valve that is palpable on the side of the head near the ear. The shunt may need multiple revisions during childhood for growth and for malfunctioning. Major complications of ventriculoperitoneal shunts are infection and obstruction. Too-rapid drainage of CSF immediately after insertion of the shunt can lead to herniation of the brain or subdural hematoma.

Quality and Safety: After surgery, the infant is positioned on the side opposite the shunt, with the head of the bed flat or slightly elevated (15–30°) to prevent rapid loss of CSF and decompression (Joseph, Killian, & Brady, 2017). The position can be rotated to supine every few hours to prevent skin breakdown. The skin should be kept clean and dry. Once the site has healed, infants may be placed on a donut on the affected side (Joseph et al., 2017). Pressure to the shunt valve should be applied only if ordered by the surgeons (Joseph et al., 2017). Infants with a shunt are observed for signs of localized or systemic infection, ileus, signs of peritonitis, and shunt obstruction. Obstruction of the shunt leads to accumulation of CSF, enlargement of the head, and signs of increased ICP. Infection of the shunt may appear as localized redness or drainage around the incision, temperature instability, altered activity, or poor feeding. Fluid status and intake and output are monitored, and the infant is observed for signs of dehydration from too-rapid loss of CSF. Signs of too-rapid decompression include a sunken fontanelle, agitation or restlessness, increased urine output, and electrolyte abnormalities (Joseph et al., 2017).

Parent teaching before discharge includes care of the infant and shunt, especially positioning and skin care. Parents must be comfortable in handling and caring for their infant before discharge. They should know the signs of shunt malfunction, increased ICP, infection, and dehydration. Continuing follow-up care of the infant and parental support are important. Parents may be referred to parent groups for peer support.

Outcomes. The severity and extent of the hemorrhage and the presence of associated problems (e.g., respiratory distress syndrome, perinatal hypoxic-ischemic injury, and sepsis) influence mortality and morbidity. Infants with a history of IVH are also at risk for developing posthemorrhagic ventricular dilation, which may be normopressive or associated with increased ICP. Infants with small or mild hemorrhages survive and generally have a good outcome, with a low incidence of major neurologic sequelae and posthemorrhagic ventricular dilation. However, these infants may have a higher risk of neurodevelopmental issues than infants without IVH (Back & Miller, 2018). Mortality and the risk of progressive ventricular dilation is increased in infants with moderate hemorrhages and still higher in infants with severe hemorrhages, especially infants <750 g birth weight (Inder et al., 2018b). Although infants with severe hemorrhages tend to have significant motor and cognitive deficits, some seem to escape significant long-term sequelae. The incidence of neurologic sequelae ranges from 15% to 25% in infants with moderate hemorrhage to 50% in infants with grade III hemorrhage and 75% in infants with PVHI (Inder et al., 2018b). Sequelae include cerebral palsy, developmental delay, sensory and attention problems, learning disorders, and hydrocephalus (Takenouchi & Perlman, 2012; Walsh et al., 2017).

White Matter Injury in Preterm Infants

WMI and its associated neuronal and axonal alterations is the most common severe neurologic insult seen in preterm infants (Kinney & Volpe, 2018a; Volpe et al., 2011). White matter hypoxic-ischemic injury involves both cystic and noncystic focal necrotic lesions as well as diffuse WMI with damage to the premyelinating oligodendrocytes, astrogliosis, and microglial infiltration (Back & Miller, 2018; Kinney & Volpe, 2018a). This injury is referred to as PVL. Leukomalacia refers to change in the brain's white matter reflective of softening. Focal cystic necrotic lesions are seen in less than 5% of infants at 24 to 32 weeks' gestation; the more common diffuse noncystic lesions associated with disturbances in myelination are seen on MRI in about one-third of infants at 24 to 32 weeks' gestation accounting for 25% of survivors (Miller & Back, 2017; Neil & Volpe, 2018). WMI often is associated with IVH, but it is a separate lesion that may also occur in the absence of IVH. IVH may contribute to the development of PVL via increased formation of free radicals (Inder et al., 2018b). PVL is a symmetric, nonhemorrhagic, usually bilateral lesion caused by ischemia from alterations in arterial circulation. Time of onset is variable; however, the time of peak vulnerability is prior to 32 weeks' gestation.

WMI is often accompanied by secondary alterations in the brain characterized by axonal and neuronal alteration that may include damage to the thalamus, basal ganglia, cerebral cortex, subplate neurons, and cerebellum, which together are referred to as the encephalopathy of prematurity (Back & Miller, 2018; Kinney & Volpe, 2018a; Neil & Volpe, 2018). Encephalopathy of prematurity is characterized by "multifaceted gray and white matter lesions in the preterm brain that reflect acquired and developmental factors in combination" (Kinney & Volpe, 2018a, p. 389). This results in decreased volume of the cerebral cortex, cerebral white matter, alterations in the basal ganglia and thalamus, and altered thalamic and gyral development (Kinney & Volpe, 2018a). Risk factors include any event during the prenatal, intrapartum, or postbirth periods that results in cerebral ischemia; this includes asphyxia, IVH, hypoxia, hypercarbia, hypotension, cardiac arrest, and infection (in which blood flow is diminished by the action of endotoxins; Miller & Back, 2017).

Pathophysiology. PVL begins with ischemic necrosis of the white matter dorsal and lateral to the external angles of the lateral ventricles, especially in the border zone area, but may extend into the cortical white matter. The border zone is the area farthest from the original source of the cerebral blood supply and thus is most susceptible to ischemic damage from diminished cerebral blood flow (Back & Volpe, 2018). Pathologic changes begin with patchy areas of focal ischemic coagulation that may occur as early as 5 to 8 hours after the initial hypoxic-ischemic insult. This is followed within a few days by proliferation of macrophages and astrocytes, along with endothelial and glial infiltration. Later changes include thinning of the white matter and liquefaction in the central portion of the necrotic area, as well as cavitation, cystic changes, and decreased myelination (Back & Volpe, 2018; Miller & Back, 2017).

The pathogenesis of WMI involves the interaction of three maturation-dependent factors: (a) immature vascular supply to the white matter that reduces oxygen delivery to vulnerable areas of the brain; (b) impairments in cerebral autoregulation, leading to pressure-passive cerebral circulation; and (c) vulnerabilities of the premyelinating oligodendrocytes to damage from reactive oxygen and nitrogen species (free radicals), glutamate, adenosine, and cytokines (Back & Miller, 2018; Volpe et al., 2011). Damage to the premyelin-producing oligodendrocytes leads to release of cytokines (indicating an inflammatory process), glutamate, and free radicals. Oligodendrocyte development and survival are impaired, leading to hypomyelination with subsequent motor, cognitive, and behavioral neurodevelopmental problems. Axonal damage and disruption also occur. Perinatal infection and an inflammatory response with release of proinflammatory cytokines are also thought

to play a prominent role in the pathogenesis of PVL, with potentially potentiating effects of hypoxia and inflammation (Back & Volpe, 2018; Volpe et al., 2011).

Assessment. WMI is multifactorial and arises from a compilation of prenatal or postnatal insults, or both. Risk factors include factors leading to hypoxia-ischemia (fetal metabolic acidosis, respiratory distress syndrome, cardiac insufficiency from a large patent ductus arteriosus, sepsis, and congenital heart disease) and hypotension and inflammation (intrauterine infection, necrotizing enterocolitis, and neonatal sepsis; Miller & Back, 2017; Neil & Volpe, 2018). Often, no clinical findings are specific to WMI or PVL during the first weeks of life unless the damage is severe. Cranial ultrasonography can identify infants at risk for, or who have, early signs of WMI, although ultrasound is not as sensitive in the diagnosis of PVL as it is with IVH. MRI can identify changes early and is especially useful with noncystic and diffuse WMI as well as neurodevelopmental prognosis (Kinney & Volpe, 2018a; Lodygensky et al., 2012; Neil & Volpe, 2018). Infants at risk for WMI should undergo serial cranial ultrasound examinations and again at discharge and with later follow-up. MRI may be of benefit for ongoing follow-up, especially for infants with severe damage with the increased association of neuromotor abnormalities and developing ventricular enlargement (Kinney & Volpe, 2018a; Lodygensky et al., 2012). As the infant matures, neurologic and motor deficits become apparent.

Management. Prevention strategies include prevention of preterm birth, use of antenatal glucocorticoids, prompt stabilization and resuscitation at birth to maintain adequate ventilation, perfusion, and oxygenation (Blackburn, 2016; Neil & Volpe, 2018). Initial management focuses on recognizing and treating the primary insult and its attendant complications and preventing further hypoxic-ischemic damage and inflammation (Blackburn, 2018; Gano, 2016). This involves preventing or minimizing hypotension, hypoxia, acidosis, and severe apneic and bradycardic episodes (Neil & Volpe, 2018). HUS and MRI are used serially to diagnose WMI/PVL and to follow its progression in infants at risk. Later management involves care related to residual problems, such as spastic diplegia and hydrocephalus. Nursing interventions focus on acute management of the primary problem and supportive care for the infant and parents. Nurses have a major role in identifying signs of hypoxia and ischemia and instituting interventions to prevent further ischemic damage. These interventions are similar to those described earlier and in Table 15.8. Environmental stressors may increase the risk for development of IVH and subsequent PVL or may cause associated developmental problems. Developmental and environmental interventions, therefore, are important aspects of nursing care.

Parents need initial and continuing support in dealing with their infant's illness and the risk of later neurologic problems. Parent teaching focuses on promoting an understanding of the infant's health status and care and providing anticipatory guidance and follow-up care. The parents should be shown how to interact with and care for their infant in a developmentally appropriate manner to foster parent–infant interaction and to promote infant organization and development. The nurse can model this type of care for the parents, collaborate with parents in identifying stressors and soothing strategies, and provide anticipatory guidance as the infant's needs and care change.

Outcomes. Infants with WMI usually survive. Those who die in the neonatal period usually do so from the original hypoxic, hemorrhagic, or infectious insult rather than from WMI/PVL per se. Infants with WMI are at higher risk for later developmental problems including cognitive deficits, language impairment, attentional dysfunction, cerebral visual impairment, and autism (Mwaniki, Atieno, Lawn, & Newton, 2012; Neil & Volpe, 2018). These infants are also at risk for spastic diplegia, especially those with multifocal cystic lesions around the lateral ventricles. In infants with spastic diplegia, descending fibers from the motor cortex cross the affected area around the ventricles. Because the leg motor fibers are closest to the ventricles, spastic diplegia of the leg is the most common sequela. With extension of the damage, arm involvement with spastic quadriplegia may occur. Infants with diffuse WMI are more likely to develop visual, cognitive, and neurobehavioral impairments (Takenouchi & Perlman, 2012).

Cerebellar Injury in Preterm Infants

The cerebellum is one of the later structures to mature, with critical developmental events occurring at the end of the second and beginning of the third trimester, accompanied by a rapid growth spurt from 24 weeks through the third trimester and birth (Blackburn, 2016; Limperopoulos, du Plessis, & Volpe, 2018). The cerebellum is important for the development of cognitive, learning, language, behavior, and motor function; it functions as a node in the distribution of neural networks with interconnections with the thalamus and parietal and prefrontal cortex, integrates sensory information, and is important in socialization skills (Blackburn, 2016; Brossard-Racine, du Plessis, & Limperopoulos, 2015; Fumagalli et al., 2015). Since the cerebellum undergoes rapid growth and complexity, and critical developmental processes during the time preterm infants are in the NICU, especially those who are very low birth weight, they are at risk for cerebellar injury (Blackburn, 2016; Brossard-Racine et al., 2015; Haines, Wang, & Pierson, 2013; Limperopoulos et al., 2018). These injuries may alter motor and language development and cognitive, socio-emotional, and behavioral function, and increase the risk of attentional and autism spectrum disorders (Blackburn, 2016; Brossard-Racine et al., 2015; Fumagalli et al., 2015; Limperopoulos, 2010; Limperopoulos et al., 2018).

Mechanisms proposed for the alterations seen in the cerebellum in very low birth weight infants include: (a) direct injury (usually due to cerebral hemorrhage) leading to atrophy and reduced growth of cerebellum; (b) indirect cerebellar injury or underdevelopment associated with cerebral injury; and (c) impaired cerebellar development, without evidence of direct or indirect injury, due to unknown causes (Blackburn, 2018). Cerebellar underdevelopment and hemorrhage are seen primarily in infants born at less than 28 weeks. These infants may have bilateral, usually symmetric, decrease in cerebellar volume. The exact etiology of cerebellar hemorrhage in preterm infants includes factors similar to that of GMH/IVH, including pressure-passive cerebral blood flow, increased venous pressure, fragility of the cerebellar germinal matrix blood vessels, and vasoocclusive injuries (Blackburn, 2018; Fumagalli et al., 2015; Limperopoulos et al., 2018). Cerebellar injury may occur concurrently with PVL or IVH.

BIRTH INJURIES

Traumatic injury to the central or peripheral nervous system can occur during the perinatal or postnatal period. Most of these injuries happen during the intrapartum period and may occur with perinatal hypoxic-ischemic events. Perinatal events most frequently associated with birth injury include midforceps delivery, shoulder dystocia, low forceps delivery, birth weight exceeding 3,500 g, and second stage of labor lasting longer than 60 minutes. The incidence of injury has declined markedly in recent years as a result of improvement in obstetrical care and increased use of cesarean

sections for abnormal presentations. However, birth injuries can also arise from trauma during a cesarean section or resuscitation. Injuries that occur before the intrapartum period usually are caused by compression or pressure injuries from an unusual fetal position. The risk of injury to the central or peripheral nervous system is greater with malpresentation (especially breech), prolonged or precipitate labor, prematurity, multiple gestation, shoulder dystocia, macrosomia, and instrumental delivery. The most prevalent types of injury to the nervous system are extracranial hemorrhage, intracranial hemorrhage, skull fractures, spinal cord injury, and peripheral nerve injury (Hoppe & Benedetti, 2018; Volpe, 2018a).

Extracranial Hemorrhage

Caput succedaneum and cephalohematoma are the most common types of birth injury, as well as the most benign. Caput succedaneum is characterized by soft, pitting, superficial edema that is several millimeters thick and overlies the presenting part in a vertex delivery. This edematous area lies above the periosteum and thus crosses suture lines. The edema consists of serum or blood, or both. Infants with caput succedaneum may also have ecchymosis, petechiae, or purpura over the presenting part. Caput succedaneum occurs in infants after a spontaneous vertex delivery or after the use of a vacuum extractor. This type of extracranial hemorrhage requires no care other than parent teaching regarding its cause and significance. It resolves within a few days after birth with no sequelae. Cephalohematoma occurs in 1.5% to 2.5% of newborns (Hoppe & Benedetti, 2018; Walker, 2018). It involves subperiosteal bleeding, usually over the parietal bone but possibly over other cranial bones. Cephalohematoma usually is unilateral but can be bilateral. This type of hemorrhage is seen most often in males, after the use of forceps, after a prolonged, difficult delivery, and in infants born to primiparas. The characteristic finding is a firm, fluctuant mass that does not cross the suture lines. The mass often enlarges slightly by 2 to 3 days of age. Approximately 5% of infants with unilateral and 18% with bilateral cephalohematomas have a linear skull fracture underlying the mass (Hoppe & Benedetti, 2018; Walker, 2018). In rare cases an infant may have a subdural or SAH.

Caput succedaneum and cephalohematoma over the occipital bone must be differentiated from encephalocele. In contrast to extracranial hemorrhage, an encephalocele is characterized by pulsations, increased pressure (tenseness) with crying, and the appearance of a bony defect on radiographic studies (Heaberlin, 2019; Volpe, 2018a). Infants with a cephalohematoma generally have no symptoms. Management includes parent teaching and monitoring for the development of hyperbilirubinemia (Watchko, 2009). Occasionally an infant with a large cephalohematoma becomes anemic. These infants should also be monitored for symptoms of intracranial hemorrhage or skull fracture. Generally, cephalohematomas resolve between 2 weeks and 6 months of age, and most resolve by 8 weeks. Calcium deposits occasionally develop, and the swelling may remain for the first year.

Subgaleal Hemorrhage. Subgaleal, or subaponeurotic, hemorrhage is the most serious form of extracranial hemorrhage in newborns (Hoppe & Benedetti, 2018; Schierholz & Walker, 2010; Volpe, 2018a; Walker, 2018). Subgaleal hemorrhage occurs in 4 per 10,000 spontaneous vaginal deliveries and 59 per 10,000 vacuum-assisted deliveries. The incidence is also increased with precipitous deliveries, macrosomia, and severe dystocia, and with failed vacuum deliveries requiring forceps. Use of soft silastic cups (rather than the rigid hard cup) with vacuum extractors is associated with fewer scalp injuries, although the soft cups are more likely to fail (Volpe, 2018a; Waller, Gopalani, & Benedetti, 2012). Mortality is 17% to 25%; however, if the infant survives the hemorrhage and does not develop HIE, the hemorrhage usually resolves in 2 to 3 weeks and outcomes are good (Hoppe & Benedetti, 2018; Inder & Volpe, 2018b; Volpe, 2018a; Walker, 2018).

Traction or application of intense shearing forces to the scalp pull the aponeurosis from the vault and rupture large emissary veins. Blood collects in a large potential space between the galea aponeurotica and the periosteum of the skull through which the large emissary veins pass (Schierholz & Walker, 2010; Volpe, 2018a). The area is called a potential space because it is not present until blood separates the galea aponeurotica from the periosteum of the skull. This space can quickly expand to accommodate 260 to 280 mL of blood. Total newborn blood volume is 80 to 100 mL/kg, so this volume may be more than the entire blood volume of some newborns (Schierholz & Walker, 2010; Volpe, 2018a).

Subgaleal hemorrhage is a clinical emergency. These infants usually present at birth or within a few hours after birth (Bonifacio et al., 2012; Hoppe & Benedetti, 2018; Schierholz & Walker, 2010; Volpe, 2018a). Clinical findings include a firm, ballotable head mass that crosses sutures and fontanelles (often extending from the orbital ridge, around the ears to the neck) and increases in size after birth. Each centimeter of enlargement is estimated to be equivalent to 40 mL of blood loss (Hoppe & Benedetti, 2018; Schierholz & Walker, 2010; Volpe, 2018a). The mass mimics edema and shifts with head repositioning. Infants usually show signs of pain on manipulation of the scalp or head. Infants may present with a rapidly falling Hct, anemia, hypovolemia, pallor, hypotension, tachycardia, tachypnea, hypotonia, and other signs of shock (Bonifacio et al., 2012; Hoppe & Benedetti, 2018; Schierholz & Walker, 2010; Volpe, 2018a). Management includes rapid recognition, cardiovascular and respiratory monitoring, administration of blood and volume expanders, and control of bleeding (Hoppe & Benedetti, 2018; Schierholz & Walker, 2010; Volpe, 2018a).

Other Types of Intracranial Hemorrhage

In addition to IVH, several other clinically important types of intracranial bleeding can occur in the neonate, including primary subarachnoid hemorrhage (SAH), subdural hemorrhage (SDH), and intracerebellar hemorrhage. These types of hemorrhage arise from trauma or hypoxia during the perinatal period.

Primary SAH. Primary SAH is the most prevalent form of intracranial hemorrhage in neonates and the least clinically significant for most infants. SAH occurs in both preterm and term infants but is more common in preterm infants. SAH may occur alone (primary SAH) or as a secondary event with other forms of intracranial hemorrhage. For example, with IVH, blood moves into the subarachnoid space via the fourth ventricle (Inder et al., 2018b; Levene & de Vries, 2009; Neil & Inder, 2018).

Pathophysiology. Primary SAH consists of bleeding into the subarachnoid space that is not secondary to subdural or intraventricular bleeding. In neonates, the source of the bleeding is venous blood; in older children and adults, SAH usually involves arterial blood. With primary SAH, blood leaks from the leptomeningeal plexus, bridging veins, or ruptured vessels in the subarachnoid space (Inder et al., 2018a; Levene & de Vries, 2009). This type of hemorrhage is associated with trauma or asphyxia. Trauma that causes increased intravascular pressure and capillary rupture is the underlying causal event in most term infants with SAH. In preterm infants, SAH usually is the result of asphyxial events. Factors that place an infant at risk for SAH include birth trauma, prolonged labor, difficult delivery, fetal distress, and perinatal hypoxic-ischemic events (Inder et al., 2018a; Levene & de Vries, 2009; Neil & Inder, 2018).

Assessment. Three clinical presentations have been described for infants with SAH (Inder et al., 2018a). The most common is a preterm infant with a minor SAH. These infants are asymptomatic. The hemorrhage is discovered accidentally, for example, during a lumbar puncture as part of a sepsis workup. With the second type of clinical presentation, term or preterm infants may show isolated seizure activity at 2 to 3 days of age, or preterm infants occasionally may present with apnea. Between seizures, the infant appears and acts healthy ("well baby with seizures"). Infants in both of these groups survive and usually do well developmentally. The third type of clinical presentation involves infants with a massive SAH that has a rapid and fatal course. This presentation is rare and often is associated with both a severe asphyxial event and birth trauma. Blood in the CSF on lumbar puncture indicates the possibility of SAH, but true hemorrhage must be distinguished from a bloody tap. MRI and CT also can help confirm the diagnosis; ultrasonography is unreliable with SAH (Inder et al., 2018a; Levene & de Vries, 2009).

Management. Management of these infants begins with efforts to prevent or reduce the risk of trauma and hypoxia during the perinatal period, so as to reduce the risk of development of SAH. Infants with SAH are observed for seizures and other neurologic signs during the early neonatal period. Nursing care is primarily supportive and includes maintenance of oxygenation and perfusion and provision of warmth, fluids, and nutrients. Nursing management also involves helping the parents to understand the basis for, and cause and prognosis of, SAH, as well as the care of their infant.

Outcomes. Generally, infants with SAH survive, and asymptomatic infants do well. Up to half of symptomatic infants with severe, sustained traumatic or hypoxic injury with further damage to the CNS have neurologic sequelae (Inder et al., 2018a; Levene & de Vries, 2009). Hydrocephalus occasionally develops in infants with a history of SAH as a result of obstruction of CSF flow by adhesions. These infants should undergo repeat ultrasonographic examinations to monitor ventricular dilation.

Subdural Hemorrhage. SDH is the least common of the hemorrhages seen in newborns; however, recognition of this hemorrhage is important as immediate intervention for large SDH can be lifesaving (Inder et al., 2018a). The incidence of SDH has declined markedly as a result of improvements in obstetrical care. This decrease has been particularly notable in term infants (Inder et al., 2018a; Levene & de Vries, 2009). Risk factors include precipitous, prolonged, or difficult delivery, use of midforceps or high forceps, prematurity, cephalopelvic disproportion, and macrosomia. SDH is seen more often in infants born to primiparas, possibly because of the more rigid birth canal. Infants with abnormal presentations (e.g., breech, foot, brow, or face) are also at higher risk for SDH (Inder et al., 2018a; Neil & Inder, 2018; Waller et al., 2012).

Pathophysiology. SDH in newborns is almost always caused by trauma during the perinatal period. Unilateral or bilateral bleeding occurs between the dura and the arachnoid. The bleeding occurs over the cerebral hemispheres or posterior fossa with or without lacerations of the tentorium or falx cerebri (see Figure 15.1). The cerebral hemispheres are the most common site for SDH. Bleeding usually occurs over the temporal convexity, with rupture of superficial cerebral veins or of "bridging" veins between the superomedial aspect of the cerebrum and the superior sagittal sinus. Because the superficial veins over the cerebrum are poorly developed in the preterm infant, this type of hemorrhage is seen less often in these infants. Bleeding over the posterior fossa involves bleeding below the tentorium and compression of the brainstem. Dural tears at the junction of the falx and tentorium near the attachment of the great vein of Galen are also associated with compression of the brainstem and midbrain (Inder et al., 2018a; Levene & de Vries, 2009; Neil & Inder, 2018).

Assessment. SDH must be distinguished from other types of intracranial hemorrhage and neurologic problems. This differentiation often can be accomplished by evaluating the infant's history and presentation and, if the infant is having seizure activity, by ruling out other causes of seizures. SDH over the cerebral hemispheres often is associated with SAH. SDH also occurs with extracranial hemorrhages, such as cephalohematoma and subgaleal, subconjunctival, and retinal hemorrhages; skull fractures; and brachial plexus or facial palsies. MRI or CT can assist in confirming the diagnosis; CT appears to be the imaging modality of choice (Inder et al., 2018a; Levene & de Vries, 2009; Neil & Inder, 2018).

Clinical signs of SDH relate to the site of the bleeding and the severity of the hemorrhage. Three patterns are seen in infants with bleeding over the cerebral hemispheres (Inder et al., 2018a). The first pattern is seen in most neonates with SDH; these infants have a minor hemorrhage and are asymptomatic or have signs such as irritability and hyperalertness. With the second pattern, primarily focal seizures develop during the first 2 to 3 days of life. Other neurologic signs that may be seen include hemiparesis; pupils that are unequal and respond sluggishly to light; full or tense fontanelle; bradycardia; and irregular respirations. The third pattern is seen in a few infants who have no or nonspecific signs in the neonatal period but in whom signs appear at 4 weeks to 6 months of age. These infants generally show increasing head size as a result of continued hematoma formation, poor feeding, failure to thrive, altered level of consciousness, and, occasionally, seizures caused by the chronic subdural effusion. Infants with abnormal neurologic signs from birth often have had bleeding over the posterior fossa with tentorial lacerations. Signs include stupor or coma, eye deviation, asymmetric pupil size, altered pupillary response to light, tachypnea, bradycardia, and opisthotonos. As the clot enlarges, these infants rapidly deteriorate, with signs of shock appearing over minutes to hours. The infant becomes comatose and has fixed, dilated pupils and altered respirations and heart rate, which culminate in respiratory arrest. Infants with small tears in the posterior fossa may have no clinical manifestations for the first 3 to 4 days of life. During this time, the clot gradually enlarges until signs of increased ICP appear. As the brainstem becomes compressed, the infant's condition deteriorates, and oculomotor abnormalities, altered respiration, bradycardia, and seizures occur (Inder et al., 2018a).

Management. Infants with a history of perinatal trauma or other risk factors are observed for seizures and other neurologic signs. Care is primarily supportive and includes maintenance of oxygenation and perfusion and provision of warmth, fluids, and nutrients. Nursing management also involves helping the parents to understand the basis for and the cause and prognosis of this type of hemorrhage, as well as the care of their infant.

Symptomatic infants with bleeding over the temporal convexity and increased ICP may require surgical evacuation if the infant's condition cannot be stabilized neurologically. Massive posterior fossa hemorrhage requires craniotomy and surgical aspiration of the clot (Inder et al., 2018a; Levene & de Vries, 2009). Infants at risk for SDH should be monitored carefully over the first 4 to 6 months after birth for late signs of bleeding and hematoma formation. Monitoring of these infants includes observation of head size, growth, feeding, activity, and level of consciousness, as well as monitoring for seizure activity.

Outcomes. The prognosis varies with the location and severity of the hemorrhage. Infants with bleeding over the cerebral hemispheres who are asymptomatic do well, as do most infants who have transient seizures in the neonatal period if no associated cerebral injury is present. Early diagnosis with CT or MRI has improved the outcome for infants with posterior fossa hemorrhage. Most infants with bleeding over the tentorium or falx cerebri die; severe hydrocephalus and neurologic sequelae usually develop in those who survive (Inder et al., 2018a).

Intracerebellar Hemorrhage. Intracerebellar hemorrhage is rare and is thought to be multifactorial with primary importance of birth trauma (breech or forceps delivery) and circulatory events. These hemorrhages occur in both term and preterm infants but are more common in preterm infants. Intracerebellar hemorrhage is seen during autopsy in infants with a history of perinatal hypoxic-ischemic events or severe respiratory distress syndrome (or both) and IVH (Bonifacio et al., 2011; Inder et al., 2018a).

Two presentations have been described. Many infants are critically ill from birth, with rapidly progressive apnea, a declining Hct value, and death within 24 to 36 hours. Other infants are less ill initially, and symptoms develop up to 2 to 3 weeks of age. Clinical manifestations include apnea, bradycardia, hoarse or high-pitched cry, eye deviations, opisthotonos, seizures, vomiting, hypotonia, and diminished or absent Moro reflex. Hydrocephalus often develops in these infants as early as the end of the first week after birth. The prognosis is poor in survivors, especially those born prematurely or with severe hemorrhage (Bonifacio et al., 2011; Inder et al., 2018a; Levene & de Vries, 2009).

Perinatal Stroke. Ischemic strokes are more common in the perinatal period than at any other time of life and are the leading cause of hemiplegic cerebral palsy, yet until recently have been poorly understood and oftentimes not diagnosed in the neonatal period. As a result, incidence is estimated to be from fairly rare (17–93 per 100,000 live births) to relatively common (1 in 1,600–5,000 live births; Benders, Groenendaal, & de Vries, 2009; Chabrier, Husson, Dinomais, Landrieu, & Nguyen, 2011; Cheong & Cowan, 2009; Inder & Volpe, 2018c; Kirton & deVeber, 2009; McAdams & Traudt, 2018; Mineyko & Kirton, 2011; Myers & Ment, 2012). Evidence suggests that preterm infants are just as likely, if not more likely, than term infants to experience perinatal ischemic stroke (Benders et al., 2009; Cheong & Cowan, 2009; Lynch, 2009; Myers & Ment, 2012). Stroke affects about 1 in 140 preterm births up to and including 34 weeks' gestation. Perinatal arterial ischemic strokes (AIS) account for 80% of diagnosed strokes in the neonatal period; the remaining 20% result from cerebral sinovenous thrombosis (CSVT; Inder & Volpe, 2018c).

Perinatal stroke was defined in 2006 by the National Institute of Child Health and Human Development and the National Institute of Neurological Disorders as the result of a focal disruption of cerebral blood flow secondary to an arterial or venous thrombosis or embolism occurring between 20 weeks' gestation and 28 postnatal day of life (Inder & Volpe, 2018c; Kirton & deVeber, 2009; McAdams & Traudt, 2018; Mineyko & Kirton, 2011; Myers & Ment, 2012). Perinatal strokes are further classified as fetal or neonatal. Fetal stroke is defined as having occurred between 20 weeks' gestation and the onset of labor or cesarean section and neonatal stroke as having occurred between the onset of labor and actual delivery. Presumed perinatal ischemic strokes are those identified by neuroimaging in infants greater than 28 days of life as having had a focal infarction at some point between 20 weeks' gestation and postnatal day 28 (Chabrier et al., 2011; Kirton & deVeber, 2009; Lynch, 2009; Myers & Ment, 2012).

Risk factors for perinatal stroke seem to be multifactorial and are still being identified to determine which factors are associated with a predilection for or direct causation of stroke. The risk factors that are being studied can be grouped into maternal, pregnancy/labor-related, and fetal or neonatal conditions (Inder & Volpe, 2018c; Lynch, 2009; McAdams & Traudt, 2018; Myers & Ment, 2012). Maternal risk factors include thrombophilias (factor V Leiden, factor VIII, protein S deficiency, protein C deficiency, prothrombin mutation, and antiphospholipid antibodies), preexisting conditions such as thyroid disease, diabetes mellitus, or gestational diabetes or history of infertility. Pregnancy/labor-related risk factors implicated in perinatal stroke include significant maternal trauma, primiparity, placental abnormalities, oligohydramnios, decreased fetal movement, prolonged rupture of membranes, chorioamnionitis, prolonged second stage of labor, or assisted delivery (vacuum or forceps). Fetal or neonatal risk factors include fetal distress during labor, cord abnormalities (tight nuchal or body cord, true cord knot), thrombophilias (same as maternal), congenital cardiac defects, and corrective surgery (Cheong & Cowan, 2009; Inder & Volpe, 2018c; Kirton & deVeber, 2009; Mineyko & Kirton, 2011; Myers & Ment, 2012). In addition, there may be a gender effect on incidence of stroke, with male gender being a risk factor over female gender (Chabrier et al., 2011; Cheong & Cowan, 2009; Kirton & deVeber, 2009; McAdams & Traudt, 2018; Myers & Ment, 2012).

Clinical signs and symptoms of perinatal stroke are determined by the timing of the initial insult. Seizures occur in 85% to 92% of affected newborns and are often the earliest manifestation of a perinatal stroke in an otherwise healthy appearing newborn. Most seizures happen within the first 72 hours of life; approximately 50% of seizures are focal motor, 33% generalized motor, and 17% subtle (Inder & Volpe, 2018c; Myers & Ment; 2012). Physical examination may reveal a bulging and/or pulsatile fontanelle, dilated head and neck veins, papilledema, asymmetrical movements or primitive reflexes, or seizure-like activity. Transient hemiparesis or generalized tone anomalies, such as hypotonia, are seen in the early newborn phase. Other symptoms of stroke are hypotonia and apnea, which are generic symptoms of any aberration in the newborn period, necessitating differential diagnosis from hypoxic, metabolic, and infectious disorders. Infants not diagnosed during the newborn stage are typically identified at a median of 6 months when asymmetry of reach and grasp is noted. Seizures occurring after 28 days of life and language delay have also been reported (Inder & Volpe, 2018c; Kirton & deVeber, 2009; McAdams & Traudt, 2018; Myers & Ment, 2012).

Diagnostic workup includes thorough history, newborn assessment, laboratory tests, and cardiac and neurologic imaging. Echocardiogram and electrocardiogram may be indicated to assess for cardiac dysfunction or rhythm disorders. EEG and neuroimaging are definitely indicated to evaluate for perinatal stroke (Inder & Volpe, 2018c; Kirton & deVeber, 2009; McAdams & Traudt, 2018; Mineyko & Kirton, 2011; Myers & Ment, 2012). During the past decade, rapid advances in the use of good quality early cranial ultrasonography and MRI with diffusion weighted sequences have facilitated improved and rapid diagnosis in the neonatal period, allowing for earlier identification and treatment and support of the affected newborn. Treatment of perinatal stroke is supportive and is directed at minimizing secondary brain injury and optimize outcome. Blood glucose, temperature, ventilation, oxygenation, and blood volume and pressure should be normalized. Hyperthermia and hyperthermic environment should be avoided. Seizures are documented and treated aggressively (Cheong & Cowan, 2009; Inder & Volpe, 2018c; Kirton & deVeber, 2009; McAdams & Traudt, 2018; Myers & Ment, 2012).

Outcome for infants with perinatal stroke varies with the area of the original insult. It is estimated that 20% to 70% of hemiplegic cerebral palsy cases are associated with perinatal stroke, with the spasticity more marked in the upper extremities. Intelligence is within normal parameters for two-thirds of affected infants (Myers & Ment, 2012).

Skull Fracture

Two types of skull fractures, linear and depressed, are uncommon but can be seen in newborns (Bonifacio et al., 2011; Hoppe & Benedetti, 2018; Volpe, 2018; White, Bouchard & Goldberg, 2018). Skull fractures occur in utero, during labor, with forceps delivery, or during a prolonged, difficult labor with compression and battering of the fetal skull against the maternal ischial spines, sacral promontory, or symphysis pubis (Bonifacio et al., 2011; Hoppe & Benedetti, 2018; White et al., 2018). The fetal skull often is able to tolerate mechanical stressors relatively well, because it is flexible, malleable, poorly ossified, and less mineralized than the adult skull. Depressed fractures occur after forceps delivery but occasionally are seen after a vaginal or cesarean birth. Compression of the skull causes buckling of the inner table without a break in the continuity of the skull. Linear fractures usually occur over the frontal or parietal bones. These fractures often are associated with extracranial hemorrhage and may underlie a cephalohematoma and are usually asymptomatic. Skull radiographs are required for the diagnosis (Hoppe & Benedetti, 2018; Tekes, Pinto, & Huisman, 2011; Volpe, 2018a; White et al., 2018). Intracranial hemorrhage rarely complicates linear fractures.

A depressed skull fracture is a visible, palpable depression, or dent in the skull, usually over the parietal area. These fractures often are described as resembling a ping-pong ball because the depression does not involve any loss of bone continuity. Unless underlying cerebral contusion or hemorrhage is present, no other signs or symptoms are seen (Bonifacio et al., 2011; Tekes et al., 2011). The diagnosis is confirmed with skull radiographs or CT scans. CT is performed to identify cerebral contusions or hemorrhage (Tekes et al., 2011; Volpe, 2018a; White et al., 2018).

Nursing assessment includes monitoring infants identified with skull fractures for signs of neurologic dysfunction, intracranial hemorrhage, meningitis, and seizures, although these findings are rare. Parents usually are concerned about their infant's appearance (with a depressed fracture) and the possibility of brain damage. They need support and teaching. Infants with uncomplicated linear fractures require no special management. Follow-up monitoring usually is recommended so that a growing fracture and development of a leptomeningeal cyst can be ruled out (Volpe, 2018a; White et al., 2018). Infants with basal fractures are treated for shock and hemorrhage.

In some infants with a depressed fracture, the fracture elevates spontaneously within the first week. Most clinicians recommend manually elevating an uncomplicated depressed fracture that does not elevate spontaneously within a few days (Tekes et al., 2011). After this time, manual elevation is more difficult or impossible. Surgical intervention usually is necessary if manual elevation fails, if the fracture is more severe and bone fragments are in the cerebrum, if neurologic deficits exist, or if ICP is increased.

Linear fractures heal spontaneously with no sequelae unless underlying cerebral damage or a growing fracture is present. Basal fractures are associated with high mortality and poor developmental outcome. Infants with depressed fractures that are small or treated early (or both) have a good prognosis. Infants with large fractures, especially if treatment is delayed, have a greater risk of sequelae. Unless a depressed fracture has lacerated the dura (a rare occurrence), neurologic deficits in these infants usually are caused by cerebral injury from the original trauma or a hypoxic event, or both, rather than by the fracture (Bonifacio et al., 2011; Hoppe & Benedetti, 2018; Volpe, 2018a). Infants with skull fractures should undergo regular evaluation of growth and development during infancy and early childhood.

Spinal Cord Injury

Spinal cord injuries are uncommon and usually occur in the midcervical to lower cervical and upper thoracic areas. Injury can occur at any point along the cord. Spinal cord injuries are caused by excessive traction, rotation, and torsion of the vertebral column and neck. Injury usually does not result from compression, but rather from stretching of the spinal cord, which is less flexible than the bony vertebral column. Damage to the spinal cord ranges from complete transection to laceration, edema, hemorrhage, and hematoma formation. Hemorrhage into the lining of the arteries may result in thrombosis, infarction, and ischemic cord damage. Risk factors are breech delivery (major factor), dystocia, macrosomia, and cephalopelvic disproportion (Bonifacio et al., 2012; Volpe, 2018a).

Infants with partial spinal cord injury have subtle neurologic signs and variable degrees of spasticity. Infants with high cervical or brainstem injuries are stillborn or die shortly after birth from respiratory depression, shock, and hypothermia. Infants with midcervical or upper cervical injury may be stillborn, born with marked respiratory depression, or have respiratory depression, with the neurologic injury going unrecognized until flaccidity, immobility of the legs, urine retention, or all three are noted. If born alive, these infants usually die within the first week, after development of progressive central respiratory depression that often is complicated by pneumonia. Other findings in this group of infants include relaxation of the abdominal wall, absent sensation in the lower half of the body, absent deep tendon and spontaneous reflexes, brachial plexus injury, and constipation. This group also includes infants with injuries at the C8 to T1 level who usually survive and may have a transient paraplegic paralysis at birth. Infants with mild injury may recover most or all of their function. Infants with moderate to severe damage are paraplegic or quadriplegic and have permanent neurologic damage (Bonifacio et al., 2011; Volpe, 2018a).

Initially, clinical manifestations are those of spinal cord shock, with hypotonia, weakness, flaccid extremities, sensory deficits, relaxed abdominal muscles, diaphragmatic breathing, Horner syndrome (ipsilateral ptosis, anhidrosis, and miosis), and a distended bladder. Infants with low cervical lesions have shallow, paradoxical respirations; these infants do not sweat. The skin over the affected area is dry and warm. Pinprick and deep tendon reflexes are absent. Areflexia may be noted over the upper and lower extremities in some infants. The degree of neurologic insult often cannot be accurately evaluated until the infant has recovered from the initial period of spinal shock and any edema or hemorrhage has been reabsorbed (Madsen, Frim, & Hansen, 2005; Volpe, 2018a). After several weeks or months, a paraplegic autonomic hyperreflexia develops that is characterized by periodic mass reflex response. This results in tonic spasms of extremities, spontaneous micturition, and profuse sweating over the paralyzed area (Volpe, 2018a).

Initial management focuses on stabilization, treatment of associated problems (e.g., asphyxia, hemorrhage, shock), and management of respiratory depression. Infants with midcervical to upper cervical or brainstem lesions require assisted ventilation. Parents are in shock initially and need time to grieve. They need continuing support and teaching regarding the care of the infant. Ongoing management of these infants and their families requires a multidisciplinary team that includes the disciplines of nursing, medicine, neurology,

neurosurgery, physical therapy, orthopedics, urology, social work, and psychology. Ultrasonography, CT, or MRI may be performed to determine the level and the extent of injury (Volpe, 2018a).

Skin integrity over the paralyzed area must be maintained to prevent pressure areas and skin breakdown. Thermoregulation may be a problem, because evaporative loss through the skin is reduced over the affected body parts in the initial period of the recovery process. The infant is positioned and repositioned regularly to promote normal alignment of body parts and prevent development of contractures and decubiti. The affected areas should be kept clean and dry and massaged with gentle, passive range-of-motion exercises. These infants need meticulous bowel and bladder care to prevent urinary tract infection and skin excoriation. Glycerin suppositories at regular intervals can help normalize bowel function. Infants are also monitored for signs of respiratory infection and pneumonia. Parental teaching before discharge focuses on normal baby care issues and concerns, as well as the special needs of a paralyzed infant.

The prognosis depends on the level and severity of the injury, but it generally is poor. Many infants with spinal cord injury are stillborn or die shortly after birth, particularly those with midcervical to high cervical or brainstem injuries. Those who survive have varying degrees of residual paralysis, respiratory problems, and bowel and bladder dysfunction, depending on the level of the injury. Most surviving infants have a spastic quadriplegia. Infants with involvement of the intercostal muscles and diaphragm often are ventilator dependent (Bonifacio et al., 2011; Volpe, 2018a).

Peripheral Nerve Injuries

Peripheral nerve injuries result from stretching, compression, twisting, hyperextension, or separation of nerve tissue (Bonifacio et al., 2012; Levene & de Vries, 2009; Volpe, 2018a). Injury can occur before, during, or after birth. Damage can range from swelling of the nerve to complete peripheral degeneration (with later total recovery) to complete division of all structures. The more common sites affected are the brachial plexus and the facial, phrenic, radial, median, and sciatic nerves. This type of injury is seen predominantly in term or LGA infants (Bonifacio et al., 2012; Volpe, 2018a).

Injury to the radial nerve usually results from compression of the nerve caused by fracture of the humerus during a breech delivery or by intrauterine compression of the arm. The infant has wrist drop with a normal grasp reflex. Recovery usually occurs over the first few weeks to months. Median and sciatic nerve injuries are typically postnatal iatrogenic events. Median nerve injury can be a complication of brachial or radial arterial punctures. These infants have diminished pincer grasp and thumb strength and a flexed fourth finger. Recovery is variable. Sciatic nerve injuries are often permanent. They arise from trauma from a misplaced intramuscular injection or from ischemia from an injection of hypertonic solutions into the gluteal muscle. Infants with this type of injury have diminished abduction and distal joint movement. Hip adduction, rotation, and flexion are unaffected (Levene & de Vries, 2009; Volpe, 2018a).

Facial Nerve Palsy. Facial nerve palsy has an incidence of 0.23% (Levene & de Vries, 2009). Injury to the peripheral nerve is caused by trauma from oblique application of forceps, prolonged pressure on the nerve during labor from the maternal sacral promontory, or pressure from an abnormal fetal posture. Although some investigators have not found any differences in incidence between forceps and spontaneous vaginal deliveries, others have noted a correlation between the type of forceps and the incidence of injury. The facial nerve of the newborn is superficial after it emerges from the stylomastoid foramen. As a result, the nerve is vulnerable to compression injury at this site or as it traverses the ramus of the mandible. The temporofacial and cervicofacial nerve branches are most often involved. The injury is most common on the left. Because the prognosis is favorable, the injury appears to be caused by hemorrhage or edema into the nerve sheath rather than by disruption of the nerve fibers (Levene & de Vries, 2009; Volpe, 2018a).

Facial nerve paralysis must be distinguished from asymmetric crying facies and nuclear agenesis. Asymmetric crying facies results from absence of the depressor muscle of the angle of the mouth. These infants close their eyes normally when crying, but the mouth does not move down and out. They suck without dribbling. This disorder generally is benign. Nuclear agenesis (Möbius syndrome) is a more significant disorder characterized by congenital paralysis of the facial muscles (Levene & de Vries, 2009; Terzis & Anesti, 2011; Volpe, 2018a).

Clinical manifestations vary, depending on whether the injury is to the central nerve, the peripheral nerve, or the peripheral nerve branch. The complete peripheral nerve injury results in a unilateral inability to close the eye or open the mouth. The lower lip on the affected side does not depress during crying, nor does the forehead wrinkle. The affected side appears full and smooth, with obliteration of the nasolabial fold. These infants dribble milk while feeding. The infant may be unable to close the eye on the affected side. Central injury usually results in a spastic paralysis of the lower portion of the face contralateral to the side of CNS injury without involvement of the eyes or forehead. Peripheral nerve branch injury results in varying degrees of paralysis of the forehead, eye, or lower face, depending on the branch involved. The paralysis is apparent at birth or within 1 to 2 days after birth.

Almost all infants recover completely. Improvement usually is apparent by 1 to 4 weeks, and complete recovery occurs after several months in most infants. Infants with severe nerve regeneration have a longer recovery period and may occasionally require later cosmetic surgery (Levene & de Vries, 2009; Terzis & Anesti, 2011).

Nursing management involves parent counseling and teaching and prevention of complications. The eye on the affected side is patched, and 1% methylcellulose eye drops are instilled every 3 to 4 hours to prevent corneal damage. Dribbling with sucking can be a transient problem. A neurosurgical consultation is recommended if no improvement is noted by 7 to 10 days or if further loss of function occurs. With partial degeneration, physical therapy, massage, or electrical stimulation may be used, although the efficacy of these therapies is controversial and not well documented. Electromyography, nerve excitability, or nerve conduction latency examinations may be performed to evaluate the extent of the damage (Terzis & Anesti, 2011).

Brachial Plexus Injury. Brachial plexus palsy involves injury of the C5 to T1 nerve roots and is seen almost exclusively in term infants. The incidence ranges from 0.5% to 2% (Volpe, 2018a). Injury to the brachial plexus results from excessive lateral flexion, rotation, or traction on the neck. The degree of injury varies, ranging from edema and hemorrhage of the nerve sheath to avulsion of the nerve root from the spinal cord. With mild-to-moderate injury the axons are shattered, but the nerve sheaths remain intact. This degree of intactness of the nerve sheaths promotes regeneration of the nerve by 3 to 4 months, with full recovery by 3 to 15 months in most infants (Alfonso, 2011; Doumouchtsis & Arulkumaran, 2009; Levene & de Vries, 2009; Volpe, 2018a). Severe injuries result in radicular rupture or intraspinal tearing of the nerve and division of the nerve into radicles. If radicular rupture occurs, the root loses contact with the spinal cord. These injuries do not recover spontaneously (Alfonso, 2011; Doumouchtsis & Arulkumaran, 2009; Levene & de Vries, 2009).

Brachial plexus injuries usually are unilateral and on the left side. Fracture of the clavicle may occur in conjunction with this type of injury. Brachial plexus injury can be seen in uncomplicated deliveries and after cesarean birth; however, this injury is usually associated with vaginal delivery of LGA infants, shoulder dystocia, breech

presentations, and prolonged labor or difficult delivery. Spontaneous injuries may occur from compression of the shoulder as it passes over the sacral prominence (Alfonso, 2011; Doumouchtsis & Arulkumaran, 2009; Levene & de Vries, 2009; Volpe, 2018a).

Clinical manifestations vary with the location and severity of the injury. Signs of injury usually are apparent from birth but may be delayed for several days to a few weeks in some infants. The major types of injury are Erb (Erb–Duchenne) palsy, an injury of the upper plexus involving C5 to C7, and Klumpke palsy or lower plexus injury at C5 to T1 (Levene & de Vries, 2009; Volpe, 2018a). With Erb palsy, the shoulder and upper arm are involved, and denervation of the deltoid, supraspinous, biceps, and brachioradialis muscles occurs. The arm lies passively at the infant's side, abducted and internally rotated, and the forearm is pronated. The wrist and fingers are flexed. This posture is referred to as the "waiter's tip" position. The Moro reflex is absent, and the biceps and radial reflexes are diminished or absent on the affected side; the grasp reflex is normal.

Klumpke palsy is seen primarily in breech infants whose arm has been hyperabducted and delivered with the head affecting the flexors of the wrist and hand. Cervical sympathetic fibers may also be affected; sweating and sensation are absent in the affected hand and arm. The infant holds the affected arm at the side of the thorax with the hand in a claw hand posture. The Moro and grasp reflexes are absent, and the triceps reflex is diminished or absent on the affected side; biceps and radial reflexes are present. If the T1 root is affected, the infant manifests Horner syndrome (Bonifacio et al., 2012; Levene & de Vries, 2009; Volpe, 2018a).

Erb–Klumpke (total) palsy is characterized by entire arm and hand involvement as a result of injury to the nerve roots of the brachial plexus from C5 to T1. Complete paralysis of the upper and lower arm and hand, flaccidity, and accompanying sensory, trophic, and circulatory changes are noted. Deep tendon and Moro reflexes are absent. If the C4 roots are also affected, an associated phrenic nerve (diaphragmatic) paralysis occurs. Involvement of the T1 root leads to Horner syndrome in about one-third of these infants (Levene & de Vries, 2009; Volpe, 2018a).

Initial management focuses on protecting the arm until localized edema and pain subside. MRI or CT is used to visualize the degree of injury. The affected arm should not be splinted or immobilized, as it has not proven beneficial to prevent contractures and further stretching of the plexus as had previously been thought. After edema subsides, at about 7 to 10 days, physical therapy gradually is instituted as the infant can tolerate it. Gentle passive range-of-motion exercises have been shown to minimize formation of contractures and to reduce permanent disability. These infants have continued physical therapy consisting of massage and exercise over the first months until total or partial recovery occurs (Volpe, 2018a). Infants with a brachial plexus injury should be evaluated for associated problems, including fractures and respiratory difficulty secondary to phrenic nerve paralysis. If improvement is not noted within the first few months, electromyography and nerve conduction studies are performed to determine the extent of the damage, to follow recovery, and to determine whether surgical intervention is needed (Volpe, 2018a). Infants with brachial plexus injuries often experience considerable pain during movement of the affected arm in the first few weeks after birth. Nursing management is directed at reducing passive and active movement of the arm and providing comfort measures to reduce pain. The paralyzed arm is supported in a position of relaxation. Parent teaching regarding positioning, prevention of contractures, and exercise is essential.

The prognosis depends on the level and severity of the injury. Approximately 65% to 95% of infants have full recovery with supportive care. Many infants recover by 3 to 4 months of age and more than 90% by 2 to 3 years. Erb palsy, the most common type of injury, has the best prognosis for full recovery. Infants with total paralysis are most likely to have residual paralysis. Residual functional deficits include alteration in abduction and external rotation of the shoulder; restricted movement of the elbow, forearm, and hand; and hand weakness. These functional impairments can lead to abnormal muscle development and arm growth (Levene & de Vries, 2009; Volpe, 2018a).

Phrenic Nerve Palsy. Phrenic nerve palsy is caused by injury of the cervical nerve roots at C3 to C5. The injury results from tearing of the nerve sheath, which is accompanied by edema and hemorrhage. Phrenic nerve palsy may occur as an isolated event or in association with brachial nerve palsy. Risk factors, especially breech delivery, are similar to those for brachial plexus injury. Paralysis of the diaphragm is a result of damage to the phrenic nerve. The injury usually is unilateral and on the right side. Because the diaphragm is paralyzed, infants with phrenic nerve injury have respiratory difficulty. This phenomenon must be differentiated from CNS, cardiac, and pulmonary problems (Gauda & Martin, 2018; Levene & de Vries, 2009; Volpe, 2018a).

Infants with mild-to-moderate phrenic nerve injury may have early respiratory difficulty, suggestive of hypoventilation that stabilizes or improves. The infant may have recurrent episodes of cyanosis and dyspnea. Respiratory efforts result in primarily thoracic movement with minimal or no abdominal excursions, opposite of the normal newborn breathing pattern. Infants with complete avulsion or bilateral injury have severe respiratory distress from birth, with tachypnea, apnea, and a weak cry (Gauda & Martin, 2018; Volpe, 2018a).

Management focuses on promoting ventilation and oxygenation. Infants are not enterally fed initially until respiratory status improves. Infants with severe distress require positive pressure ventilation or constant positive airway pressure for support until recovery occurs. Surgical plication of the diaphragm is performed if no improvement is noted or if the infant is still ventilator dependent at 4 to 6 weeks of age (Gauda & Martin, 2018; Volpe, 2018a).

The infant is positioned on the affected side. If the infant cannot be fed, adequate fluid and calories must be provided. Feeding is instituted gradually, most likely by gavage tube initially. When oral feeding is started, the infant is fed slowly and given ample opportunity for rest and monitoring of respiratory status. Because recovery takes several months, parents must be taught feeding, positioning, and comfort techniques. The developmental needs of infants requiring prolonged hospitalization must be met; sensory input and play activities appropriate to their maturity and health status must be provided. Most infants recover by 6 to 12 months of age. Other infants recover clinically but have residual abnormalities of diaphragmatic movement on radiography (Gauda & Martin, 2018; Volpe, 2018a).

SUMMARY

Infants with neurologic dysfunction present a significant challenge to the neonatal nurse. The nurse must respond to infants with life-threatening conditions, such as perinatal hypoxic-ischemic injury and intracranial hemorrhage; to those with transient problems, such as an isolated seizure; and to those with chronic problems, such as NTDs. Nurses must also deal with their own responses and those of the families of infants who may die during the neonatal or early infancy periods or whose short-term and long-term outcome may be altered by the extent of neurologic insult. To optimally care for these infants and their families, nurses must understand the basis for, and the implications of, specific types of neurologic dysfunction; they must recognize the clinical manifestations of these types of dysfunction; and they must respond appropriately in concert with other healthcare professionals.

The nursing care of infants who have or who are at risk for neurologic dysfunction involves assessment and monitoring of the infant's neurologic status and responses to the extrauterine environment, as well as of subtle signs that may indicate a change in status. Nursing management of the infant involves activities to address alteration in level of consciousness, potential for injury related to trauma or infection, impairment of skin integrity, alterations in comfort, impaired mobility, alterations in thermoregulation, alterations in nutrition and fluid and electrolyte status, and promotion of neurobehavioral organization and development. The nurse must also assess family coping, interactive processes, knowledge, and grieving to assist the family in coping with the birth of an ill infant and, for many families, with the uncertainty or certainty of long-term neurologic deficits in their infant.

CASE STUDY

■ **Identification of the Problem.** Term female infant vaginal delivery with vacuum assist; presented with apnea, no tone, requiring resuscitation intervention.

■ **Assessment: History and Physical Examination.** The term female infant was delivered vaginally to a 24-year-old G2 P1 woman following prolonged labor at term after an uncomplicated pregnancy. The vaginal delivery was assisted with a vacuum apparatus. Gestational age was term with a birth weight of 3.3 kg.

Upon delivery, the infant was limp, cyanotic/pale, and apneic. The infant was successfully resuscitated following the Neonatal Resuscitation Program (NRP) guidelines; required 2 minutes positive pressure ventilation by T-piece resuscitator to initiate effective ventilation when spontaneous respirations were noted; infant received 10 minutes of CPAP via the T-piece resuscitator; heart rate was greater than 100 beats/minute (bpm) by 1 minute of age. Pulse oximetry was initiated by 1 minute of age, reading 44% oxygen saturations initially and gradually improved to 85% by 5 minutes of life; room air was used throughout resuscitation.

She remained pale with thready pulses and poor peripheral perfusion at 10 minutes of life; spontaneous respiratory rate 40 to 60 seconds with easy respiratory effort without CPAP; pulse oximetry saturations 88% to 94%; heart rate 160 seconds. The infant was brought to the NICU for ongoing care.

Apgar scores were 4^{1}, 6^{5}, 8^{10}

■ Physical Examination on Admission to the NICU

GENERAL: pale with thready pulses, poor peripheral perfusion; heart rate 180 bpm. Respiratory rate 46, shallow; saturations 88% to 92% in room air

HEENT: increasingly boggy, enlarging scalp hematoma; eyes open, no blink; pupils reactive to light; positive red reflex and normal facies

RESP: lung fields bilaterally clear and equal to bases; gasping respiratory effort

CV: rate regular with no murmur noted. Poor peripheral perfusion, capillary blood refill time greater than 5 seconds, and thready pulses were noted

ABD: abdomen soft and nontender with no hepatosplenomegaly or masses palpable; three-vessel cord. The anus appeared patent

Genitourinary: normal female infant genitalia

NEURO: decreased responses, with eyes open and unblinking; extremities were well formed; muscle tone was markedly decreased

SKIN: pale with general cyanotic undertones, pronounced circumoral and acrocyanosis

EXTREMITIES: well formed; 10 digits per extremity; generalized cool and mottled. Umbilical arterial and venous catheters were placed, and 10 mL/kg normal saline was given for volume expansion; dopamine was initiated because of low blood pressure and ongoing poor perfusion. Labs were drawn via the umbilical arterial catheter: arterial blood gas, complete blood count (CBC)/differential, and disseminated intravascular coagulation (DIC) panel, transfusion panel (type and cross for transfusion). The scalp hematoma was noted to be rapidly enlarging during this time. The infant was immediately intubated and was given an emergency blood transfusion of 15 mL/kg.

■ Differential Diagnoses

- Subgaleal hemorrhage
- Perinatal hypoxic-ischemic injury
- Shock
- DIC
- Intracranial hemorrhage
- Sepsis screen
- Congenital cardiac defects screen

■ Diagnostic Tests

Laboratory Tests:

- CBC/differential: WBC 10.3, segmented cells 44; bands 1; Hct 21%, platelet count 168,000/mm^3
- Coagulation (DIC) panel: prothrombin time (PT) greater than 100 seconds, partial thromboplastin time (PTT) greater than 100 seconds, fibrinogen 54 mg/dL, and D-dimers 2 to 4 mg/mL
- Blood, tracheal, and surface cultures for bacterial and/or viral infections: all negative

Imaging Tests:

- Head CT scan (performed within 4 hours of age): extensive blood within the extracranial soft tissues, mild IVH and SAH
- Transcranial Doppler and nuclear medicine flow scan (performed at 24 hours of age): no cerebral blood flow
- EEG (performed on day of life 3): absence of cortical activity

■ Working Diagnosis

Extensive subgaleal hemorrhage with hematoma

Based on clinical, laboratory, and imaging findings, data from history and physical assessment

■ Development of Management Plan

Continuous monitoring of arterial blood pressure, vital signs, and neurologic status, every 2 to 4 hours Hct, platelet count, PT/PTT, and fibrinogen

Maintenance fluid support; fluid boluses to support intravascular volume

Ensure adequate blood volume, clotting factors: colloids (fresh frozen plasma with cryoprecipitate, whole blood, packed red blood cells, platelets) as needed to treat DIC, anemia

Respiratory support with mechanical ventilation as needed

Vasopressors to maintain adequate blood pressure and cerebral blood flow

Antibiotics until cultures negative for 72 hours

■ Implementation and Evaluation of Effectiveness

Implementation of management plan: (immediately after initial assessment in the NICU)

The infant was intubated within the first half hour of life

Multiple blood transfusions, fresh frozen plasma with cryoprecipitate, whole blood and packed red blood cell transfusions, and normal saline boluses given to normalize the coagulation studies by 24 hours of age, with a total of 476 mL neonatal red blood cells, 8 U of cryoprecipitate, and 140 mL of fresh frozen plasma

Dopamine 10 mcg/kg/minute initiated by 1 hour of life; weaned to 5 mcg/kg/minute by 36 hours

■ Effectiveness of Management Plan

Respiratory status stable by 2 hours of life

Blood pressures were normalized by 2 hours of life

Metabolic acidosis and coagulation panel results were normalized within the first 24 hours of life

Severe brain involvement was suspected on day of life 2, with dismal results of the Doppler and flow scan and flat EEG results

■ **Outcome.** Brain death was determined on day of life 3. Life support was terminated on day of life 4. The autopsy was remarkable for an extensive subgaleal hematoma and moderate SAH and SDH.

CASE STUDY

■ **Identification of the Problem.** A 6-day-old former term infant turned blue at home on day of life 4 and was admitted to the local hospital.

■ **Assessment: History and Physical Examination.** A 6-day-old former term neonate was delivered vaginally following an uncomplicated pregnancy with a birth weight of 2,990 g. Prenatal laboratory results were remarkable for positive group B streptococcus (GBS) vaginal culture, for which the mother received prophylactic perinatal antibiotics. The infant did well after delivery, breastfed vigorously, and was discharged home with his mother on day 2 of life. At the time of admission, his weight was 2,950 g, occipitofrontal circumference was 33 cm, and length was 49.5 cm.

After initial admission to the local hospital, the infant was screened for sepsis (normal CBC and differential, negative cultures for viral and bacterial sepsis). On day 2, at the local hospital, the infant had a seizure consisting of lip smacking, apnea, cyanosis, and bicycling of lower extremities; was given 10 mg/kg phenobarbital; and was taken to CT, which showed a right IVH. The infant was transferred to the NICU of the tertiary care hospital.

■ Physical Examination

GENERAL: vital signs within normal limits; somewhat sleepy and irritable with handling

HEENT: anterior fontanelle large and soft, with sutures split to just above eyebrows, lateral sutures proximate. Pupils equal and reactive to light; bilateral positive red reflex; sunset eyes when crying; nares patent bilaterally; palate and clavicles intact

LUNGS: clear and bilaterally equal; easy work of breathing with spontaneous respirations

CV: heart regular rhythm and rate, no murmur; peripheral pulses 2+ in all extremities, good peripheral perfusion; capillary blood refill time ~3 seconds

ABD: abdomen was soft and nontender; liver right costal margin; no hepatosplenomegaly or masses palpable; umbilical stump dry

GU: normal male genitalia; testes bilaterally descended; well-developed scrotum

NEURO: arched with handling, moved all extremities with increased tone; occasional tongue thrust; positive sunset eyes, positive gag reflex, positive blink response; no clonus

EXTREMITIES: well formed with good muscle mass, 10 digits/extremity

SKIN: pale pink; good turgor and healing areas from previous lab draws and intravenous access attempts. No petechiae or rashes were noted

SOCIAL: maternal history is significant, for a cousin died of "fits" at 3 months of age; other relatives suffered frequent bone fractures or sundown eye sign; father is reportedly short-statured with short-statured children

■ Differential Diagnoses

- Seizures of unknown etiology
- Rule out herpes simplex infection and other viral or bacterial meningitis
- Rule out brain structure abnormalities
- Rule out nonaccidental trauma (NAT)
- Rule out intracranial and intraventricular hemorrhage
- Hypoventilation of unknown etiology

■ Diagnostic Tests

Laboratory Tests:

- CBC/differential: WBC 10.6, segmented cells 27, bands 0, Hct 60.2%, platelet count 254,000/mm^3
- Electrolytes: sodium 132, potassium 4.7, chloride 96, bicarbonate 29, calcium 11.9, ionized calcium 1.42, phosphorus 2.9, alkaline phosphorus less than 5, ammonia 45, lactate 2.2, BUN less than 1, and serum glutamic-oxaloacetic transaminase 33
- Blood and central spinal fluid bacterial and viral cultures: negative
- Urine drug screen: negative

Imaging Tests:

- Serial EEGs: excessive background discontinuity and prominent high-amplitude spikes and polyspikes, but no seizures; repeat EEG (hospital day 7) significantly improved but still mildly abnormal due to focal moderate amplitude, midline vertex, and negative spikes without seizure activity
- MRI of the brain: hemorrhage located either in subependymal location or cavum velum interpositum not consistent with shear injury
- Head CT: placement of the hemorrhage in the right thalamic area with extension into the lateral ventricles and stable ventricle size

Consults: (pediatric specialists)

- NAT team: ophthalmic examination: normal without ocular hemorrhages; skeletal radiographic study no fractures; evidence of metaphyseal fraying in the lower extremities consistent with developing rickets

Neurology, metabolic, and endocrine services

■ Working Diagnosis

Six-day-old infant with seizures due to probable hypophosphatemia

Laboratory results effectively ruled out sepsis, meningitis, electrolyte imbalances, and metabolic disease as etiologies for seizure activity

The extremely low-alkaline phosphorus, low phosphorus, and high calcium and ionized calcium levels were indicators for endocrine disease

EEG was moderately abnormal due to excessive background discontinuity and prominent high-amplitude spikes and polyspikes, but no seizures and improved by hospital day 7

Imaging results ruled out NAT and other structural causes for the clinical presentation of seizure-like activity

Skeletal radiographic study gave further support for endocrine disease due to the early radiographic indication for rickets

NAT team concluded that the seizures were not caused by brain injury due to NAT

Neurology service concluded that the etiology of the seizures was not structural or related to brain injury but most likely due to pyridoxine deficiency or some endocrine or metabolic syndrome

Endocrinologists considered the seizures to be related to hypophosphatasia

■ Development of Management Plan

Monitor the infant

Provide respiratory, fluid, and nutritional support with a low-calcium formula

Initiate vitamin D supplements to delay bone decalcification and rickets

Provide teaching and support for the parents

Arrange follow-up with the primary care provider and the pediatric neurology, orthopedic, and endocrinology services

■ Implementation and Evaluation of Effectiveness. During the examination phase, pyridoxine was given for a seizure-like event on hospital day 2 that included bicycling, sneezing, and clonic–tonic movements with paroxysmal respiratory pattern. Maintenance pyridoxine was given until hospital day 10, when it was determined the seizures were caused by hypophosphatemia. The infant was NPO with peripheral intravenous fluids until a special low-calcium formula could be delivered, and vitamin D supplements were started to delay bone decalcification and rickets. At the time of discharge, the infant was taking good amounts of the formula by nipple and gaining weight slowly. His mother was learning what little there is to know about this rare congenital disease and learning to prevent fractures as much as possible. Follow-up care was arranged with the primary pediatrician, neurology, orthopedics, and endocrinology.

■ Outcome. The prognosis for symptomatic congenital hypophosphatasia is poor, with death usually occurring within the first year of life. Parents initially denied being told about the infant's condition at first follow-up visit with the primary pediatrician; however, the parent was feeding the infant the correct formula and following all discharge instructions.

CASE STUDY

■ Identification of the Problem. A term infant male was limp and not breathing after home-birth delivery.

■ Assessment: History and Physical Examination. The infant boy was born at 40 6/7 weeks by vaginal delivery to a 24-year-old, G1 P0 > 1 woman at home with a certified nurse midwife present. Prenatal laboratory results and history were unremarkable with negative GBS status. The pregnancy was uncomplicated. Membranes were spontaneously ruptured with clear fluid approximately 11 hours prior to delivery, and no maternal fever was documented; the mother received antibiotics about 4 hours prior to delivery. Active pushing in second stage was 4 hours, followed by shoulder dystocia after the infant's head was delivered. The infant was limp and apneic after delivery. The certified nurse midwife performed mask-delivered positive pressure ventilation with room air with improvement in respiratory effort. Apgar scores were 1^{1}, 2^{5}, 4^{10}, 5^{15} per the nurse midwife report.

The infant was emergently brought to the NICU.

Admission weight: 3,765 g, head circumference: 37 cm, and length: 54 cm.

HEENT: anterior fontanelle was soft, flat, sutures opposed, proximate with a right cephalohematoma; eyes equal and reactive to light with a positive red reflex; nares bilaterally patent; palate and clavicles intact

RESP: breath sounds coarse bilaterally, slightly decreased over the lower right lung field. Increased work of breathing with increased subcostal and substernal retractions, slight tracheal tug, and flared nares

CV: mildly tachycardic, no murmur; peripheral pulses 1+ in all extremities; poor peripheral perfusion and capillary blood refill time of greater than 4 seconds. Low-borderline cuff blood pressure

ABD: abdomen soft and nontender; no hepatosplenomegaly or masses palpable; three-vessel cord

NEURO: responsive and alert on admission

EXTREMITIES: well formed; slightly decreased muscle tone

SKIN: pale pink and slightly mottled, with acrocyanosis and circumoral cyanosis

■ Development of Management Plan

- Nasal CPAP to support respiratory effort
- Peripheral intravenous fluids at 80 mL/kg/day maintenance
- Fluid bolus 10 mg/kg normal saline as needed
- Place umbilical arterial and venous catheters
- Chest radiograph confirmed right pneumothorax
- Needle aspiration was performed for small amount of air
- Chest radiographs as needed
- Monitor for abnormal activity showed pneumothorax resolved. Infant initially improved but on day 2 of life developed apnea, tonguing, lip smacking, and rhythmic extremity movement.

■ Differential Diagnoses

The differential diagnoses for an infant following a difficult delivery with positive pressure ventilation include:

- Respiratory distress versus transient tachypnea of the newborn
- Rule out pneumothorax
- Rule out hypoxic-ischemic encephalopathy
- Rule out intracranial hemorrhage
- Sepsis screen
- Shock
- Rule out seizures

- Congenital cardiac defects
- Metabolic and/or endocrine defects

■ Diagnostic Tests

Laboratory Tests:

- CBC with differential: WBC 11.7, segmented cells 33, bands 2; Hct: 56; platelets: 156,000/mm^3
- Blood cultures for bacterial and viral growth: negative
- Electrolytes, lactic acid, and ammonia levels, amino acid assays and urine organic acids, and liver function tests: normal

Imaging Tests:

- Chest radiography: small right pneumothorax
- Head CT: (24 hours of life) no evidence of hydrocephalus, ischemia, or intracranial hemorrhage
- Serial EEGs: (48 hours of life) moderate to severely abnormal EEG due to discontinuous low-amplitude background with asynchrony and frequent, subclinical, electrographic seizures from midline vertex and left central region. Second EEG: (72 hours) improvement from initial EEG with no electrographic seizures. There were positive sharp transient waves that were of concern for underlying structural abnormalities and can be consistent with anoxic and hypoxic events as reflected with clinical presentation. Third EEG: (5 days) abnormal due to predominantly right temporal sharp waves and possibly two brief electrographic seizures.
- MRI: (11 days) abnormalities on T2 and diffusion weighted imaging (DWI) consistent with perinatal HIE

Consult:

- Pediatric neurology: seizures due to HIE

■ Working Diagnoses

- Seizures due to HIE
- Respiratory distress
- Pneumothorax

■ Development of Management Plan

The management plan included:

- Monitoring
- Respiratory support with mechanical ventilation as needed
- Fluid support; initiate feeds
- Sepsis screen
- Antibiotics
- Needle aspiration of small right pneumothorax
- Chest tube insertion if indicated
- Lactic acid and ammonia levels, amino acid assays, and urine organic acids
- Expedite state newborn screen testing

■ Implementation and Evaluation of Effectiveness

Implementation of management plan: (immediately after initial assessment in the NICU)

- Antibiotics were given for 48 hours for the sepsis screen
- Right pneumothorax was reduced with needle aspiration and resolved without further intervention
- Seizure activity noted on day of life 2, confirmed with EEG, given phenobarbital 15 mg/kg, with resolution of the seizure
- Subsequently intubated at approximately 36 hours of life for a prolonged apnea event requiring positive pressure ventilation, given another 15 mg/kg phenobarbital loading dose and initial lorazepam (Ativan) dose to control seizures
- Metabolic etiology was ruled out with normal lactic acid and ammonia levels and normal amino acid assays and urine organic acids results
- State metabolic screening results were normal
- Neurologic examination deteriorated over the first 4 days, with the infant presenting with no gag, no corneal reflex, passive hypertonicity, active hypotonia, consistent and rhythmic hyperventilation, and periodic apnea, clonic–tonic movements of predominantly the left extremities by the end of day 3 of life, and persisting through day 5 of life
- Maintenance phenobarbital was initiated on day 3 of life, and lorazepam was given periodically for seizure activity during days 4 to 5 of life. Seizures were no longer observed after day 5 of life; infant gradually improved clinically with improved passive and active tone, improved gag and positive corneal reflex
- Extubated on day 6 of life to high-flow nasal cannula of 2 L/minute flow of room air; weaned quickly to room air without nasal cannula flow
- Feeds of expressed mother's milk had been initiated per gavage tube on day 3 of life; infant was tolerating full volume by day 7 by gavage every 3 hours. Breastfeeding and nipple feeds were initiated on day 8, but infant needed most of his feeds by gavage at time of discharge on day 18. Follow-up care was arranged for neurology clinic and EEG 1 month after discharge.

■ **Outcome.** Infant was discharged with phenobarbital and gavage feeds; was breastfeeding well, gaining weight, and thriving at the neurology follow-up appointment at 1 month of life.

EVIDENCE-BASED PRACTICE BOX

HIE is the major cause of encephalopathy in newborns. HIE is an injury to the brain caused by oxygen deficit resulting from either systemic hypoxemia or ischemia or a combination of the two conditions. The hypoxemia and ischemia may occur simultaneously or sequentially, and it appears from recent evidence that ischemia is the more important of the two oxygen deprivation states in causing the brain injury. Subsequent reperfusion of the affected brain area has been shown to be the time at which the majority of the injury to the brain occurs. Glucose deprivation also plays a part in the severity of the brain injury.

(*continued*)

EVIDENCE-BASED PRACTICE BOX (*continued*)

HIE causes transient organ dysfunction in 4 to 6 in 1,000 live births and results in death or significant neurologic deficits in 1 per 1,000 live births. Traditionally, the newborns affected by HIE have been treated by symptoms of the resultant multiorgan and multisystem effects. A recent development in proactive treatment with the use of controlled hypothermia has proven to be effective for newborns with moderate-to-severe HIE (Back & Volpe, 2018).

Induced mild hypothermia is increasingly the treatment of choice for infants greater than or equal to 36 weeks' gestation with moderate-to-severe HIE in addition to establishing ventilation and adequate perfusion and preventing or minimizing hypotension, hypoxia, and acidosis, rapid alterations in cerebral blood flow and systemic blood pressure, and severe apneic and bradycardic episodes in providing supportive care. Mild hypothermia is induced using either selective head cooling or whole-body cooling. A systematic review and meta-analysis of seven randomized controlled trials including 1,214 newborns done by Tagin, Woolcott, Vincer, Whyte, and Stinson (2012), provided evidence that hypothermia with either total body cooling or selective head cooling improves survival and protects neurodevelopment in newborns with moderate-to-severe HIE. Simbruner, Mittal, Rohlmann, Muche, and neo.nEURO.network Trial Participants (2010) reported that in their randomized controlled trial involving 129 newborns, of which 111 participated in neurodevelopmental follow-up at 18 months, hypothermia treatment provided strong neuroprotective effect for infants with severe HIE. A multicenter international randomized controlled trial done by Jacobs et al. (2011) provides supporting evidence that whole-body hypothermia reduced the risk of death or major disability at 2 years of age.

Selective hypothermia, if begun within 6 hours of life and carefully controlled within a tertiary level NICU environment for 72 hours while providing multisystemic and multiorgan support, appears to reduce mortality and improve morbidity for newborns with moderate-to-severe HIE.

PARENT VOICES

Heather McKinnis

When Owen was born at 25 weeks, he was so tiny but so perfect in our eyes. Each ultrasound that first week of his life showed worsening degrees of brain bleeds. When the day 7 scan showed that the bleeding had spread beyond his ventricles and into his brain tissue, we were devastated. By that time, I had read so much about IVH and my one consolation was that his weren't grade IV. I knew what that ultrasound may mean for my child. Bilateral grade IV IVH is the worst bleeds he could have. Our doctors sat us down and went through every single limitation and challenge he may face. They explained the risks over the next weeks and then his delays as he grows. Not once, during those conversations, did one person give us hope. I understand the need for realistic and statistically based information, but as an overwhelmed and terrified first-time mom, I needed someone to give me a glimmer of hope for my baby. That one person was our nurse Barb. After a couple of weeks of stable head ultrasounds and encouraging development from Owen, she encouraged me to just stop anxiously waiting for the bad and to enjoy the good. She told me to watch my baby. He responded to my voice, calmed at my touch, and moved both sides of his body. She reminded me how incredible the brain is and the amazing things she's seen in her time in the NICU. She did not tell me he was going to be OK. She did not give false hope or negative statistics. She held my hand, hugged me when I cried, and helped me find hope in a bleak situation. Owen is now 8 years old. He's healthy, happy, and thriving with his peers. I tell him about Barb often and how she was the first person to see his incredible potential.

CHAPTER 16

Auditory System

Kathleen Haubrich

INTRODUCTION

Hearing is a fundamental prerequisite to cognitive, social, and emotional development. Any impairment, either temporary or permanent, from birth to 18 months of age can have a profound effect on the auditory stimulation necessary for early language development (Kennedy et al., 2006). Auditory development, in particular, development of speech, depends on an exposure to a rich acoustic and linguistic environment. Hearing newborns recognize their mothers' voices as they are accustomed to hearing them in utero. Sensory deprivation affects the acquisition of communication skills, even though the hearing loss may be corrected. To prevent or minimize the detrimental effects on social, cognitive, and educational development, hearing impairment must be identified as early as possible (Yoshinaga-Itano, Johnson, Carpenter, & Brown, 2008). A study of childhood language development and academic achievement reported that hearing impairment has a significant impact on the development of a child as evidenced by limited speech. Korver et al. (2010) looked at another aspect of childhood development, namely, receptive and expressive language skills, and found that children with a hearing impairment demonstrated a significant delay in the development of these skills and slower academic achievement.

Approximately 1 to 6 per 1,000 newborns in the United States demonstrate hearing loss (American Speech-Language-Hearing Association [ASHA], 2018b). Risk factors include prematurity and a neonatal intensive care unit stay, among others.

EARLY SCREENING FOR HEARING LOSS

Historically, screening for hearing loss in infants and very young children was limited to observations of behavioral responses to sound such as the ringing of a bell outside of the view of a child. This method was fraught with difficulty and delay in early identification of hearing loss. During the past three decades, great strides have been made toward universal newborn hearing screening (UNHS) through early identification, development of reliable screening programs, consideration of adverse side effects, evaluation of availability and effectiveness, and evaluation of long-term outcomes for earlier diagnosis and interventions (Lim, Kim, & Chung, 2012; Patel & Feldman, 2011; Vohr, 2018). Since the initial Joint Committee Position Statement on Infant Hearing (Joint Committe on Infant Hearing, 1995) through subsequent revisions (Joint Committe on Infant Hearing, 2007; Task Force on Newborn and Infant Hearing, 1999), the American Academy of Pediatrics (AAP) and the U.S. Preventive Services Task Force (USPSTF; Nelson, Bougatsos, & Nygren, 2008), having based recommendations on available evidence, supported the practice of UNHS. UNHS has been widely accepted throughout developed regions of the world with research reports of screening modalities and program evaluation reported through scientific publications (De Capua et al., 2007; Korver et al., 2010; Langagne, Schmidt, Leveque, & Chays, 2008; Ohl, Dornier, Czajka, Chobaut, & Tavernier, 2009; van Dommelen et al., 2010; Verhaert, Willems, Van Kerschaver, & Desloovere, 2008).

ANATOMY OF THE EAR

The ear is the anatomic unit involved in hearing and equilibrium. It consists of three parts: the external ear, the middle ear, and the inner ear. The external ear is composed of the auricle (pinna) and the external ear canal (Figure 16.1). A complex cartilage framework gives structure to the auricle. Because of this anatomic position, the auricle is susceptible to trauma from external forces. The external ear canal is curved posterosuperiorly and anteromedially. The canal is oval in shape, and the long axis is positioned superoinferiorly. Normally, the outer portion of the canal is cartilaginous, and the medial

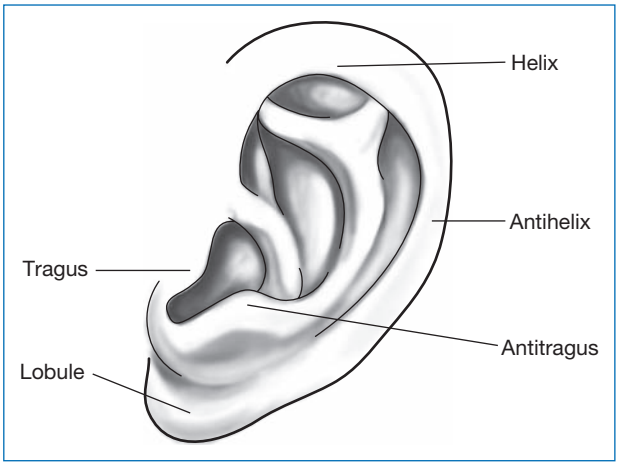

FIGURE 16.1 Anatomy of the external ear.

portion is bony. Before 34 weeks' gestation, the pinna is a slightly formed, cartilage-free double thickness of skin. In the newborn, however, most of the canal is cartilaginous and collapsed (Moore & Linthicum, 2007). However, as ear development ensues, the cartilage becomes firmer, making the outer two-thirds of the canal more patent (Figure 16.2). Cerumen glands and tiny hairs are present in the outer portion of the cartilaginous canal. The medial two-thirds of the canal lie immediately over a bony area and are referred to as the osseous region. The external auditory meatus assumes an irregular path from the concha to the tympanic membrane.

At the termination of the external canal is the eardrum, or tympanic membrane, which forms the boundary between the outer and the middle ear (Figure 16.3). The tympanic membrane has a complicated shape that loosely resembles a flat cone, and moves with changes in air pressure. Because the tympanic membrane is oval and translucent, the middle ear structure often can be visualized through it. The short and long processes of the malleus are attached to the fibrous layer of the tympanic membrane and are visible on the lateral surface. In the middle ear, the malleus, incus, and stapes occupy the region between the tympanic membrane and the oval window of the middle ear. During otoscopic examination, the long process of the incus often can be seen through the tympanic membrane. The middle ear cavity is an air-filled space connected by an air cell system posterior to the mastoid and by the eustachian tube anterior to the nasopharynx. Neither of these is in a dependent position for drainage of fluids. Ciliated columnar cells cover the walls of the tympanic cavity and mastoid air cells. Secretory cells are distributed throughout the middle ear, with the greatest number in the eustachian tube. The stapedius and the tensor muscles of the tympanic membrane attach in the middle ear to the malleus and the stapes by tendons. The chorda tympani nerve passes across the posterior surface. The medial wall of the middle ear cavity contains the oval and round windows. Between these two windows, the lower portion of the cochlea forms a prominence known as the promontorium tympani on the medial wall of the middle ear.

The inner ear consists of a bony labyrinth composed of three parts: the semicircular canals, the vestibule, and the cochlea. A dense, bony capsule in the petrous protein of the temporal bone surrounds these hollow spaces; this capsule contains perilymph and endolymph. Each of the semicircular canals has a dilated portion at the end, referred to as ampulla, which contains the crista ampullaris, a vestibular sense organ. In the vestibule, the utricle and saccules are formed; these structures contain sensory endings important for maintaining equilibrium.

The cochlea is a tubular structure with 2.5 turns; it closely resembles a snail shell, having a base and an apex. The cochlea

is divided into the scala vestibuli, the scala media, and the scala tympani. The scala vestibuli begins at the oval window, and the scala tympani terminates at the round window. The basilar membrane side of the duct gives rise to the organ of Corti, the organ of hearing. The organ of Corti includes hair cells and supporting cells; attached to the hair cells is a gelatinous membrane called the tectorial membrane.

The membranous labyrinth of the inner ear is composed of connective tissue filled with endolymph that forms in the bony labyrinth. Hair cells of the cochlea and the vestibular labyrinth are attached by afferent nerve fibers to the neurons of the auditory system, the spiral ganglion, and the Scarpa ganglion in the temporal bone. Efferent nerve fibers from ganglia form the auditory and vestibular division of the eighth cranial nerve and exit the temporal bone on its posterior surface to enter the brainstem.

PHYSIOLOGY OF AUDIOLOGIC FUNCTION

External Ear

The external ear consists of the auricle (pinna) and the external auditory meatus (external canal). The primary function of the external ear is to funnel sound to the tympanic membrane. Absence of the auricle contributes to difficulty in sound localization.

Middle Ear

Advancing sound entering the auditory canal directly strikes the tympanic membrane. This membrane and the ossicles serve as transmitters from the outer ear to the inner ear. The malleus, which is continuous with the tympanic membrane and is connected with the incus and stapes, moves the ossicles. Ossicles transfer sound energy into the inner ear through the oval window, which holds the stapes by means of an angular ligament.

The middle ear is lined with respiratory mucosa composed of ciliated columnar epithelial cells, supporting cells, and secretory cells. Secretory cells secrete mucus that forms a complex mucous layer. The cilia of the middle ear interact with the mucus by transporting mastoid and middle ear secretions through the eustachian tube to the nasopharynx, where they are swallowed. This mechanism is known as the mucociliary transport system. Glycoproteins in the mucus determine the viscosity and elasticity of the middle ear mucus. Mucus that is too thick or too thin impedes effective transport of bacteria and cellular debris from the mastoid and middle ear cleft: this transport has a protective effect against ear infections. In addition to serving as an exit for secretions into the nasopharynx, the eustachian tube equalizes the pressure between the middle ear and the ambient atmosphere.

Inner Ear

Before this point in the hearing mechanism, all of the sound energy is contained in the air-filled spaces of the external and middle ear. From the stapes onward, the pathway for sound moves through fluid-filled spaces. When sound is transferred from the tympanic membrane to the inner ear, the stapes creates a fluid wave that is transmitted to the round window. This transmission creates fluid waves that travel from the basal aspect of the cochlea to the apex. As the fluid wave moves, it displaces the basilar membrane. Maximum movement of the basilar membrane occurs at the point specific to the frequency of sound entering the ear; that is, high-frequency sounds cause minimal disturbance at the basal end of the cochlea, and low-frequency sounds cause minimal disturbance at the apex.

Vibrations in the basilar membrane cause movement of the organ of Corti. This organ contains receptor hair cells that are on the basilar membrane. Vibrations of the hair on the hair cells cause either polarization or depolarization, depending on the direction of the bend. When sufficient depolarization occurs, action potentials are produced that are propagated along the auditory pathway to the auditory cortex. The cochlea provides input by coding information about loudness and frequency in the action potentials sent to the cortex, giving meaning to the sound. Hair cells of the spiral organ of Corti are stimulated as they touch the tectorial membrane. Hair cells act as transducers that convert mechanical energy into electrical impulses; this action occurs in the fibers of the spiral ganglion. Axons of these cells become the auditory nerve (vestibulocochlear nerve). Nerve fibers pass to the medulla, the pons, and the midbrain, and finally to the temporal lobes of the cortex, where the impulses are interpreted as sound.

The vestibular system is similar to the auditory system. Fluid moves within the vestibular labyrinth when the head moves. The semicircular canals respond to angular acceleration (rotation), and the utricle and saccule respond to linear acceleration (position). Movement of endolymph exerts force on the hairs of the sensory cells of the cristae and the maculae. Depolarization of the sensory cells produces action potentials, which are transmitted to the vestibular cortex. The vestibular apparatus functions in conjunction with proprioception and visual orientation to maintain balance.

HEARING IMPAIRMENT

The ASHA defines hearing impairment as "a loss of auditory sensitivity that can be measured at birth and for which intervention strategies are known and available." Hearing impairment represents a spectrum of hearing loss classified as mild, moderate, severe, or prolonged.

Types of Hearing Impairment

The types of hearing impairment have been classified according to the location of the problem. Impairment may be one of three types: *conductive*, *sensorineural*, or a *combination* of these. Conductive losses arise from conditions that affect the outer and middle ear; sensorineural loss results from inner ear disorders; and combination losses result from disruptions in both areas of the ear.

Conductive hearing loss exists when dysfunction in the outer or middle ear disrupts the normal sequence of sound localization and vibration. Frequently, the external auditory meatus becomes occluded by cerumen (wax), which impedes the transmission of sound. Otitis media, an infection of the middle ear, is the most common cause of conductive hearing loss. In this instance, fluid accumulates in the middle ear, preventing the tympanic membrane and ossicular chain from vibrating normally (Boudewyns et al., 2011). Congenital deformities of the outer ear also can inhibit the neonate's ability to hear. Because the function of the external ear is to funnel sound, variations in the structure and protrusion of the pinna may contribute to conductive hearing loss. A missing or deformed pinna can result from a malformation of the auricular folds. Atresia of the auditory meatus or abnormal development of the ossicular chain may arise from defective development of the brachial chain (Jones, 2006). Infants with *conductive hearing loss* have difficulty hearing low-frequency sounds (i.e., those in the 125 to 500 Hz range). Management of the neonate with conductive hearing loss is directed toward early observation, detection, and intervention to eliminate the source of infection, to remove the blockage, and to provide amplification, resulting in the restoration of normal hearing.

Sensorineural hearing impairment results from damage to the sensory nerve endings of the cochlea or dysfunction of the auditory nerve (eighth cranial nerve). A typical characteristic of inner ear dysfunction is the inability of the inner ear to interpret fluid

changes in the cochlea. Sensorineural hearing loss may manifest as a congenital inner ear abnormality, resulting in congenital deafness. Other conditions that may cause sensorineural hearing loss are trauma to the inner ear, the effects of certain drugs, prolonged exposure to loud noise, infections, infectious conditions such as measles, and the effects of aging (Harlor & Bower, 2009).

IDENTIFICATION OF THE HEARING-IMPAIRED INFANT

Physical Examination

The physical examination of the infant should be performed in a quiet, warm, draft-free area appropriate for observation and inspection of auditory structures and function. Observing the infant's behavior before examining the ear yields baseline assessments. The alert, normal, full-term newborn reacts by turning toward the sound of human speech or the ring of a bell; this infant also startles to the stimulus of a loud noise. Observation of the preterm infant is deferred to a later time, prior to discharge when the behavioral response has matured. Observation of infant response alone provides only a crude estimate of neonatal hearing ability.

Inspection of the Ear

Inspection of the ear begins with the medial and lateral surfaces of the pinna and the surface of the scalp, face, and neck. Development of the pinna correlates with the infant's gestational age. At term, the pinna of the newborn is well shaped and has sufficient cartilage to maintain normal shape and resistance (Figure 16.2). Before 34 weeks' gestation, the pinna is a slightly formed double thickness of skin. The relationship of the pinna to the other structures of the head and face is important in the initial assessment. With normal placement, the helix is located at the level of the outer canthus and the tragus is roughly level with the intraorbital rim. Low-set auricles frequently are associated with abnormalities of the urinary system. Unilateral conductive hearing loss may be present in children with normal-size pinnae and unilateral absence of the superior crus or in patients with a fused antihelix-helix; thickened, hypertrophied earlobes; a "cup" ear; and a protruding pinna. The pinna may be abnormally small (microtia) or absent (anotia). Atresia (closure of the external auditory canal) may be observed. The condition is classified as mild, indicating a small ear canal; medium, indicating that a bony atretic plate has replaced the canal with ossicular malformation; or severe, indicating a small or absent ear canal and middle ear space.

Several combinations of atresia and microtia may be seen; therefore, all children with these abnormalities should be suspected of having middle ear abnormalities. These infants may also have sensorineural hearing loss. Atresia often is observed with cranial, facial, mandibular, or acrofacial dysostoses. Abnormalities of the skeletal system or chromosomal aberration may also be accompanied by atresia. Aural atresia may be associated with facial, labial, or palatal clefts. Infants with atresia often have conductive hearing loss related to the inability of the ear canal to transmit sound. Preauricular abnormalities, including pits or tags (Figure 16.4) and branchial fistulas, often are accompanied by external or middle ear malformations. These appendages may be present with an otherwise normal-appearing pinna. Preauricular tags or pits usually require only cosmetic surgery or excision if they are draining.

The pinna should be inspected for location and for its relationship to other facial structures. Normal attachment is to the side, level with the middle-third of the face, and fixed in position to the lateral aspect of the external auditory canal. The major

FIGURE 16.4 Preauricular tag.

Source: Adapted from Schreiner, R. L., & Bradburn, N. C. (1987). *Care of the newborn* (2nd ed.). New York, NY: Raven Press.

convolutions of the pinna are the helix, antihelix, tragus, antitragus, and lobule. The lobule of the external ear has no cartilage. The angle of placement of the pinna is almost vertical, and if the angle is more than 10 degrees off normal, it is considered abnormal. The superior helix is located at the outer canthus of the eye, and the tragus is roughly level with the infraorbital rim.

Low-set auricles frequently are associated with other abnormalities of the first and second branchial clefts and with abnormalities of the urinary system. Other abnormalities that may be noted are skin tags, sinuses, or pits, which often are associated with other auditory or renal malformations. The pinna often may be observed to have bruising from a forceps delivery. Depending on the degree of bruising, the discoloration should subside within the first week of life.

The external auditory meatus should then be observed for patency. Atresia or stenosis of the external meatus may be seen. This abnormality results in a conductive hearing loss because sound transmissions are blocked; the condition should be noted as part of the physical findings.

Inspection of the Middle Earand Tympanic Membrane

The depths of the external meatus can be examined with a brightly illuminated pneumatic otoscope. Vernix caseosa frequently is encountered in the ear canal of the neonate. The otoscope is introduced into the ear canal by exerting gentle traction posterosuperiorly on the auricle. In the neonate, the tympanic membrane lies in a nearly horizontal plane. The tympanic membrane is visualized through the collapsed neonatal ear by gently dilating the ear canal with the speculum as the cartilaginous canal is traversed. The tympanic membrane should be examined for thickness, vascularity, and contour. All areas, including the area above the short process of the malleus (pars flaccida), should be visualized for completeness. Normally the tympanic membrane appears translucent. White shadows of the ossicles usually can be seen through the membrane. The mobility of the tympanic membrane can be assessed by applying intermittent pressure through a bulb or by blowing through a polyethylene tube connected to an otoscope.

Otitis media can occur in the first days of life and can be diagnosed by otoscopic examination. Otitis media often manifests as a poorly mobile, bulging, yellow, opacified tympanic membrane. Complications of otitis media are common. Otitis media with middle ear effusion may cause hearing loss, perforation of the tympanic membrane, and possibly intracranial complications, including meningitis, encephalitis, and brain abscess (Vartiainen, 2000). Middle ear effusion occurs in both outpatient and inpatient groups of neonates.

Inspection of the Head and Neck

The anatomy of the head and neck should be assessed for deficits as part of the screening process for all neonates. Ear anomalies associated with head and neck anomalies may occur as a result of a primary regional defect; secondary to a primary defect in an area contiguous to the temporal bone; as part of an inherited defect involving the skeletal system; or as part of a chromosomal disorder. Malformations of the head and neck may be relatively simple or complex. Any neonate with a defect, even a minor one, should be closely examined for hidden major malformations.

Nose. Examination of the nose should be directed toward identification of suspicious defects, such as unusual broadness with a flat base and a short length (saddle nose), small nostrils, and notched alae. Deformities of the nose often appear with other craniofacial abnormalities.

Mouth. Defects in the oral cavity are the most common defect associated with hearing impairment. A child with cleft lip and/or palate has a deficiency in the palate musculature that is primarily related to the inability of the tensor muscle of the velum palatinum to dilate the eustachian tube actively during swallowing. Hearing problems may be observed in patients with cleft palate, depending on the patient's age on examination and the means of the exploration. Cleft lip or palate leaves the child vulnerable to the effusion of fluid and, as a result, to varying degrees of hearing loss. The consequences of effusion raise the rate of otitis media, of which 50% to 90% of incidences have been reported. The hearing loss associated with cleft lip or palate generally is conductive; however, sensorineural and combination losses have been reported. Infants younger than 12 months of age who had cleft palate that was surgically repaired often have a detectable degree of hearing loss. The degree of loss is directly related to the severity of the palatal defect.

Eyes. Deformities of the eyelids are the most common abnormality involving the eyes. A variation in eyelid configuration has been noted in which the upper eyelid forms an almost vertical curve at the level of the medial limit of the cornea and fuses with the lower eyelid. The distance of the two medial angles is increased. These findings typically are noted in Waardenburg syndrome, an autosomal dominant disorder that results in mild to severe sensorineural hearing loss in 50% of patients. The hearing loss may be unilateral or bilateral and progressive.

Epicanthal folds that are true vertical folds extending from the nasal fold into the upper eyelid are commonly noted in infants with Down syndrome, or trisomy 21. Other physical features seen in Down syndrome are low-set ears, small pinnae, and a narrow external ear canal. Infants with this syndrome tend to have recurrent otitis media and anomalies of the middle ear ossicles. The incidence of hearing loss is high, and the condition may be the sensorineural, conductive, or combination type.

Hair. An unusual hair texture or hairline should raise suspicion in the assessment for abnormalities associated with hearing loss. Twisted hair (pili torti) has been associated with sensorineural hearing loss. The hair may be twisted, dry, brittle, or easily broken. Aberrant scalp hair patterns may also be significant.

Neck. Defects of the neck that may be associated with hearing impairment are branchial cleft fistulas and mildly webbed or shortened neck. Not all infants with defects of the head or neck also have hearing impairments; many variations may be observed in the normal neonate population. The presence of such defects does increase the risk of hearing impairment, however, and should be followed up in the long-term interest of the child.

History

The importance of a comprehensive history for identifying the infant at risk cannot be overemphasized. The newborn carries a history extending back to the time of conception and is influenced by both perinatal events and parental genetic composition. Gathering of data on the infant's history is the first step in identifying infants at risk for hearing impairment. A thorough history of familial hearing loss, presenting either at birth or at childhood through adolescence, is significant.

Family History

More than 50 types of hereditary hearing loss have been described. A significant number of hearing impairments may be classified as genetically based. Hereditary hearing loss must be identified on the basis of a thorough medical and family history, which should include the following components:

1. Determination of the cause and circumstances under which the hearing impairment was first noticed: many different circumstances surrounding the onset of the hearing loss may cause it to be labeled as congenital or hereditary, or both. An example of hearing loss that is hereditary and not congenital is Alport syndrome, an autosomal dominant trait resulting in deafness that begins in preadolescence.
2. A complete family history: This should include a history of previous and current pregnancies.
3. An extended family history of data relating to hearing impairments of both immediate and extended family members.
4. A thorough physical examination: The head and neck regions, particularly, should be examined for abnormalities.
5. Selective testing procedures for assessing possible causes of sensorineural hearing loss.

A questionnaire can be used to obtain information on familial hearing loss from the mother. Although the questions easily may be asked orally, the form provides a structure that can ensure consistency and is the preferred method of data gathering in most settings. The questionnaire should be given to all new mothers and should be completed prior to discharge. The questionnaire provides an excellent opportunity for educating the mother on normal speech and language development.

HEREDITARY HEARING LOSS

Autosomal Dominant Inheritance

Autosomal dominant inheritance accounts for 10% to 25% of cases of hereditary hearing impairment. The hearing loss may be unilateral or bilateral, and males and females are affected equally. Autosomal dominant hearing disorders vary in severity ("variable expressivity") and in progression of hearing loss. A typical example of an autosomal dominant hearing disorder occurs in

Waardenburg syndrome, which is characterized by hypertelorism, a high nasal bridge, synophrys, and hypoplastic alae nasi. Pigmentation abnormalities include a white forelock, partial albinism, hypopigmentation of the fundi, blue irises, and premature graying. In this syndrome, severe to profound bilateral sensorineural hearing loss is present with integumentary system involvement. The histopathologic characteristics are absence of the organ of Corti and atrophy of the spiral ganglion.

Another example of an autosomal dominant hearing loss with incomplete penetrance and variable expression occurs in Treacher Collins syndrome. Major features of the syndrome include facial anomalies; small, displaced, or absent external ears; external auditory canal atresia; and poorly developed or malformed tympanic ossicles. Deafness generally is complete and conductive.

Klippel-Feil syndrome, if familial, is another example of autosomal dominance with variable expression. The characteristics of this syndrome are craniofacial disorders, fusion of some or all of the cervical vertebrae, cleft palate (occasionally), and severe sensorineural hearing loss. Crouzon disease is another disorder in which hearing loss is attributed to autosomal dominance with variable expression. An abnormally shaped head, a beaked nose, and marked bilateral exophthalmos caused by premature closure of the cranial sutures characterize this disease. Hearing loss may be conductive because of middle ear deformities or sensorineural abnormalities.

Autosomal Recessive Inheritance

Autosomal recessive inheritance accounts for about 40% of childhood deafness. An estimated one in eight individuals is a carrier for a recessive form of hearing impairment. The incidence of recessive inheritance is higher in marriages of recent common ancestry, such as siblings or cousins. This type of union increases the possibility that each parent will be the carrier of an identical defective gene that may express itself as an abnormal trait. Hearing loss in people with an autosomal recessive gene tends to be more severe than in those with autosomal dominant inheritance, because most cases of recessive hearing loss are associated with the Scheibe deformity of the cochlea. With Scheibe dysplasia, the entire organ of Corti is rudimentary; hair cells are missing, and the supporting cells are distorted or collapsed. The vestibular membrane usually is collapsed. Pendred syndrome, a condition marked by hearing loss and goiter detected in the first 2 years of life, is an example of an autosomal recessive disorder.

X-Linked Disorders. Approximately 3% of hereditary deafness is due to the X-linked mode of transmission (Northern & Downs, 2002). The mutant gene is on the X chromosome, and males transmit only Y chromosomes to their male offspring; therefore, only males are affected. The female is the carrier and has the chance to transmit the gene to 50% of her sons, who manifest the disease, and 50% of her daughters, who carry the abnormality. The hearing loss characteristically is not present at birth but develops in infancy to varying degrees. X-linked hearing losses, with exceptions, are sensorineural, and some retention of hearing in all frequencies often occurs. Recessive, or X-linked, Duchenne muscular dystrophy is an example of this type of disorder. Characterized by muscle wasting, the severe infantile form of muscular dystrophy also is associated with mild to moderate sensorineural hearing loss.

Cytogenetic Disorders. Cytogenetic disorders are caused by structural changes in one or more of the chromosomes or by errors in the distribution of the chromosomes. Down syndrome, which is caused by an extra chromosome 21, is the most common chromosomal aberration syndrome, with an incidence of 1 in 600 to 800 births. Approximately 5% of cases of Down syndrome are due to translocation and fusion of part of chromosome 21 to chromosome 14. Children with trisomy 21 have a high incidence of hearing loss.

Characteristic otologic findings that have an impact on the hearing performance of these children during the early years are a high incidence of (1) stenosis of the external auditory canal, (2) serous otitis media, and (3) a cholesteatoma-persistent growth of squamous epithelium from the ear canal into the middle ear or mastoid through a tear in the tympanic membrane. The narrowed segment is located at the junction of the cartilaginous and bony portions of the canal. With increasing age, the canal has been noted to assume a more typical appearance as the thickened tissue recedes.

The degree of hearing loss in these infants varies, but is rarely profound. On examination of the aperture, some of these children are found to have congenital ossicular malformations and destruction caused by inflammations arising from chronic infection.

Mental retardation is a clinical condition frequently seen with Down syndrome or trisomy 21. The impact of the otologic handicap on the developmental potential of these children is uncertain. **Emergency Alert: Because of the high incidence of hearing loss in this group, early and frequent monitoring is imperative.** Collaborative research studies need to be done to identify factors affecting the otologic problems of infants with Down syndrome and to devise early strategies to optimize these infants' potential (Park, Wilson, Stevens, Harward, & Hohler, 2012).

Differential Diagnosis

No differential diagnosis exists for deafness, although generally a differential diagnosis to determine the etiology of the hearing impairment is listed.

Diagnostic Test

- Laboratory testing is not of benefit in the diagnosis of deafness; however, if a genetic syndrome is suspected, biochemical evidence may be of benefit in determining the etiology.
- Connexin-26 is a genetic marker for deafness (Wang et al., 2011).
- Laboratory testing for perinatal infections such as syphilis, and other toxoplasmosis, other agents, rubella, cytomegalovirus (CMV), and herpes simplex (TORCH) infections may be indicated.
- For bilateral hearing loss, markers for general inflammatory disease, such as sedimentation rate, rheumatoid factor, or 68-kDa protein a marker especially for autoimmune ear disease, may be evaluated.
- CT scanning and MRI may be used to establish a malformation of the cochlea or cochlear nerve. MRI scanning may be used to identify an enlarged vestibular aqueduct, in the case of a sensitive ear in a child with a minor head trauma who presents with deteriorating hearing.

SCREENING METHODS FOR IDENTIFICATION OF HEARING LOSS

Neonatal Hearing Screening is the standard of care in hospitals throughout the United States as well as developed countries worldwide (ASHA, 2018b). The primary focus of hearing screening for neonates (ages 0–6 months) is but one part of a program of comprehensive Early Hearing Detection and Intervention (EHDI)

program of service. The primary focus includes newborn hearing screening as an early identification of infants who are likely to have hearing loss and who will require further evaluation. The secondary purpose is to identify newborns with medical conditions that can present with late-onset hearing loss, to establish for this family unit a plan for continued care monitoring of their child's hearing status (Joint Committee on Infant Hearing, 2007). The EHDI guidelines include hearing screening completion by 1 month of age, diagnosis of a hearing impairment, selection and fitting of a device within 1 month of confirmation of a hearing loss, if parents choose that option, as well as entry into early intervention (EI) services by 6 months of age.

In the past 15 years, programs and procedures for screening newborns have been developed, modified, and improved. The goal of any screening program is to accomplish the task rapidly, accurately, and economically. EHDI refers to the practice of screening every newborn for hearing loss prior to hospital discharge. All 50 states and the District of Columbia have EHDI laws or voluntary compliance programs that screen hearing. The EHDI program is responsible for creating, operating, and continuously improving a system. In addition, institutions are advised to use the risk factors associated with permanent congenital, delayed onset, and/or progressive hearing loss in children. Box 16.1 is a guide to identify infants whose history indicates that degenerative disease or intrauterine infection may cause progressive, fluctuating, or late-onset hearing loss. In these cases, it is recommended that the child have follow-up for 2 years in addition to initial screening.

Box 16.1

RISK FACTORS ASSOCIATED WITH PERMANENT CONGENITAL, DELAYED ONSET, AND/OR PROGRESSIVE HEARING LOSS IN CHILDREN

1. Family history of permanent childhood hearing loss
2. Neonatal intensive care for 2 days or more or any of the following: extracorporeal membrane oxygenation-assisted ventilation, exposure to ototoxic medications (gentamicin and tobramycin) or loop diuretics (furosemide/Lasix), and hyperbilirubinemia requiring exchange transfusion
3. In utero exposure to infections such as CMV, herpes, rubella, syphilis, and toxoplasmosis
4. Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies
5. Syndromes associated with hearing loss or progressive or late-onset hearing loss, such as Waardenburg, Alport, Pendred, Ushers, and neurofibromatosis
6. Neurodegenerative disorders such as Hunter syndrome
7. Culture-positive postnatal infections associated with sensorineural hearing loss, including confirmed bacterial and viral meningitis
8. Head trauma
9. Chemotherapy
10. Recurrent or persistent otitis media
11. Concerned parent; child may have hearing loss

Source: Adapted from U.S. Preventive Services Task Force. (2008). Universal screening for hearing loss in newborns. U.S. Preventive Services Task Force recommendation statement. *American Family Physician, 122*(1), 143–148. doi:10.1542/peds.2007-2210

The Joint Committee on Infant Hearing (2007) has endorsed universal screening of all newborns. In all cases, before discharge, the parents should be informed about speech and hearing milestones and should be provided with information about community agencies available for long-term follow-up if needed (Figure 16.5).

Peripheral Measurements of Hearing Function

Assessment of hearing function in the neonate has focused on a two-tiered approach in which the evoked otoacoustic emissions (OAEs) test is used initially, and the automated auditory brainstem response (ABR) test is used as follow-up for infants who show hearing impairment on the initial screening. OAEs are low-intensity sounds that can be measured by placing a sensitive microphone in the ear canal. Hearing screening using OAEs is quick, inexpensive, and relatively accurate. Newborns delivered at home, or at birthing centers without hearing screening facilities, need to have some referral mechanism for newborn hearing screening and follow-up mechanism.

If hearing impairment is detected on the OAE test, the ABR test can confirm the validity of that result. The ABR test records the electrical potentials that arise from the auditory nerve system. During this test, disk electrodes are attached to the vertex and mastoid areas, and repetitive sounds are presented to the ear in the form of clicks caused by a direct current pulse. The recorded response is a sequence of waves that represents the action potential of the auditory nerve. The wave latencies in infants at risk tend to show smaller and more prolonged responses. The absolute latency of the ABR waves depends on the intensity of the click stimulus. Reducing the click stimuli from 60 dB to 30–40 dB identifies thresholds of hearing. Absence of all waves indicates the presence of a peripheral lesion.

An abnormal ABR result may be defined as one that shows an absence of response at 40 dB or a wave V latency that exceeds the norm by two standard deviations. Wave V responses are used to determine abnormality because they are highly repeatable in infants and show little variability in normal-hearing subjects. The ABR test appears to be a sensitive method in that no false-negative results have been reported. Considering that any screening method should be quick, inexpensive, and easily administered and should allow easy interpretation of a large number of infants, the drawback to the ABR test is that it is more costly than the OAE test. Nevertheless, the ABR test can be justified as the initial neonatal hearing test, especially in preterm or high-risk infants. The Joint Committee on Infant Hearing (1995, 2007; Task Force on Newborn and Infant Hearing, 1999) specifies that an audiologist should supervise the infant hearing screening program.

In some infants whose initial ABR test results are passing, but the infants meet risk criteria, continuing audiologic follow-up and management may be appropriate as designated by USPSTF for the following 3 years. Those infants include one with risk factors associated with possible progressive or fluctuating loss, such as a family history of progressive hearing loss, CMV infection, and persistent fetal circulation.

Infants who do not demonstrate a repeatable ABR wave V to the signal presented at 40 dB in at least one ear should have a comprehensive hearing evaluation at no later than 6 months of age. This follow-up includes a general physical examination, including examination of the head and neck; otoscopy; identification of relevant physical abnormalities; and laboratory tests for perinatal infections. A comprehensive audiologic evaluation may include additional evoked potential evaluation and acoustic immittance measurements. Although precise data on hearing sensitivity cannot

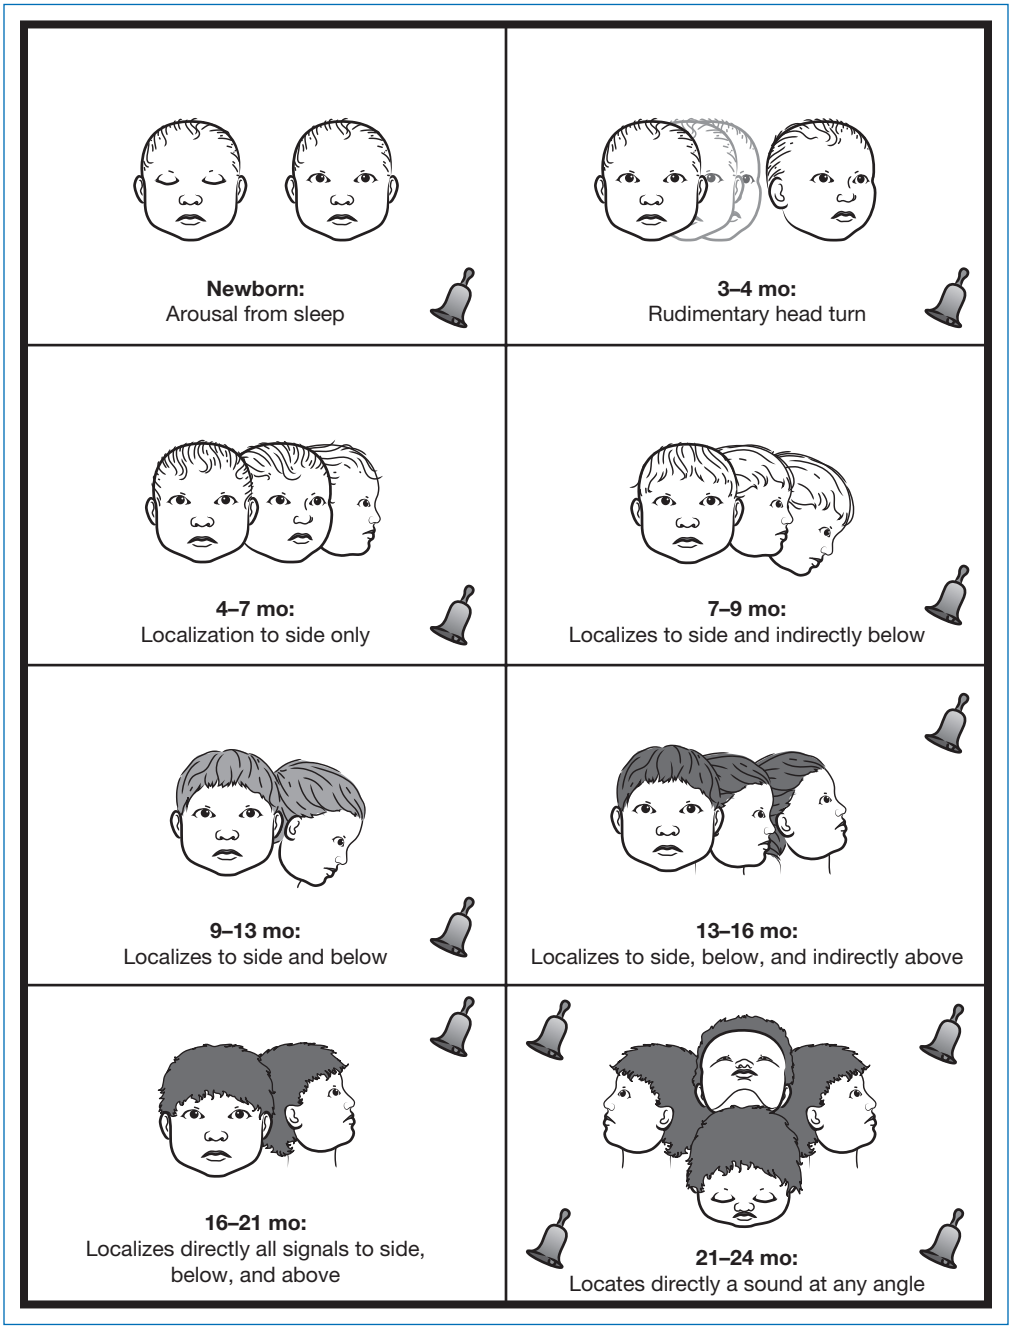

FIGURE 16.5 Maturation of auditory response.

Source: Redrawn from Northern, J. L., & Downs, M. P. (2002). *Hearing in children* (5th ed.). Baltimore, MD: Lippincott Williams & Wilkins.

be obtained until the infant can respond to operant conditioning test procedures at approximately 6 months of age, habilitation should not be delayed.

Infants can be fitted with hearing aids before 3 months of age. Attention to early identification, amplification, and education does not necessarily ensure speech and language acquisition but certainly facilitates it, even in the most profoundly hearing-impaired child.

DEVELOPMENT OF A TREATMENT PLAN FOR THE HEARING-IMPAIRED NEONATE

Hearing screening of all infants should be completed before discharge or no later than 1 month of age. Those who do not pass the newborn screening should undergo audiologic and medical evaluation before 3 months of age for confirmatory testing. If confirmation of a diagnosis is made, then a treatment plan and habilitation can begin. **Quality and Safety: Infants whose history indicates that they are at risk for late-onset hearing loss should be observed by periodic audiologic testing for 3 years.** For the infant with a confirmed hearing loss, efforts are directed at treatment. In accordance with Public Law 99, EI services are (1) evaluation and assessment and (2) development of an individualized family service plan. The full evaluation plan is to be completed within 45 days of referral. This plan may include various methods directed at treatment of serous otitis media, which is a major cause of temporary conductive hearing loss. For the infant with a permanent conductive hearing loss, amplification with a hearing aid may facilitate stimulation in the early critical period. Infants can

be fitted with a hearing aid device as soon as the impairment is diagnosed. In addition to amplification, the family should be taught total communication skills that will enhance interaction between the sender and the receiver. The basic premise is to use every means to communicate, such as gesturing, touching, and attending to stimuli.

The infant with severe to profound hearing impairment who is not at risk for recurrent otitis media and who does not get satisfactory results with a hearing aid is a candidate for cochlear implants (discussed in section "Cochlear Implants"). For the hearing-impaired infant, multiple referral sources exist in which a multidisciplinary approach optimizes the infant's potential for growth and development.

Cochlear Implants

Cochlear implants are not new, but they increasingly are being used to treat infants with severe to profound sensorineural hearing loss. Cochlear implants are electronic devices that are surgically implanted in the inner ear and bypass the damaged part of the ear to deliver electrical signals to the hearing nerve. A cochlear implant system is composed of a microphone, an external sound processor, transmitter, internal cochlear receiver, and electrode array. The external sound processor captures sound with a microphone and converts the sound to digital information. The digital signal is sent to the internal receiver and converted to electrical signals, which stimulate tiny electrodes in the inner ear. The electrodes send the electrical signal to the hearing nerve. These signals are then interpreted by the brain as sound. Implants work only if some spiral ganglion cells are present to transmit the auditory signal. An issue for patients of any age with any type of cochlear implant is the comfortable level of sound. This sometimes is difficult to determine in infants, who cannot provide feedback as to what they are hearing.

Cochlear implants are Food and Drug Administration approved for adults and children as young as 12 months of age. Research has shown that earlier implantation is associated with better speech and language development (Svirsky, Teoh, & Neuburger, 2004). **Quality and Safety: It is critical that infants with hearing loss be diagnosed and early intervention be initiated without delay.** The later the child receives the implants, the more likely it is that speech and language development will be delayed.

Hearing screening is a task for a team of professionals that includes pediatricians, otolaryngologists, audiologists, neurologists, and nurse practitioners. Local public health agencies may provide services such as data collection and referral. Many large metropolitan medical centers have speech and hearing centers as part of a broad base of services ranging from diagnosis to rehabilitation.

Implementation and Evaluation

The multidisciplinary, multiservices approach should be instituted only when all components are available to the infant and the family (ASHA, 2018a). In addition to qualified professionals and services, other factors influence the management and habilitation of the hearing-impaired infant. These factors can facilitate or hamper entry into the system and compliance with the treatment regimen (Box 16.2).

Parental Support

Support for the parents of a hearing-impaired child is based on the foundation of trust and acceptance between the practitioner and the family. Notification of a hearing impairment is an extremely traumatic and deeply disturbing situation for the parents, one that often provokes denial. Often, identification of the problem is delayed because the parents cannot admit that something is wrong. Some practices in the diagnostic workup for hearing impairment seem to favor separation of the parents from the diagnostic process. OAE and ABR testing may foster denial because the findings are abstract, and parents need to have visible, tangible evidence of the impairment. The practitioner plays a major role in reiterating, interpreting, and reinforcing the information conveyed by the audiologist. Sensitivity to the parents' need to grieve the loss of the "perfect child" is important. Acceptance of the handicap can be aided by enlisting the parents as codiagnosticians. Asking the parents what they think the problem is and making them part of the decision-making process objectifies the diagnoses and aids future compliance with the habilitative regimen. Through encouraging dialogue with other parents with similar children's needs and coaching parents with question prompts, the facilitator simulates decision making (Coulter & Ellins, 2007). By listening to the parents' feelings of inadequacy and by indirect teaching, practitioners can help the parents acquire more fruitful coping strategies. Sices, Egbert, and Mercer (2009) investigated parents' and EI specialists' beliefs and experiences regarding discussing child development in primary care. Focus groups were used to collect data from mothers of young children with typical development as well as those who received EI services and specialists. Themes from the data revealed that most mothers preferred a nonalarmist style of communication

Box 16.2

FACTORS INFLUENCING THE MANAGEMENT AND HABILITATION OF THE HEARING-IMPAIRED INFANT

Factors That Facilitate Management and Habilitation

- Acknowledging the parents' sense of loss and feelings of inadequacy: a nonalarmist style of communication
- Interpretation of test results and proposed plan of care
- Information about expected developmental skills, suggestion for promoting skills, and a time frame for follow-up
  Encouragement to seek out and dialogue with other parents of hearing-impaired infants
- Family can be taught total communication skills (gesturing, touching, and attending) to support interaction with the infant.
- Expeditious arrangements for referral
- Parental involvement, offering a wide range of programs that are family-centered focused

Factors That Hamper Management and Habilitation

- Long waiting lists
- Proximity to resources
- Difficulty scheduling appointments
- Parents were unaware of the plan of care.
- Focus should be on the infant sooner, and not the child later.
- Parents wanted more involvement.
- Decision making was therapist centered, not family centered.
- Poor communication between speech and hearing departments

when developmental delays are suspected. Some mothers preferred a more direct approach, including the use of labels to help them understand. The importance of preparation to accept development delays emerged as a theme in all groups. Elements of preparedness included information about expected developmental skills, suggestion for promoting skills, and a time frame for follow-up. The mother–infant relationship is potentially damaged when the infant is hearing impaired. Reciprocal communication that normally occurs between the mother and the infant on an affective and a verbal level has been reported to be diminished with infants who are hearing impaired. The handicapped infant may miss intended signals from parents and may emit signals that are not understood. The parents must capture their infant's visual attention so that their efforts are effectively stimulating. An asynchrony may develop that can retard the infant's ability to acquire language even beyond the limits of the hearing loss itself. The family can be taught total communication skills (gesturing, touching, and attending) to support interaction with the infant.

OUTCOME MEASURES

Outcome measures of the treatment program include early identification and implementation of a comprehensive habilitation plan, in order to maximize communication potential and parental acceptance of the infant's disability. Bailey, Hebbeler, Scarborough, Spiker, & Mallik (2004), in a nationally representative sample of families of children (average age of diagnosis 7.4 months of age) with or at risk for disability, reported very positive first experiences with EI. A small percentage experienced significant delays and wanted more involvement, and nearly 20% were unaware of the existence of a written plan for service. N. W. Pappas, McLeod, McAllister, and McKinnon (2008), in a study of belief in and practice of speech language pathologists in service planning and delivery for children with hearing impairment, revealed that stated beliefs do not always reflect practice: decision making was therapist centered rather than family centered. McCracken and Marsh (2008), in a qualitative study of parental reflections on very early audiologic management, concluded that to be most effective, the focus should be on the infant sooner, rather than on the child later. Ingber, Al-Yagon, and Dromi (2010) examined the actual versus desired family-centered practice in EI for children with hearing loss from the professional and parental viewpoint. Results revealed that parental involvement in the program was perceived positively; however, a wide range of programs needs to be offered for parents.

SUMMARY

On the horizon, as a result of the countless efforts of many, 98% of the babies born in the United States and its territories receive hearing screening in the newborn period (CDC, 2016; NCHAM, 2007). Successful outcomes for children with hearing loss are within reach as a result of advanced knowledge, skills, and hearing technology available to these children and their families. However, only slightly more than half of the infants who do not pass hearing screening receive follow-up diagnostic testing and only a third diagnosed with hearing loss receive intervention by 6 months of age (NCHAM, 2005). Clearly, positive outcomes can only be achieved if babies identified with hearing loss receive appropriate EI services in a timely manner. That is the challenge that lies in the future.

EVIDENCE-BASED PRACTICE BOX

The multidisciplinary, multiservices approach should be instituted only when all components are available to the infant and the family (American Speech-Language-Hearing Association, 2007).

In addition to qualified professionals and services, other factors influence the management and habilitation of the hearing-impaired infant. These factors can facilitate or hamper entry into the system and compliance with the treatment regimen (Box 16.2).

PARENT VOICES

Keira Sorrells

Aside from having the most wonderfully supportive lactation nurses in our unit, the neonatal therapists were equally incredible. I will never forget when I walked in for a visit and our primary nurse said she had scheduled an appointment for the occupational therapist (OT) to teach me infant massage. This was a highlight of our time in the NICU, where the OT gently coached me and encouraged me to care for my daughter using the healing power of touch. She taught me important cues to look for, as well as potential areas for concern, as we worked together. Being able to provide this type of massage for my girls allowed me an additional manner in which to bond, empowered me to feel more like a "real" mom, and was something I continued to do for my girls on into their toddler years.

CHAPTER 17

Ophthalmic System

Lori Baas Rubarth and Debra M. Parker

INTRODUCTION

Newborn eyes begin to develop during intrauterine life, making them susceptible to malformation, deformation, and disruption injuries. Congenital anomalies, congenital infections, and prematurity can affect visual acuity, which can lead to blindness. In addition, other maternal or neonatal diseases can affect the eyes. Therefore, early detection and treatment of eye disorders are essential for the best possible outcome.

This chapter outlines the embryologic development of the eye, reviews the methods of assessment of a newborn's eyes, describes specific ophthalmic disorders of the eye, and describes diseases that can affect the eyes, including prematurity. Nursing care of the patient and family will be discussed.

EMBRYOLOGY

Eye development has its beginnings during early embryogenesis with the formation of a single eye field in the neural plate (Schoenwolf, Bleyl, Brauer, & Francis-West, 2015). Many transcription factors early in development regulate and induce eye development. Without these transcription factors and other enzymes or proteins, anomalies can occur. The initial single eye field is stimulated by the sonic hedgehog protein to split into two separate optic fields. Without this early splitting stimulation, holoprosencephaly (failure of brain to split into two hemispheres) and cyclopia (a single, midline eye) would occur (Schoenwolf et al., 2015). Lack of transcription factors leads to anomalies like anophthalmia (absence of the eye) or microphthalmia (small eye).

The eye develops from the following embryonic tissues: ectoderm, neuroectoderm, neural crest cells, and mesoderm. The lens develops from the ectoderm during the fifth to seventh week. The cornea develops from the ectoderm and mesoderm. The pigmented epithelium and part of the retina develop from the neuroectoderm. The ciliary and iris muscles, part of the choroid, and the sclera develop from neural crest cells. Part of the choroid also develops from the mesoderm (Figure 17.1).

At about 22 days after fertilization, lateral grooves form, which mark the early placement of the eyes in the embryo (Schoenwolf

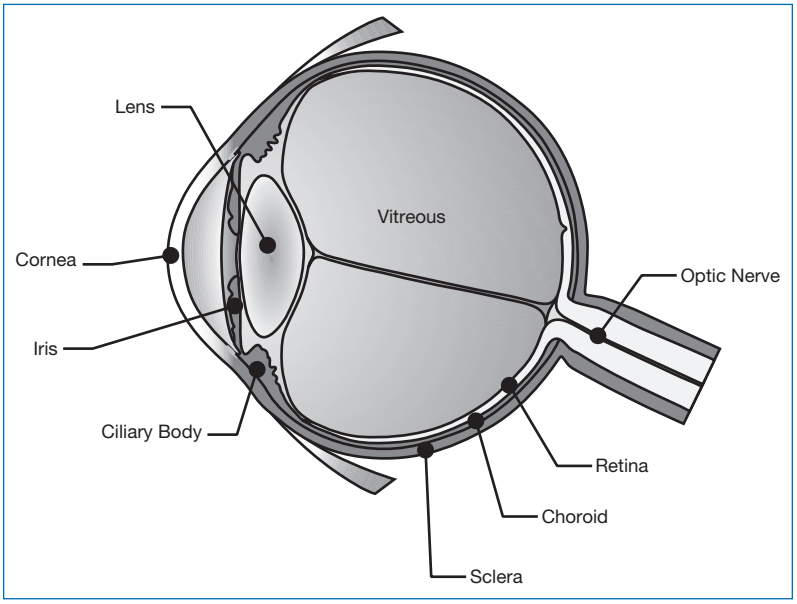

FIGURE 17.1 Anatomy of the eye.

et al., 2015). Bilateral invaginations of the neural tube occur with formation of the optic vesicles. These two optic vesicles remain in contact with the developing brain. By about 32 to 34 days, the optic vesicles change shape to appear as a "goblet" with an additional invagination of the ectoderm inward becoming the lens of the eye (Schoenwolf et al., 2015, p. 490). The fibers within the lens become transparent with the assistance of crystallins, which are soluble proteins within the eye. With the invagination of the optic cup, there are two layers formed, which develop into the inner retina containing rods and cones and the outer melanin containing pigmented epithelium. These two layers of the retina do not fuse completely, but can separate, causing a retinal detachment with many types of trauma to the head. Both layers expand over the lens from the edges of the optic cup, becoming the iris. The color of the iris is either light blue or gray at birth but becomes fully developed with increased pigment by about 6 months of age.

Cellular differentiation and development continues within the eye throughout fetal life. Macular differentiation occurs during the sixth month, and the fovea centralis, the area needed for sharp, high-acuity vision, does not mature until months into the postpartum period (Schoenwolf et al., 2015). Therefore, the term newborn's vision is present, but limited during the first few days and weeks of life. Newborns are most interested in high-contrast shapes that are about 8 to 12 inches from the eyes.

The eyelids develop as surface ectoderm folds over the cornea by about the sixth week of fetal life. The eyelids fuse together by the eighth week, but separate again sometime between the fifth and seventh months of fetal life. The lacrimal glands form from the ectoderm, but are still immature until about 6 weeks after birth (Schoenwolf et al., 2015). Tear production in newborns is limited until that time.

ASSESSMENT AND EXAMINATION TECHNIQUES

History

With an evaluation of the eye, it is important to understand the background of neonatal eye disorders (see Other Disorders That Affect the Eyes). Understanding of these disorders can assist the nurse in determining whether there are any risk factors for eye problems, for example, maternal diabetes, prematurity, alcohol consumption, or congenital diseases. The nurse can question the parents or view the maternal medical record to determine known family, maternal, or perinatal risk factors associated with vision problems. The nurse should look specifically for exposure to infectious diseases such as gonorrhea, chlamydia, rubella, or cytomegalovirus (CMV), which are known to cause significant eye problems in newborns. The nurse should also look at the perinatal history for signs of hypoxia or anoxia (e.g., low Apgar score), as well as conditions associated with possible damage to the brain including vision. Parents who have had a previous preterm birth may already have knowledge or experience with retinopathy of prematurity (ROP). Nurses also need to understand the terminology involved in assessment of the newborn eye (Table 17.1).

Examination

After birth, a screening examination of the eye is indicated. A full eye examination is not practical or indicated unless the newborn presents with some eye pathology. A knowledge of eye anatomy is important as you examine the eye (Figure 17.1). For a newborn screening examination, the external eye, eyelids, pupillary

TABLE 17.1

NEWBORN EYE ASSESSMENT TERMINOLOGY

Definitions	
Amblyopia	Known as "lazy eye" where one eye wanders from a straight line of vision
Aniridia	Much or all of the iris is missing
Anisometropia	A major difference in refractive error between the eyes
Anophthalmos	Complete absence of the ocular tissue within the orbit
Antimongoloid slant	An inner canthus that is higher than the outer canthus
Blennorrhea	Excessive mucus discharge from the eye
Brushfield spots	Speckled iris; frequently associated with Down syndrome
Coloboma	Defect or opening that results from failure of part of the eye to close during embryogenesis; can occur in the iris or eyelids
Ectropion	A condition in which the eyelid is turned outward
Endophthalmitis	Inflammation of the internal eye tissues and fluid
Epicanthal fold	Skin that appears to overlap and partially obscure the inner canthus
Epiphora	Excessive tearing
Esotropia	Inward deviation of the eyes—presents as "cross-eyed"
Exophthalmos	An eye that appears to be bulging
Exotropia	Outward deviation of the eyes
Heterochromia	Pigmentation of the two irises is different
Hyperopia	Farsighted
Hypertelorism	Increased interorbital distance or wide space between the eyes
Inner canthus	The angle of the eyelid nearest the nose

(*continued*)

TABLE 17.1

NEWBORN EYE ASSESSMENT TERMINOLOGY (*continued*)

Definitions	
Interpupillary distance	The distance between the centers of each pupil
Leukocoria	"White" reflex, instead of red
Microphthalmia/ microphthalmos	Small eyes
Mongoloid slant	An outer canthus that is higher than the inner canthus
Myopia	Nearsightedness
Nystagmus	The involuntary rhythmic or oscillating movements of the eyes
Outer canthus	The outer angle of the eyelid
Palpebral fissure (width)	Width of the eyelid opening from inner canthus to outer canthus (fissure = opening)
Proptosis	Bulging of the eyes (exophthalmos)
Ptosis	Drooping of the upper eyelid
Strabismus	Cross-eyed; a condition where the eyes aim in different directions
Synophrys	An abnormal extension of the eyebrows so that they meet in the middle (midline)

response, and red reflex are the major components. During the examination, the newborn should be quiet, awake, and alert. Dimming the lights or a darkened room will assist with the pupillary assessment and the parts of the examination. Holding the infant upright can facilitate spontaneous opening of the eyes. It is important to protect the eye from injury and still evaluate as much of the eyes as possible. This requires a gentle opening of the eyes without stress on the infant and without scratching of the eyes. One hand is usually used to open the eyelids with two fingers, while the other hand holds the ophthalmoscope or light source. A second examiner is helpful during an examination of the eyes. Premature infant eye examinations may be delayed until approximately 32 weeks' gestation or longer for evaluation of the pupils and retina.

External Eye. Examination of the external features of the eye begins with inspection. Newborn eyes are examined for shape, symmetry, and size, as well as the presence of eyebrows and eyelashes. The eyes should appear clear, symmetric in size, and without discharge.

Eyelids. The eyelids are examined for movement, redness, swelling, colobomas, or other abnormalities. Infants with an inability to

TABLE 17.2

EXTERNAL EYE DIMENSIONS (TERM NEWBORN)

Interpupillary distance	33–46 mm (average 39 mm)
Inner canthal distance	13–26 mm (average 20 mm)
Palpebral width (medial to lateral canthus)	17–22 mm (average 18 mm)
Pupil size	2–4 mm
Cornea	9–10 mm

The eye—Part 1: Examination and common problems of the neonatal eye. In R. J. Martin, A. A. Fanaroff, & M. C. Walsh (Eds.), *Fanaroff & Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (10th ed., Table 103-2). Philadelphia, PA: Elsevier Saunders; and Scanlon, J. W., Nelson, T., Grylack, L. J., & Smith, Y. F. (1979). *A system of newborn physical examination.* Baltimore, MD: University Park Press.

open their eyelids or who have ptosis (drooping) of one or both eyelids can develop amblyopia and poor visual development. Infants must be able to view images on the retina during the first months of life for normal vision to occur (Pineles & Isenberg, 2016). Deprivation amblyopia due to drooping eyelids can lead to poor vision. The presence of unusual folds (e.g., epicanthal folds near the inner canthus) and the slant of the eye (upward or downward) should be noted.

Pupils. The pupils are examined for size, shape, symmetry, and reaction to light. An examination with an ophthalmoscope is indicated to check for red reflex. The color, clarity, and intensity of the red reflex should be checked and compared bilaterally. In dark-skinned infants, the red reflex may be more of a pale orange or gray rather than red (Johnson, 2015). It can be difficult to obtain a red reflex on premature infants under 28 weeks' gestation due to cloudy corneas, cloudy vitreous, and vasculature of the lens. A "white" reflex (leukocoria) would indicate a blockage of light getting to the retina. The differential diagnosis of leukocoria includes cataract, retinoblastoma, persistent hyperplastic primary vitreous, retinal detachment, ROP, uveitis, Peter's anomaly, and Coats' disease (Cagini, Tosi, Stracci, Rinaldi, & Verotti, 2017; de Alba Campomanes & Binenbaum, 2018). If dark spots are noted, this could be due to cataracts, retinal damage, or hemorrhage. A significant variation between the two eyes would need further retinal assessment. The onset of pupillary constriction in response to light is present by about 30 to 34 weeks' gestation. Interpupillary distance and pupil size can also be assessed (Table 17.2).

Cornea. The cornea is the clear layer covering the pupil and is examined for clarity and size (Table 17.2). **Emergency Alert: A cloudy cornea may be caused by congenital glaucoma, errors of metabolism, or congenital corneal dystrophy. This condition is almost always indicative of a serious eye problem.** Trauma at birth can result in injury to the cornea, giving the cornea a hazy appearance. Preterm infants may also have a transient haziness of the cornea during the first week of life.

Iris and Lens. The iris is examined for coloboma and color. The iris or eye color of dark-skinned Caucasian and African American infants is often darker due to earlier melanin deposition. The deposition of color in most infant eyes occurs by 6 months of age. Heterochromia is a color variation, where the two eyes are of different colors or it can be that there are two colors within the same eye. **Quality and Safety: Heterochromia can be a clue to the development of other disorders, including Sturge–Weber syndrome (with port-wine stain), Waardenburg syndrome, or Hirschsprung disease, and would indicate the need for further follow-up** (de Alba Campomanes & Bineebaum, 2018). The iris is examined for coloboma resembling a keyhole within the pupil. The presence of coloboma may also indicate a need to look for abnormalities in other systems also, for example, fetal alcohol syndrome (FAS). Infants with FAS can have colobomas, cataracts, and microphthalmos. The presence of these findings should alert the nurse to look for other features of the syndrome. The maternal history should also be reevaluated for alcohol use during the pregnancy.

The lens is located behind the iris. A cataract results in cloudiness or a white, opaque lens. A pediatric ophthalmologist needs to evaluate any cataract found in a newborn as soon as possible to determine if it is visually significant. Surgery would be performed to remove vision-threatening cataracts as soon as possible.

Sclera. The sclera is examined for color and hemorrhages. The sclera of term infants should be white in color. The infant sclera can take on a bluish white appearance in the premature infant due to the thinness of the sclera. **Quality and Safety: In term infants, a blue sclera is indicative of possible osteogenesis imperfecta.** Subconjunctival hemorrhages are frequently visualized on the sclera of normal, healthy term infants following a vaginal delivery due to the pressure changes throughout the birthing process. They present no significant long-term complication for these infants.

Eye Movements. It is also important to note the infant's eye movements during the examination. In the neonate, the location or position of the eyes varies with immaturity and/or activity. Many infants display deviations in eye movements, exhibiting exotropia, esotropia, or nystagmus (Table 17.1). These are types of eye wandering or twitching movements of the eye that occur in almost all infants and are considered normal. These eye movements should disappear within the first few months of life. Any persistent deviation needs to be evaluated.

Vision. The infant's vision can also be assessed immediately after birth. Infants will look around at objects in the environment. Newborns can follow an object when placed in front of them. A term newborn's vision is immature. Determining a newborn's visual acuity cannot be done easily and will not be discussed as an examination method in this textbook. But understanding of the infant's vision progression is necessary for caring for these infants. All newborns are born with some degree of myopia or nearsightedness and appear to see best at about 8 to 10 inches from their faces. Infants appear to enjoy highly contrasted (black and white) objects, especially faces in the environment (A. M. Brown, Lindsey, Cammenga, Giannone, & Stenger, 2015). Premature infants have a higher incidence of refractive errors, including myopia, hyperopia, and astigmatism (Kaya, Berk, & Yaman, 2017; Zhu et al., 2017). Premature infants also have anisometropia more commonly than term infants (Stewart, Hernandez, & Duncan, 2017). Many of these eye disorders are corrected with eye glasses.

Measurements. During an eye examination, it can be difficult to assess whether an eye is larger or smaller than normal. Therefore, certain measurements can be taken and compared with published data (Table 17.2). These measurements can be obtained during an eye examination. The interpupillary distance and the width of the palpebral fissure can be determined and abnormal values can indicate an underlying syndrome, for example, the small eyes of FAS. The interpupillary distance determines whether the eyes are spaced correctly. Hypotelorism and hypertelorism are abnormalities where the eyes are either too close together or widely spaced. The palpebral fissure is the eye opening and can be determined if the opening appears smaller than normal.

Retinal Examination. Although routine retinal examinations on all normal newborns are not indicated, a retinal examination or ophthalmology consult is indicated for the premature infant at risk for ROP or if physical examination findings suggest serious problems, such as cataracts or glaucoma. In addition, a retinal examination can be done with an ophthalmoscope and pupil dilation if needed to rule out abuse or trauma in older infants. About 26% to 32% of newborns born by spontaneous vaginal deliveries will have retinal hemorrhages at birth, most often bilateral, between the optic discs and the macula (Laghmari et al., 2014; Watts et al., 2013). The risk of retinal hemorrhage is greater with vacuum-assisted delivery (about 43%) and instrument-assisted deliveries with vacuum (about 52%; Laghmari et al., 2014; Watts et al., 2013). The incidence of retinal hemorrhage is decreased with an uncomplicated cesarean section (about 21%; Laghmari et al., 2014; Watts et al., 2013). Most retinal hemorrhages from birth resolve within 1 to 2 weeks; however, resolution of retinal hemorrhages may be delayed if labor was induced or forceps used for the delivery (Laghmari et al., 2014). **Emergency Alert: Shaken baby syndrome would need to be part of the differential diagnosis of retinal hemorrhage seen after a month or longer of age.**

Eye Drops. Specific eye drops are used routinely for dilating the eyes in newborns who require a retinal examination. These medications, which are adrenergic agonists (phenylephrine) and cholinergic antagonists (cyclopentolate), can be absorbed into the newborn's systemic circulation. Complications from dilatation medications need to be observed for in the premature or term infant undergoing a retinal examination. These systemic effects are hypertension, tachycardia, arrhythmias, feeding intolerance, and skin rashes (de Alba Campomanes & Binenbaum, 2018). As a result, intracranial and intraventricular hemorrhage (IVH), necrotizing enterocolitis, and other major insults can occur, especially in a premature infant.

Quality and Safety: To decrease absorption by the infant, excess medication needs to be readily cleaned away from the skin to prevent systemic absorption. Also, applying pressure to the lacrimal sac for about 1 to 2 minutes after instillation may minimize reabsorption (de Alba Campomanes & Binenbaum, 2018).

After a retinal examination, the infant's eyes should be shielded from light or covered with eye shields until the pupils return to normal size. Dilated eyes exposed to bright lights may cause pain, distress, agitation, apnea, or bradycardia (Wood & Kaufman, 2009).

NEONATAL CONJUNCTIVITIS

Neonatal conjunctivitis or ophthalmia neonatorum ("pink eye") is an eye infection or inflammation of the conjunctiva or covering of the eyes causing redness, swelling, and discharge within the first 30 days of life. It can occur due to bacteria, virus, or other pathogen, often in the vaginal canal at birth. Aseptic conjunctivitis can occur because of a chemical reaction to eye medication administered after birth, which rarely occurs with erythromycin ointment. The incidence of septic neonatal conjunctivitis with either gonorrhea or chlamydia in the United States is low (about 1%–2%). Chlamydial infection has replaced gonorrhea as the most common cause of eye infection in the United States and many other countries

(Zloto et al., 2016). Gonorrhea remains the most serious type of conjunctivitis in the United States. Septic neonatal conjunctivitis usually manifests with a discharge that develops shortly after birth. Because the origins of newborn conjunctivitis can vary, it is important to determine the exact cause of the infection. In some cases of conjunctivitis, rapid treatment is important to prevent vision loss.

The presentation of neonatal conjunctivitis varies with the cause of the inflammation or infection. Some findings, such as purulent eye discharge and erythema and edema of the eyelids, are present in almost all cases. Transient tearing or watery discharge may be noticed early in the infection process.

Eye Prophylaxis

Most of the United States requires prophylaxis against newborn gonorrheal conjunctivitis. **Quality and Safety: Erythromycin ophthalmic ointment (0.5%) is the only CDC-recommended therapy for prophylaxis of ophthalmia neonatorum available in the United States** (Mabry-Hernandez & Oliverio-Hoffman, 2010). Silver nitrate was first used as a prophylactic agent against ophthalmia neonatorum caused by the bacteria *Neisseria gonorrhoeae* and other bacteria in 1881. One drop of 1% silver nitrate into the eyes of newborns prevented gonococcal infection, corneal scarring, and possible blindness. During the early 1900s, many state legislatures passed laws requiring physicians to treat all newborns with a silver nitrate solution. Although penicillins were discovered in the late 1940s, silver nitrate continued to be used as the main prophylactic agent until the mid-1990s. Silver nitrate was effective against *N. gonorrhoeae* and most bacteria; however, it was not effective against *Chlamydia* organisms. For this reason, erythromycin ointment is now used for routine prophylaxis in newborn eyes after birth. Erythromycin and tetracycline ointments are both effective against a variety of microorganisms, including chlamydia and gonorrhea, but must be inserted into the eye and must be done soon after birth to prevent gonorrhea from invading the eye (American Academy of Pediatrics [AAP], 2018; de Alba Campomanes & Binenbaum, 2018).

Chlamydial Conjunctivitis (Inclusion Conjunctivitis)

Chlamydia trachomatis is the most common cause of conjunctivitis in the newborn. The bacteria are transmitted from the infected mother to the infant at birth, and conjunctivitis may appear at about 5 to 7 days of life (de Alba Campomanes & Binenbaum, 2018). The condition may be mild or moderate, and with proper treatment it resolves within 6 weeks. Pneumonitis or a chlamydial pneumonia can occur with the conjunctivitis. Clinical symptoms of conjunctivitis include swelling of the eyelids and a mild mucopurulent discharge. Chronic infection can lead to more serious consequences, such as conjunctival scarring, adhesions of the eyelid, and deposits of connective tissue under the cornea.

Although the eye infection generally is not serious, a chlamydial pneumonitis can develop in some infected neonates. Systemic therapy with oral erythromycin for 3 weeks is often necessary to eradicate the organism from the respiratory tract.

Gonorrheal Conjunctivitis

Routine prophylaxis of newborns has greatly reduced the incidence of gonorrheal conjunctivitis. Because of the potential for blindness from this infection, early detection and prompt treatment are critical. Gonorrheal conjunctivitis typically manifests as an acute, purulent, bilateral conjunctivitis with eyelid edema. **Quality and Safety: If not treated appropriately and quickly, the infection may progress to corneal ulceration, endophthalmitis, and perforation of the globe** (de Alba Campomanes & Binenbaum, 2018). Gram stains and cultures should be performed routinely in all cases of neonatal conjunctivitis. The presence of *N. gonorrhoeae* confirms the diagnosis. Treatment consists of administration of intravenous or intramuscular antibiotics and application of topical antibiotics to the eye.

Staphylococcal Conjunctivitis

Staphylococcal conjunctivitis is a bacterial infection usually acquired during vaginal delivery or by contact with an infected individual. Symptoms normally appear about 2 to 4 weeks after birth. In most cases, the conjunctivitis is mild and produces a purulent discharge. It may progress to corneal ulceration, endophthalmitis, or generalized skin infection. The diagnosis is made with cultures and Gram stain. Because staphylococci can be found in the conjunctiva of healthy neonates, laboratory results should be interpreted cautiously. Treatment includes application of topical antibiotic ointment and cleansing of exudate from the eyelids.

Herpes Simplex Conjunctivitis

Herpes simplex infection at birth may be a feature of either localized or systemic disease. The newborn usually is infected during passage through the birth canal. Infants with herpes conjunctivitis exhibit eyelid swelling, inflammation, and corneal opacification. The onset of the conjunctivitis usually occurs about 2 to 14 days after birth. The disseminated form of the disease may also lead to chorioretinitis, microphthalmia, cataracts, optic atrophy, apnea, respiratory distress, and death (James & Kimberlin, 2015). This disease should always be kept in mind when the mother or father has a history of genital herpes. Treatment should be instituted immediately upon diagnosis. Systemic treatment (intravenous) is necessary for infants whose conjunctivitis has spread to be a systemic infection.

Infectious Conjunctivitis Caused by Other Microorganisms

There have been some case reports describing neonatal infectious conjunctivitis caused by other more unusual microorganisms. This is a rare occurrence but has been seen with a term infant readmitted at 10 days of age with conjunctivitis caused by *Neisseria meningitidis*, a gram-negative meningococcal disease (Chacon-Cruz et al., 2017). These infants require local and systemic treatment. *Neisseria meningitidis* can cause a serious, systemic infection with significant morbidity and mortality, and needs to be considered with an ill infant with a purulent conjunctivitis.

Premature infants in the neonatal intensive care units (NICUs) frequently are colonized with *Pseudomonas aeruginosa* or a variety of *Candida* species. These infants often will develop a purulent mucus discharge from the eyes. The infants may also develop simultaneous systemic infections. Eye involvement usually is limited to chorioretinitis that resolves with systemic antifungal therapy. Very low birth weight infants are at risk for more serious and deadly complications of any infection. Conjunctivitis has also occurred in the preterm infant with coagulase-negative *Staphylococcus*, *Klebsiella pneumoniae*, *Escherichia coli*, methicillin-susceptible or -resistant *Staphylococcus aureus*, *Enterococcus* species, and with various types of viruses.

LACRIMAL DYSFUNCTION

Obstructed Nasolacrimal Duct

Blockage of the nasolacrimal duct occurs when the duct fails to canalize at the entrance to the nose, leaving a thin membrane. This blockage occurs in about 5% of all newborns and is a common

cause of chronic conjunctivitis in infants (de Alba Campomanes & Binenbaum, 2018). After a month of age, the infant shows excessive tearing and mucus discharge in the inner canthal region. Pressure on the lacrimal sac area usually causes pus or mucus to exude from the opening. Because the problem resolves spontaneously in most affected infants by 6 months of age, conservative treatment involving lacrimal massage and application of topical antibiotics is recommended. Dacryocystitis can occur as a result of this temporary obstruction. Dacryocystitis is a secondary infection of the lacrimal sac. Obstruction that lasts beyond 6 to 12 months may require lacrimal probing. Nasolacrimal duct blockage should be differentiated from other causes of conjunctivitis, a foreign body on the eye, or corneal injury.

Mucocele

Mucoceles occur because of the one-way valve effect at the end of the nasolacrimal duct. Mucus accumulates or amniotic fluid is trapped in the nasolacrimal sac, and the infant develops a bluish mass in the inferomedial region of the eyelid. This swelling most often is confused with a hemangioma. If simple massage does not decompress the mucocele, probing of the nasolacrimal duct may be necessary.

CONGENITAL DEFECTS

Aniridia

Aniridia is a severe ocular abnormality that manifests as a bilateral absence of the iris. Cataracts, corneal pannus (fine blood vessel growth on the cornea), macular dysfunction, and glaucoma usually accompany the defect. Most of these infants have significantly diminished visual acuity. Aniridia can be caused by a deletion of a part of chromosome 11. Some children with aniridia develop Wilms' tumor during childhood due to the Wilms tumor gene is close to the aniridia gene location and these defects can occur together (Örge & Grigorian, 2015).

Persistent Hyperplastic Primary Vitreous

Persistent hyperplastic primary vitreous is a unilateral disorder that affects both genders equally. It results from persistence of the hyaloid vessels that connect the optic nerve and the posterior surface of the lens during fetal development. It should be considered in the differential diagnosis of leukocoria. The involved eye is usually small with an absent red reflex. Surgery may improve the integrity of the eye, and useful vision is sometimes restored.

Capillary Hemangioma of the Eyelid

Capillary hemangiomas are relatively common in newborns and tend to occur on the eyelids and nape of the neck. They are sometimes referred to as salmon patches or stork bites. They usually disappear over time and require no treatment. The larger and deeper strawberry hemangiomas tend to enlarge, stabilize, and then regress by the time the child is between 5 and 10 years old. These hemangiomas are usually elevated and reddish purple at their peak size. There are also larger and deeper hemangiomas called cavernous hemangiomas, which usually grow under the skin. No treatment is usually necessary, but it would depend on the location of the growth. Superficial tumors of the eyelid may cause cosmetic and visual problems. Parents often are concerned with hemangiomas on the face and want them removed, but no treatment is the best option to prevent scarring. Pressure on the eye from the tumor may result in significant astigmatism and subsequently amblyopia. Hemangiomas may be treated with surgical removal, radiation, or steroid injections. Tumors that are exclusively cosmetic should be allowed to regress without intervention.

Another type of hemangioma is called the port-wine stain, because of its dark purple pigmentation and location on the face. It is also called nevus flammeus and is associated with Sturge–Weber syndrome. These birth marks are extensive and usually removed with laser therapy.

Ptosis

Ptosis is a drooping of one or both eyelids due to neurologic, muscular, or mechanical factors. If the ptosis is significant enough to cover the pupil, amblyopia may result. If bilateral ptosis is present, the infant may have slowed motor development and delayed ambulation later in life. Congenital ptosis is usually caused by an abnormality in the development of the levator palpebrae muscle, but other causes can be third nerve palsy, Horner's syndrome, and blepharophimosis syndrome (de Alba Campomanes & Binenbaum, 2018). A thorough family history should be obtained as well as ruling out birth trauma to the cervical ganglion. Direct trauma to the eyelid or a tumor in the eyelid may also cause ptosis. Surgical repair corrects this defect.

Congenital Glaucoma

Primary congenital glaucoma occurs when there is a rise in the intraocular pressure causing enlargement of the eye with a cloudy cornea. This increased pressure results in damage to the optic nerve. Glaucoma is rare in newborns but because of the potential for blindness, glaucoma must be detected early and treated. The newborn shows tearing, light sensitivity, eyelid spasm, and a large, cloudy cornea. The diagnosis is often missed until the child is about 2 to 3 months of age. Conditions associated with glaucoma include trisomy 21, congenital rubella, Marfan syndrome, neurofibromatosis, oculodentodigital syndrome, Rieger's syndrome, Sturge–Weber syndrome, Rubinstein–Taybi syndrome, and Weill–Marchesani syndrome (Örge & Grigorian, 2015).

Emergency Alert: It is critical that congenital glaucoma be differentiated from other diseases that have similar symptoms. Nasolacrimal duct obstruction involves tearing but does not cause light sensitivity or a cloudy cornea. Difficult labor or forceps injury may damage the cornea and cause temporary clouding, but the intraocular pressure is not elevated, a hallmark feature of glaucoma. The large eyes of the infant with congenital glaucoma may appear beautiful to the parents, but health professionals should be alert to the possibility of this disease.

The abnormality in congenital glaucoma is a deformity of the filtering system that controls the level of intraocular pressure in the eye. Congenital glaucoma is treated surgically. The results usually are good, but parents must be educated about the need for continued monitoring of this condition throughout the child's life.

Congenital Cataracts

The causes of significant lens opacity in the newborn are numerous. Cataracts are an important cause of blindness because they may interfere with the process of visual development early in the infant's life. For this reason, visually significant cataracts must be detected and treated before they cause amblyopia, which may be unresponsive to the most persistent treatment.

Heredity is an important cause of congenital cataracts. A thorough family history is critical in determining the cause of the lens opacity. The inheritance pattern may be autosomal dominant, autosomal recessive, or sex linked. A maternal history of diabetes, x-ray exposure, or malnutrition may be an important factor in cataract formation. In premature infants, transient cataracts or insignificant opacities are commonly seen as a result of

remnants of developmental tissues. ROP can also lead to cataracts in premature infants. Several inborn errors of metabolism cause cataracts, including galactosemia, Alport syndrome, Fabry disease, and Lowe syndrome. Intrauterine rubella infection is also associated with cataracts in the neonate.

Cataract surgery early in life is critical to the infant's visual rehabilitation. Useful vision is especially difficult to achieve in eyes with monocular cataracts. It is important for nurses to work closely with the infant's parents. The parents' persistence in handling contact lenses and in amblyopia therapy often determines the outcome for their child's vision.

Retinoblastoma

Retinoblastoma is a rare disorder, but also the most common eye neoplasm in childhood. Most tumors occur sporadically without a family history of the disease in approximately 1 in 14,000 to 18,000 live births in the United States (de Alba Campomanes & Bininbaum, 2018). Most retinoblastomas occur unilaterally with only about 25% bilateral, and most children are diagnosed before their second birthday (de Alba Campomanes & Bininbaum, 2018).

Quality and Safety: The most common presenting symptom is leukocoria. The tumor is highly malignant and may spread to the bone marrow, central nervous system (CNS), or other organs. Untreated patients rarely survive. The standard treatment for advanced cases of retinoblastoma is enucleation (removal of the eye). Less severe cases are treated with radiation, laser photocoagulation, or cryotherapy. Children with this tumor require close follow-up for possible recurrence after treatment. Parents must be educated about the disease so that they are aware of the need for constant monitoring of their child.

CONGENITAL INFECTIONS

Cytomegalovirus Infection

Most infants with congenital CMV will be asymptomatic. But in infants with symptomatic disease, ocular lesions may include chorioretinitis, optic nerve atrophy, strabismus, cataract, macular scarring, and visual impairment or blindness. Many infants with symptomatic CMV disease will have moderate to severe visual impairment (Khahaeni, 2017). Parents should be advised to seek routine eye screenings during childhood and later in life.

Rubella

Congenital rubella or German measles has virtually been eliminated in the United States due to its vaccination program, but the virus can still be found in other parts of the world; therefore, with international travel and parents withholding vaccinations, rubella may return. The rubella virus is responsible for many eye complications including cataracts, glaucoma, and microphthalmia, often together. The majority of newborns with congenital rubella have hearing, eye, and cardiac defects. Parents of a child with congenital rubella need to understand that vision problems may occur at any time and their child must be screened regularly.

Herpes Simplex Virus

Herpes simplex virus causes a wide variety of eye disorders in newborns. Though skin vesicles are the main sign of a herpes virus infection in the newborn, eye damage and CNS manifestations can also occur (Purewal et al., 2016). Other eye conditions that can be seen with a herpes virus infection are conjunctivitis, chorioretinitis, and cataracts (de Alba Campomanes & Binenbaum, 2018).

Varicella

Although rare, congenital infection caused by varicella, commonly known as chickenpox, produces eye anomalies in more than half of affected infants. These defects include microphthalmia, chorioretinitis, cataract, optic nerve atrophy, nystagmus, and anisocoria (unequal pupils; Mandelbrot, 2012).

Toxoplasmosis

Toxoplasma gondii is a parasitic organism with an affinity for brain and eye tissue. As with many other congenital infections, ocular anomalies vary depending on fetal age at the time of infection. The most common clinical presentation is chorioretinitis (often bilateral). Chorioretinitis is part of the classic triad of congenital toxoplasmosis with hydrocephalus and intracranial calcifications. Other ocular manifestations that can occur in the newborn are microphthalmia, strabismus, retinal detachment, and blindness (McAuley, 2014).

Lymphocytic Choriomeningitis Virus

Another viral infection, lymphocytic choriomeningitis virus (LCV), can also cause ocular defects. LCV is a single-strand RNA virus found in rodents, including house mice and hamsters. Outbreaks of LCV infection associated with mice tend to occur in trailer parks, inner-city dwellings, and substandard housing. The virus probably is transmitted by airborne droplets and by food contaminated by rodent urine or feces. It may also be transmitted by the bite of an infected animal (Kinori, Schwartzstein, Zeid, Kurup, & Mets, 2018).

Congenital LCV results in many ocular findings, including generalized chorioretinitis leading to scarring, optic nerve atrophy, nystagmus, and strabismus. Eye abnormalities may be the first or only manifestation noted initially with this viral infection (Kinori et al., 2018). Newborns with congenital infection are at significant risk for neurologic damage and death.

RETINOPATHY OF PREMATURITY

ROP, a disease arising from proliferation of abnormal blood vessels in the newborn retina, was first reported by Terry in 1942. His description of a fibrous growth behind the lens and retinal detachment in premature infants gave birth to the name retrolental fibroplasia (RLF). The name was changed to ROP in 1984 by an international committee charged with providing a uniform classification system for the disease. The original classification system, International Classification of Retinopathy of Prematurity (ICROP), used a standard description of the location of retinopathy (using zones and clock hours), the severity of the disease (stage), the presence of special risk factors (plus disease), and the features of regression (International Committee for the Classification of Retinopathy of Prematurity, 2005; Figure 17.2 for zone diagram).

In 2005, the International Committee for the Classification of ROP published updates to the original ICROP. Three changes to the ICROP were introduced: (a) recognition of a more virulent form of ROP, aggressive posterior ROP (AP-ROP); (b) an intermediate grade of plus disease (pre-plus) that occurs between normal posterior pole vessels and frank plus disease; and (c) a clinical tool for estimating the extent of zone I involvement.

AP-ROP is defined as a rapid, progressive form of ROP that quickly progresses to stage 5 ROP if left untreated. Characteristics of AP-ROP include posterior location and prominence of plus disease, usually in zone I, but may be in posterior zone II. Because of the aggressive nature of this disease, the diagnosis of AP-ROP is

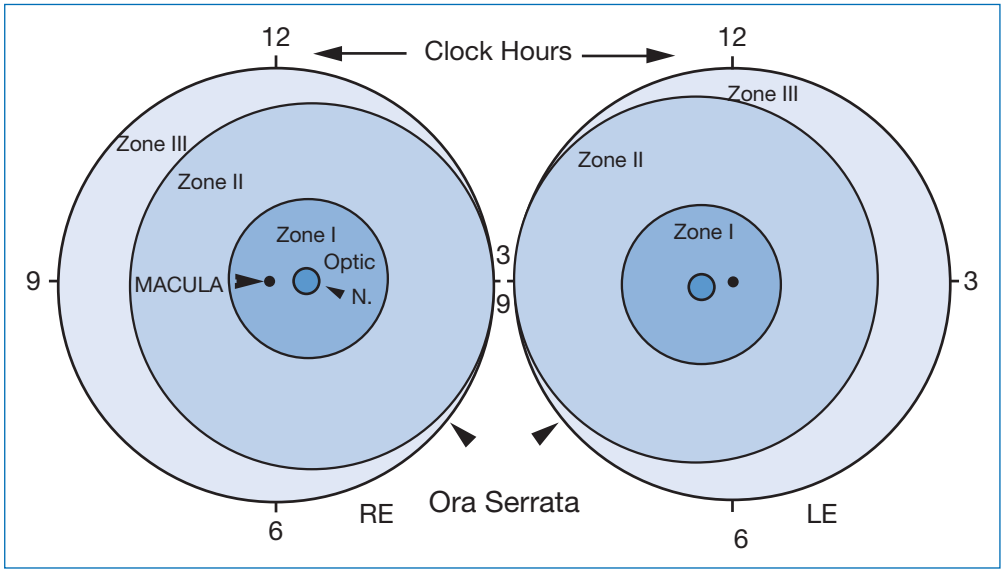

FIGURE 17.2 Diagram of zones of the eyes.

normally made during a single examination. The diagnosis of plus disease was modified from the presence of vascular dilatation and tortuosity in two to four quadrants. The new recommendations also included adding the + symbol after the ROP stage number to designate the presence of plus disease (e.g., stage 3+). The new term of pre-plus disease was defined as vascular abnormalities of the posterior pole that are insufficient for the diagnosis of plus disease but that demonstrate more arterial tortuosity and more venous dilatation than normal.

The 1986 multicenter CRYO-ROP trial led to the definition of threshold and prethreshold ROP. Threshold disease was considered the minimum disease needed for treatment. The 2000 to 2002 multicenter ET-ROP trial results substituted type 1 and type 2 as the equivalent but newly defined intervention and pre-intervention point. Type 1 is defined as zone I, any stage ROP with plus disease; zone I, stage 3 ROP without plus disease; or zone II, stage 2 or 3 with plus disease. Type 2 ROP is defined as zone I, stage 1 or 2 ROP without plus disease; or zone II, stage 3 ROP without plus disease (Reynolds, 2010).

ROP was responsible for an epidemic of blindness in young children in the 1940s and early 1950s until the link to supplemental oxygen therapy was made in 1952. Subsequently, the practice of limiting oxygen administration in the care of premature infants led to the near disappearance of the disorder; however, cerebral palsy and death increased. Improvements in neonatal healthcare in the past 35 years have increased the survival of tinier and sicker infants. As technology helped these smaller infants survive, the rate of ROP rose. The younger the gestational age and the lower the birth weight, the stronger the correlation with incidence of ROP (Drack, 2006). Results from the CRYO-ROP, LIGHT-ROP, and ET-ROP multicenter trials revealed that ROP occurs in 65% to 70% of premature infants with birth weights of 1,250 g or less (ET-ROP, 2003, 2005; Reynolds, 2010; Reynolds et al., 2002).

Pathophysiology

ROP is a disease caused by an abnormal adaptation of normal maturational processes in the face of physiologic stress. The disease develops gradually and is divided into five stages of increasing clinical severity (Table 17.3). Some ophthalmologists use the term stage 0 if the retina's vascularity is immature.

The key factor in the development of ROP, especially in premature infants, is the developing retinal blood vessels. The pathophysiology of ROP occurs in two phases. Phase I is delayed growth of the retinal vascularity following preterm birth. Phase II occurs when the hypoxia created during phase I stimulates the growth of new blood vessels (Smith, 2003). Retinal vascularization begins at the optic nerve at about 16 weeks' gestation. Retinal vascular development proceeds slowly and reaches the retinal periphery (ora serrata retinae) during the ninth month of gestation (Chen & Smith, 2007). The incompletely vascularized retina has a peripheral avascular zone that varies with the degree of immaturity of the retina (Smith, 2003). The in utero growth of retinal blood vessels is stimulated by the release of vascular endothelial growth factor (VEGF) and insulin-like growth factor-1 (IGF-1). VEGF is found at the front line of the growing retinal blood vessels, whereas IGF-1 is maintained at a constant level in the retina microenvironment. VEGF is a cytokine regulated by the amount of oxygen (hypoxia). IGF-1 is a nonoxygen-regulated cytokine involved in the regulation of endothelial cell survival and proliferation (Smith, 2004).

Following preterm birth, the normal growth of the retina vascularity stops and some of the already developed vessels are lost. The retina, however, remains metabolically active and becomes hypoxic because of the lack of blood vessels. This hypoxia becomes a potent inducer of new vessel growth (neovascularization) by stimulating the expression of VEGF at 32 to 34 weeks postmenstrual age. As the new blood vessels proliferate, they tend to grow into the vitreous and cause bleeding and the formation of fibrous tissue (Smith, 2003).

Many preterm infants in the NICU receive supplemental oxygen to treat their respiratory distress. The hyperoxia caused by oxygen use suppresses VEGF and IGF-1, resulting in programmed cell death, or apoptosis, of vascular endothelial cells, which in turn causes hyperoxia-induced vaso-obliteration and scarring of the retinal vessels (Smith, 2004).

As the preterm infant matures, the growing retina triggers a release of VEGF; IGF-1 levels will also rise. This creates an environment for new vessel growth (neovascular proliferation) that leads to the progression of retinopathy (Smith, 2003). Milder degrees of ROP are often transient and regress once the abnormal stimuli are removed or corrected. Moderate retinopathy can lead to excessive fibrous tissue formation or scarring in the peripheral retina, which may lead to traction on the macula and reduced vision. In severe

TABLE 17.3

STAGES OF RETINOPATHY OF PREMATURITY WITH POSSIBLE OUTCOMES

Stage	Finding	Possible Outcome
1	Demarcation line at avascular retina	Complete resolution probable
2	Ridge with height and width	May resolve
3	Ridge with fibrosis extending into vitreous	May resolve; prevention of detachment needed if plus disease
4	Partial retinal detachment with or without macula/fovea area involved	Visual impairment
5	Complete retinal detachment	Visual impairment/blindness
Pre-plus disease	Some increased tortuosity of retinal vessels	May resolve
Plus disease	Increased dilation and tortuosity of retinal vessels in two or more quadrants	Increased risk of impaired vision
Type 1 ROP	Zone I = any stage ROP with plus disease or stage 3 ROP without plus disease Zone II = stage 2 or 3 ROP with plus	Higher risk of impaired vision
Type 2 ROP	Zone I = stage 1 or 2 ROP without plus Zone II = stage 3 ROP without plus	Lower risk of impaired vision

ROP, retinopathy of prematurity.

cases of ROP, fibrous tissue development may lead to retinal detachment and blindness. Severely affected neonates may also have leukocoria, glaucoma, or both.

Risk Factors

ROP is a multifactorial disease that occurs primarily in premature infants. Although many risk factors have been identified, prematurity and low birth weight remain the most important factors leading to the development of ROP (Allegaert, deCoen, Devilieger, & EpiBel Study Group, 2004; Reynolds, 2010). The incidence of ROP strongly correlates with birth weight and gestational age at birth. ROP is twice as common in infants born at less than 750 g than infants born between 1,000 and 1,250 g (Reynolds, 2010). Even more dramatic, these two groups have a sevenfold difference in the incidence of threshold ROP.

Other epidemiologic facts include a higher risk of ROP in White infants than Black infants, infants born at outlying hospitals that require transport to a Level III NICU, and infants of multiple births (Reynolds, 2010). Other risk factors are associated with the management of the extremely preterm infant: supplemental oxygen, fluctuating oxygen saturations, continuous positive pressure ventilation, IVH, acidosis, blood transfusions, maternal preeclampsia, and intrauterine growth restriction (IUGR; Allegaert et al., 2004; Anderson, Benitz, & Madan, 2004; Darlow et al., 2005; Reynolds, 2010; York, Landers, Kirby, Arbogast, & Penn, 2004).

According to Chow, Wright, Sola, and the CSMC Oxygen Administration Study Group (2003), the rate of severe, stage 3 and 4 ROP was reduced from 38% to 12% in infants with a birth weight less than 750 g by strictly maintaining oxygen saturations between 85% and 95% (and between 83% and 93% on the smallest infants). The studies that keep oxygen saturations in the low 90% level can reduce the rate of severe ROP significantly (Drack, 2006). Recently, the BOOST II Collaborative Group (2013) published data showing a lower mortality rate in infants less than 28 weeks who were kept in lower oxygen (with saturations <90%) compared with infants whose saturations remained higher than 90%. Their study shows that even though the rates of ROP can be lowered with lowered oxygen saturations, the higher risk of death in these tiny infants must also be considered. Therefore, many NICUs are now keeping oxygen saturation levels of the extremely premature infants in the low 90s.

Other factors such as breast milk feedings and the use of nitric oxide in the treatment of respiratory distress in preterm infants may provide some protection against the development of ROP. Hylander, Strobino, Pessullo, and Dhanireddy (2001) found that preterm infants weighing less than 1,500 g at birth who received human milk feedings had a lower incidence of ROP when compared with preterm infants who were formula fed. The positive benefit of human milk feeding remained after adjusting for confounding variables such as birth weight, race, and duration of oxygen therapy. Mestan, Marks, Hecox, Huo, and Schreiber (2005) reported that treatment with nitric oxide improved the neurodevelopmental outcomes of preterm infants at 2 years of age. The incidence of severe ROP was 24% in the nitric oxide group and 46% in the placebo group of preterm infants.

Although most ROP occurs in premature infants, rare cases of the disease have been reported in full-term infants, stillborn infants, and infants who have not received supplemental oxygen. In several studies, variations in the Norrie disease gene, a gene responsible for an X-linked form of congenital retinal detachment or dysgenesis, were more common in infants with severe ROP than in those in whom the disease resolved on its own. Each individual carries genetic predispositions to certain disorders, but less understood are the genetic proclivities toward outside effects—trauma, hypoxia, and premature birth among them (Drack, 2006). Further research is needed to increase our understanding of the cause and the pathophysiology of this disease.

Treatment

Treatment of ROP can be divided into three categories: preventive, interdictive, and corrective. Until premature birth can be eradicated, the major focus of ROP treatment is early detection and appropriate follow-up of significant disease. Despite the international effort to standardize ROP and the efforts of the several multicenter, randomized clinical trials, no universally accepted guidelines exist for the screening of premature infants. Screening protocols vary from institution to institution, among different countries, and even with the level of development of the countries (Table 17.4; Fierson & AAP, 2018; Jefferies, 2016; Royal College of Ophthalmologists, 2008).

According to Roth et al. (2001), indirect ophthalmoscopy by an experienced ophthalmologist in the NICU has traditionally been considered the standard method for detection of ROP. These examinations can be physiologically stressful for the infants, time consuming for the ophthalmologist, and costly for the medical system. A mydriatic agent (e.g., phenylephrine 2.5%, cyclopentolate 0.5%, or tropicamide 0.5%) is instilled topically for pupil dilation approximately 30 to 45 minutes prior to the examination. A topical anesthetic, such as 0.5% proparacaine HCl ophthalmic solution, should be instilled in each eye, to dull the corneal and conjunctival sensitivity and decrease the newborn's pain before the examination. A lid speculum and a sclera depressor, individually sterilized for each infant's examination, is used to visualize the peripheral retina and ora serrata, the anterior border of retinal vascularization, or retinopathy (Figure 17.3). Examinations are performed with the binocular indirect ophthalmoscope and 30-diopter lens, first evaluating the posterior pole and then the periphery with sclera depression. The presence or absence of ROP disease, its location and extent, and the presence or absence of plus disease are documented at the time of examination according to the international classification of ROP.

A wide-field digital camera (RetCam) is being used as an alternative to indirect ophthalmoscopy for screening infants for ROP. Retinal images taken by the camera can be stored, transmitted to an expert, reviewed, analyzed and sequentially compared

TABLE 17.4

RETINOPATHY OF PREMATURITY SCREENING GUIDELINES

Recommending Group	Infant Criteria	First Examination Date	
American Academy of Pediatrics American Academy of Ophthalmology American Association of Pediatric Ophthalmology and Strabismus	• Birthweight <1,500 g or gestational age ≤30 weeks • Selected infants between 1,500 and 2,000 g with an unstable clinical course	*GA @ birth*	*Age at initial examination*
		22 weeks	9 weeks
		23 weeks	8 weeks
		24 weeks	7 weeks
		25 weeks	6 weeks
		26 weeks	5 weeks
		27–32 weeks	4 weeks
Canadian Pediatric Society Canadian Association of Pediatric Ophthalmologists	• Birthweight ≤1,250 g OR • Gestational age ≤30 6/7 weeks	• ≤26 6/7 weeks @ birth, age at initial examination should be @ 31 weeks PMA • ≥27 weeks @ birth, infant should be 4 weeks chronologic age	
Royal College of Ophthalmologists	• Birthweight <1,501 g or <32 weeks at birth SHOULD be screened • Birthweight <1,251 g or <31 weeks at birth MUST be screened	• <27 weeks @ birth, initial examination should be @ 30–31 weeks PMA • 27–32 weeks @ birth, initial examination should be @ 4–5 weeks chronologic age • >32 weeks @ birth, but with birth weight <1,501 g, initial examination should be @ 4–5 weeks chronologic age	

ROP, retinopathy of prematurity.

Sources: Adapted from Fierson, W. M., & American Academy of Pediatrics Section on Ophthalmology, American Academy of Ophthalmology, American Association for Pediatric Ophthalmology & Strabismus, American Association of Certified Orthoptists. (2018). Screening examination of premature infants for retinopathy of prematurity. *Pediatrics, 142*(6), e20183061.

FIGURE 17.3 Premature infant during eye examination undergoing indirect ophthalmoscopy using eyelid speculum and sclera depressor.

FIGURE 17.4 Premature infant during retinal evaluation using the RetCam.

over time, and are useful for telemedicine purposes (Chawla et al., 2012). The same eye drops must be utilized to dilate the pupils and anesthetize the area. The eyelid speculum is also used, but the scleral depressor is not needed. A water-soluble gel is applied to serve as a barrier between the eye and the lens.

Timing for eye examinations can be frustrating for not only the NICU staff, but also for the ophthalmologist. Often, the ophthalmologist may arrive to examine an infant when the infant is due to eat, or the infant has just completed his feed, or during the infant's scheduled "quiet time." Use of the RetCam allows examinations to be scheduled at the convenience of the NICU staff, are less traumatic to the infant, and provide for permanent documentation through the digital images (Roth et al., 2001; Figure 17.4).

Oxygen monitoring has been the major emphasis in the prevention of ROP. Elaborate policies and practices for continuous monitoring of oxygenation have evolved over the years, including evasive methods (fiberoptic umbilical catheters) and noninvasive techniques (transcutaneous oxygen monitoring, and pulse oximetry). Despite these efforts, little data indicate a safe level of oxygenation in premature infants at risk for ROP (Saugstad, 2005). Early efforts at restricting oxygen delivery in the 1950s and 1960s traded visual problems for neurologic sequelae. Recent practice changes are aimed at minimizing oxygen exposure while preserving optimum functioning of vital organs. Further research is being done to determine appropriate strategies.

Environmental lighting in NICUs has been implicated as a contributing factor in the development of ROP. Although some clinical studies claimed to show this relationship, they had many limitations. A large multicentered, randomized controlled trial (RCT) was completed and published in 1998, which showed that there was no statistically significant difference between the infants exposed to ambient lighting and those wearing light-reduction goggles during their first few weeks of life (Reynolds et al., 1998). Despite this evidence, many NICUs continue to institute reduced environmental lighting and shielding of incubators as part of a developmental approach to care.

The second strategy for treating ROP focuses on therapies aimed at minimizing or preventing blindness once the disease has developed. Interdictive therapies include cryotherapy, laser photocoagulation, and/or treatment with anti-VEGF drugs (Shah et al., 2016).

Cryotherapy was developed in Japan in the 1970s. It gained popularity in the United States in the 1980s after the release of data from the Cryotherapy for ROP Study. Cryotherapy is a surgical procedure involving insertion of a probe cooled with liquid nitrogen on the medial aspect of the eye. Confluent spots on the avascular retina are ablated (destroyed by freezing), reducing the release of angiogenic factors that appear to induce retinal vasoproliferation.

Transpupillary laser photocoagulation delivered through an indirect ophthalmoscope has essentially replaced cryotherapy as the treatment of choice for ROP (Coats & Reddy, 2009). Argon and infrared diode lasers are used to ablate the avascular retina in a manner similar to that used in cryotherapy. Advantages of the laser photocoagulation therapy include the technical ease of performance and its usefulness in posterior ROP that was difficult to treat with cryotherapy, and requires less eye manipulation. In addition, it is less traumatic for the patient, and there are fewer delayed consequences of myopia and retinal detachment. Using cost-utility analysis, healthcare economists have determined that laser ablation surgery for threshold ROP is cost effective (M. M. Brown & Brown, 2005; M. M. Brown, Brown, & Sharma, 2004).

Treatment can be performed in either the operating room or within the NICU. Sedation and either retrobulbar anesthesia or general anesthesia can be utilized, dependent on the preferences of the ophthalmologist and anesthesiologist, and the medical condition of the infant. Major potential complications of laser treatment include diminished peripheral vision, intraocular bleeding, cataract formation, myopia, and retinal detachment (Coats & Reddy, 2009). A known side effect of laser ablation therapy is angle-closure glaucoma in infants with severe ROP (Trigler, Weaver, O'Neil, Barondes, & Freedman, 2005).

Results of multicenter clinical trials suggest that earlier treatment of ROP is more important than the type of treatment. The Early Treatment for ROP (ET-ROP) clinical trial found that unfavorable outcomes at the 9-month follow-up appointment were significantly reduced in the early treatment of eyes (ET-ROP Cooperative Group, 2003). Both cryotherapy and laser photocoagulation were used in the clinical trial, and the study group recommended retinal ablation therapy "for any eye with type 1 ROP" and serial examinations for those with type 2 ROP. In another study comparing early versus conventional treatment of prethreshold disease, no significant differences were noted in the prevalence of myopia (Davitt et al., 2005). Thus, it appears that early treatment of ROP is beneficial to the infant.

Research with anti-VEGF drugs has revealed a new treatment for ROP that is showing promising results. The U.S. Food and Drug Administration (FDA) approved the use of bevacizumab for the treatment of metastatic colorectal cancer in 2004. The drug was shown to reduce the size and number of new vessels feeding the area of metastasis. Off-label use of bevacizumab for the treatment of neovascular ophthalmologic diseases began shortly thereafter (Hård & Hellström, 2011).

According to Mintz-Hittner, Kennedy, Chuang, and BEAT-ROP Cooperative Group (2011), bevacizumab (Avastin) is relatively inexpensive and is available for recommended use in infants with zone I posterior stage 3+ disease. Administration of the drug decreases the high levels of VEGF in the vitreous gel, which are not reduced by conventional laser therapy. Development of peripheral retinal vessels continues after treatment with intravitreal bevacizumab, whereas conventional laser therapy leads to the permanent destruction of the peripheral retina. Compared to laser ablation surgery, where the infant requires intubation and where there is known peripheral field loss and possibly myopia, the use of bevacizumab is relatively benign; anesthesia is achieved through topical drops. The drug is administered intravitreally. Using a tiny needle. Ocular inflammation has been observed after seven or more injections of the drug.

There are other FDA-approved drugs for eye injections, such as ranibizumab (Lucentis), aflibercept (Eylea), and pegaptanib (Macugen), also are being studied and used as ROP treatments. Intravitreal bevacizumab reduces the risk of refractive errors during childhood when used as monotherapy while intravitreal pegaptanib reduces the risk of retinal detachment when used in conjunction with laser therapy in infants with type 1 ROP. However, the long-term systemic adverse effects of these drugs are not known (Sankar, Sankar, Mehta, Bhat, & Srinivasan, 2016).

VEGF plays many positive roles in neural, vascular, and lung development. Bevacizumab has been shown to leak into the systemic circulation, suppressing systemic VEGF at least 8 weeks after injection, which may cause changes in brain and other organ development in very preterm infants (Shah et al., 2016). There are also concerns for recurrence of ROP after bevacizumab injection much later when compared with conventional laser peripheral retinal ablative therapy (16 ± 4.6 vs. 6.2 ± 5.7 weeks), requiring longer follow-up to ensure ROP requiring treatment does not recur (Mintz-Hittner et al., 2011).

According to the CARE-ROP study, ranibizumab was identified as an effective anti-VEGF alternative to bevacizumab. In comparison, ranibizumab has been shown to not suppress systemic VEGF levels, thus limiting unwanted effects on organs, like brain and lung, that are still undergoing development at the time of ROP treatment (Stahl et al., 2018).

Systemic propranolol, IGF-1 replacement, granulocyte colony-stimulating factor, Jun kinase inhibitor, and omega-3 polyunsaturated fatty acid supplementation are the newer preventive strategies being evaluated through insights into the molecular pathogenesis of ROP in animal studies. Newer emerging therapeutic options have the potential to complement current therapies and improve treatment outcomes (Shah et al., 2016). Continued research is necessary before changes in current modalities occur.

The focus of corrective treatment is surgery for the repair of the detached retina. Scleral buckling, vitrectomy, or both, with or without lensectomy, are the techniques most often used. Scleral buckling involves the placement of a silicone or plastic band

around the globe of the eye. The band is tightened, which brings the sclera closer to the retina, facilitating retinal reattachment. This procedure is often performed in conjunction with laser therapy to salvage any remaining vision (Ertzbischoff, 2004).

When retinal detachment progresses beyond the point of scleral buckling, the ophthalmologist must consider anatomic reattachment of the retina. Vitrectomy involves surgically opening the eye, removing the lens, and gently excising the proliferative scar tissue; this allows the retina to lie against the pigmented epithelium and hopefully reattach. Despite the skill required for these procedures, most infants who undergo corrective therapy do not experience significant improvement in their vision. The best surgical reattachment rates (>50%) occurred when the surgery was performed on infants between 2 and 9 months of age. In addition, the level of visual function did not correlate with the degree of retinal reattachment. Poor visual outcomes have occurred regardless of the timeliness or delay in surgical reattachment (Ertzbischoff, 2004).

Outcome studies suggest that the incidence of long-term problems associated with ROP has been underestimated. Although studies on the natural history of ROP in the postsurfactant era consistently support an increased rate of mild ROP, which usually regresses, the consequences of severe ROP, especially stage 3 or greater, disease remain less than desirable. At 18 months of age, 34.5% of preterm infants with threshold ROP had complications consisting of strabismus, nystagmus, myopia, and late retinal detachment (O'Connor, Vohr, Tucker, & Cashore, 2003). Fifteen percent of the infants were legally blind.

Prematurity without ROP is also associated with poor visual outcomes. According to Cooke, Foulder-Hughes, Newsham, and Clarke (2004), preterm infants are three times more likely to wear glasses, three to four times more likely to have poor visual acuity or stereopsis (3D vision or depth perception), and 10 times more likely to have strabismus. Poor school performance in this population of preterm infants was also attributed to visual impairments. Because none of the infants with poor visual outcomes had intraventricular hemorrhages (IVH) or periventricular leukomalacia (PVL), poor school performance could not be explained by neurologic problems. Larsson, Rydberg, and Holmstrom (2005) showed that preterm infants have decreased distance and near vision acuities when compared with full-term infants.

Collaborative Care

Health professionals have to be concerned about care of the individual infant with ROP and the families of those infants. A nursery nurse may be caring for a convalescing infant who is being transported back to a community hospital, or an infant who is discharged prior to the first ROP screening examination. Attar, Gates, Iatrow, Lang, and Bratton (2005) found that infants transported back to a community hospital often missed their follow-up eye examinations when compared with those discharged directly from the regional perinatal–neonatal unit. The same authors found that infants discharged prior to their first ROP examination were more likely to miss follow-up eye care than those infants who had their first examination while in the NICU. It is imperative that there is clear, concise communication to the receiving hospital and to the parents about the importance of initial and follow-up eye examinations.

The development of ROP is concerning to parents of premature infants. Open communication between the neonatal healthcare team and the parents is crucial for helping the parents successfully cope with the stress of a hospitalized premature infant. At first, general information about the relationship of ROP and prematurity can be shared with the parents. After the initial eye examination has been performed, the information can be specific to their baby. The neonatal healthcare team must work closely with the ophthalmologist to provide a consistent message to the family. Parent teaching should focus on providing a basic understanding of ROP, the purpose of the screening examinations, and the importance of regular vision testing for their infant after discharge. Misconceptions about the disease and the use of oxygen need to be corrected.

Once ROP is diagnosed in an infant, parents may need more support than usual. Some parents may exhibit denial because they cannot see any physical evidence of a problem. Families of infants who need surgical intervention may feel greater stress from their concern for their infant's vision and may need the added communication with an ophthalmologist or retinal surgeon. NICU staff members can help parents cope by providing support during decision-making sessions with the eye specialists, by asking questions to clarify information, and by reinforcing information provided. It is also important to determine if parents are obtaining information from outside sources on the Internet. An analysis of 114 Internet sources on ROP found that 62.5% of the sites evaluated contained poor to fair information (Martins & Morse, 2005). Of the websites analyzed, 25% were academic, 20% were organizational, and 55% were commercial.

Information given to the parents about the prognosis of ROP in their infant must be included in any discharge planning. Parents need to understand that eye problems are more common in premature infants and may develop in infants with regressed ROP. Myopia (nearsightedness), strabismus (crossed eye), astigmatism, and amblyopia (lazy eye) are common sequelae. Glaucoma and late retinal detachment are common sequelae in infants with severe ROP.

Clearly, early detection and referral to programs for visual impairment are essential. Parents need to understand the importance of regular eye examinations by a pediatric ophthalmologist or by an ophthalmologist knowledgeable about ROP and its complications. Many families may benefit from referral to community resources, support groups, and special programs for children with visual problems.

Lastly, the nursing staff and unit managers have to maintain vigilance about infection control practices during eye examinations, laser ablation surgery, or intravitreal injections that occur within the NICU. Major risk factors for nosocomial infection are unwashed or poorly washed hands, and the sterility of instruments such as eyelid speculums and eye probes.

OTHER DISORDERS THAT AFFECT THE EYES

Fetal Alcohol Spectrum Disorders

Maternal ingestion of alcohol during pregnancy results in fetal alcohol spectrum disorders (FASDs) including the most severe type, FAS. Infants with FAS have mental deficiencies (CNS damage), dysmorphic facies, and severe IUGR. The abnormalities of the eyes common in infants with FAS include microphthalmia, short palpebral fissures, hypertelorism, coloboma, strabismus, ptosis, and optic nerve hypoplasia (Nash & Davies, 2017). Most affected infants have diminished visual acuity and some infants can develop blindness (Burd, 2016; O'Neil, 2011).

Zika Virus

Zika virus is a mosquito-borne virus that was discovered in Uganda in the 1940s, but has now been found in South America, Central America, and even in the southern part of the United States. Adults bitten by a Zika-infected mosquito often develop only a mild version of the disease. Zika virus can also be transmitted to the fetus if the mother was infected with the virus during pregnancy. The fetus can develop brain damage and death depending on the extent of the exposure and infection.

Infants who are exposed to the Zika virus in utero can develop a number of congenital malformations. The most common

is microcephaly, but infants can also develop abnormal development of the eye, including inflammation of the optic nerve, lens subluxation, iris colobomas, damage to the retina (chorioretinal atrophy), macular atrophy, or even blindness. About one-third of infants develop some type of eye disorder (de Miranda et al., 2016; Jampol & Goldstein, 2016; Russo & Beltrao-Braga, 2017).

Maternal Diabetes

Although maternal diabetes is recognized for its teratogenic effects, craniofacial anomalies are rarely reported. Infants of diabetic mothers should be carefully examined for the presence of oculoauriculovertebral (OAV) complex of disorders, including displaced inner canthi, lens opacity, microphthalmia, optic nerve hypoplasia, tear duct obstruction, and ocular lipoma (Ewart-Toland et al., 2000). Wang, Martinez-Frias, and Graham (2002) suggested that OAV occurred as a result of faulty neural crest cell migration in diabetic women with poor control during pregnancy.

Periventricular Leukomalacia

PVL is a major cause of visual impairment in premature infants. Impairments found in infants with PVL included diminished visual acuity, eye movement disorders, and visual field restriction. Other eye problems included optic disc anomalies, nystagmus, strabismus, delayed visual maturation, and visual perceptual-cognitive problems (Jacobson & Dutton, 2000; Jacobson, Ygge, Flodmark, & Ek, 2002).

Intraventricular Hemorrhage

IVH without PVL is also associated with eye abnormalities. Visual impairments, including ROP, were common in infants with IVH, including strabismus, optical atrophy, small visual field, and poor acuity (O'Keefe, Kafil-Hussain, Flitcroft, & Lanigan, 2001). The increased cranial pressure on the developing eye and optic nerve with hydrocephalus-associated IVH can cause more visual acuity problems.

SUMMARY

Visual disturbances, although sometimes difficult to detect in newborns, can have a dramatic impact on a newborn's behavioral and psychosocial development. PVL and severe IVH with hydrocephalus can cause serious eye disease in premature infants. Significant advances are being made every day in the diagnosis, treatment, and follow-up of extremely low birth weight infants. Neuroprotective bundles and caffeine may improve long-term vision outcomes by decreasing the incidence of IVH and PVL (Chorna, Guzzetta, & Maitre, 2017). But visual morbidity continues to be a concern as these small neonates survive the NICU.

The treatment of vision problems requires collaborative efforts among the neonatal healthcare team, the ophthalmologist, and the families of affected children. Clear, consistent communication between healthcare providers and parents, parental education, and good follow-up are important to the quality of care.

CASE STUDY

■ **Identification of the Problem.** Premature infants, especially those weighing less than 1,500 g, are at risk for complications from immature development of the eyes and the effects of supplemental oxygen on the developing eyes. As a result of the supportive therapies used in the NICU, ROP can develop. This case study presents a patient born at 25 weeks' gestation who is presently 11 weeks of age or 36 weeks corrected gestational age. Due to his early birth, the infant has chronic lung disease (CLD), is on a mild diuretic, and continues to require a low amount of oxygen via nasal cannula. The plan is to discharge to home within 5 to 7 days.

■ **Assessment: History and Physical Examination.** Baby Boy TS was born on June 4, 2012, at 25 weeks' gestation to a 23-year-old, gravida 1, para 0 mother whose pregnancy was complicated by preterm labor. She received prenatal care and delivered spontaneously by vaginal route following 2 days of unsuccessful tocolysis treatment and rupture of membranes approximately 15 hours prior to birth. Baby Boy TS was born with minimal respiratory effort, requiring intubation, bagging, and surfactant treatment in the delivery room, but was extubated to nasal continuous positive airway pressure (CPAP). By 4 hours of age, he required moderate ventilation and his condition deteriorated, requiring high-frequency oscillatory ventilation by 24 hours of age. He received a second dose of surfactant and remained on ventilation for approximately 3 weeks. He was weaned to nasal CPAP, to high-flow oxygen, and then to low-flow oxygen. He remains on 200 to 250 mL/minute of oxygen via nasal cannula. He had umbilical lines placed after birth, peripherally-inserted central catheter (PICC) line for 12 days, started on nasogastric (NG) feedings that were well tolerated, and advanced to full feedings. He has been nippling feeds with occasional apnea and bradycardia.

■ **Physical Examination**

- GENERAL: preterm, male infant
- HEENT: slight dolichocephaly, anterior fontanel soft and flat with widened sagittal sutures; eyes clear, no drainage or redness; pupils reactive to light; positive red reflex OU; eyes and ears normoset with palate intact
- RESPIRATORY: lung fields clear and equal bilaterally; minimal respiratory effort; respiratory rate = 48 with saturations 89% to 93% on 200 mL/L nasal cannula oxygen
- CARDIOVASCULAR: regular rate and rhythm with no murmur; pulses strong, regular and equal in all extremities; good peripheral perfusion 2+/4+ and capillary blood refill time less than 3 seconds
- ABDOMEN: soft and nontender with no masses palpable and positive bowel sounds throughout; liver edge down 2 cm below right costal margin; no splenomegaly; patent anus
- GENITOURINARY: normal male genitalia with testes descended into scrotum bilaterally
- NEURO: awake and active; cries when distressed or disturbed; sleep pattern appropriate for near-term infant; normal tone and responsiveness for gestational age
- EXTREMITIES: moves all four extremities with normal range of motion; hips—no click; clavicles—no crepitus; good muscle tone of all extremities; 10 digits per extremity
- SKIN: pink, warm, dry, and intact; no rashes or bruising noted; mucous membranes pink and moist

Premature infants are at risk for many complications due to their immaturity and treatments.

■ **Premature Diagnoses**

- Respiratory distress syndrome—can develop into CLD
- Hypoglycemia
- At risk for patent ductus arteriosus
- Possible sepsis/pneumonia
- At risk for IVH
- At risk for ROP
- Apnea of prematurity
- Anemia of prematurity

■ ROP Examinations

Dates	Age (weeks)	Gestational Age (weeks)	Results	Plan
July 16, 2012	6	31	Immature vascularity in both eyes (stage 0, zones II–III bilaterally)	Follow-up in 2 weeks
July 30, 2012	8	33	Stage 1–2, zone II with questionable plus disease	Follow-up in 1 week
August 6, 2012	9	34	Stage 2–3+, zone II on right; stage 2+, zone II on left	Referral for laser treatment
August 8, 2012	9½	34½	Stage 3+, zone II bilaterally	Laser photocoagulation was performed

Note: According to the American Academy of Pediatrics (AAP), the first eye examination would be done at 6 weeks' gestation.

■ Discharge Diagnoses

- Premature male infant
- CLD
- Apnea of prematurity
- ROP

EVIDENCE-BASED PRACTICE BOX

In evaluating infants with ROP, neonatal researchers have conducted studies to assess the effects of supplemental oxygen provided to preterm infants in the NICU. There have been numerous studies on neonates with ROP or prevention of ROP (see Table 17.5). This table provides an in-depth look at studies between 1988 and 2010 on neonatal ROP prevention from around the world. The significant findings are listed within the table. On searching for meta-analyses of ROP studies, the Cochrane review (www.cochrane.org) has listed 20 literature summaries dealing with ROP in neonatal care. These summaries involve a variety of prevention methods, including uses of supplemental oxygen, early light reduction, retinal ablation therapy, and early versus late oxygen reduction.

On searching eye disorders, there are two literature summaries in neonatal care. There continue to be many studies on the prevention of eye disease and disorders, especially ROP. By searching Internet sites, nurses can find the newest evidence-based protocols for prevention of ROP and other eye disorders.

TABLE 17.5

ROP STUDIES

First Author	Location	Years Included	Gestational Age of Subjects	Birth Weight of Subjects	Type of Study	Significant Findings
Good (Chair)	US ET-ROP	2000–2002		<1,250 g	Prospective	Incidence of ROP 68% with more zone I and prethreshold disease than in the CRYO-ROP study of 1986–1987. Incidence unchanged by race; however, more prethreshold disease seen in White infants
Markestad	Sweden	1999–2000	22–27 weeks	500–999 g	Prospective, observational	33% of 23 weeks preterm infants needed ROP treatment compared with 0% >25 weeks

TABLE 17.5

ROP STUDIES (*continued*)

First Author	Location	Years Included	Gestational Age of Subjects	Birth Weight of Subjects	Type of Study	Significant Findings
Larsson (*cont*)						*Incidence by BW:* ≤750 g—9% vs. 5% 751–1,000 g—27% vs. 24% >1,000 g—64% vs. 72%
Hameed	UK	1990–1994 1995–1999		≤1,250 g	Observational comparison in same geographic region	Survival—76% (1995–1999) Survival—62% (1990–1994) ≥Stage 3—12% (1995–1999) ≥Stage 3—4% (1990–1994)
O'Connor	US	1994–2000		≤1,250 g	Retrospective	Incidence of ROP increased from 2% to 5% Highest incidence and severity seen in BW <750 g
Fledelius	Denmark	1993–1997		<1,750 g	Retrospective	Incidence of ROP—10%
Mintz-Hittner	US multicenter BEAT-ROP		<30 weeks	<1,500 g	Prospective, randomized, controlled	Increased efficacy of intravitreal bevacizumab as compared with conventional laser therapy for stage 3+ ROP when both zones I and II are considered
STOP-ROP	US multicenter STOP-ROP	1994–1999			Prospective, randomized, controlled	Use of supplemental oxygen with pulse oximetry saturations of 96%–99% did not cause additional progression of prethreshold ROP. But it also did not significantly reduce the number of infants requiring peripheral ablation surgery.
Reynolds	US Multicenter LIGHT-ROP	1995–1997	<31 weeks	<1,251 g	Prospective, randomized, controlled	A reduction in the ambient light exposure does not alter the incidence of ROP.
BOOST II	UK, Australia, New Zealand	2006–2010	<28 weeks	<1,100 g	Prospective, randomized, controlled	Targeting of oxygen saturation monitoring at levels <90% was associated with an increased death rate

BW, birth weight; ROP, retinopathy of prematurity.

PARENT VOICES

Jennifer Degl

Retinopathy of prematurity (ROP) had not been on my radar for the first 2 months that my baby was in the NICU. I had spent my time researching about what things could take her life and how to watch for signs and help prevent her from developing those complications. Once she was a few months old and relatively stable and the doctors told me that she had passed the window of time where I had to be afraid every day, I was informed that she would likely develop an eye condition called ROP. All that was explained to me initially was that ROP is a disease of premature babies that causes abnormal blood vessels to grow in the retina. This growth can cause the retina to detach from the back of the eye, leading to blindness and that high levels of oxygen given to preemies exaggerate this condition. How is it that oxygen, needed for survival, can cause babies to go blind? It really does not make sense, but it is so. At first my daughter had her eyes checked at the bedside every week, beginning at 8 weeks old. The eye specialist (pediatric ophthalmologist) told me that my daughter had between stage 3 and 4 ROP and that there was nothing to do but wait and try to lower her oxygen levels as much as possible, but that was not up to me. A few weeks later she had developed stage 4 ROP. I was so afraid that my daughter would have tunnel vision or go completely blind and there was nothing I could do about it. When my daughter was a little over 3 months old, the doctor told me that her ROP was improving. Each week it continued to improve and she was discharged from the NICU with only stage 1 ROP. We were instructed to follow up with a pediatric ophthalmologist. We saw the pediatric ophthalmologist every month for 1 year and then every 3 months and then every 6 months, and now we only go once a year. Today, at 6 years old, my daughter is cleared of ROP and only needs to wear glasses when she colors, reads, or does any close-up work.

CHAPTER 18

Genitourinary System

Leslie A. Parker

INTRODUCTION

Comprehensive nursing care of infants with renal or genital disorders requires a thorough understanding of normal anatomy and physiology. Development of renal and genital systems arises from shared structures; therefore, abnormalities in one system may indicate abnormal development in the other. Because nurses provide hands-on care to infants in both the newborn nursery and neonatal intensive care unit (NICU), they are often the first to recognize abnormalities in the renal and genital systems. To readily identify such disorders and participate in their collaborative management, nurses need a clear understanding of the normal anatomy and physiology of the genital and renal systems and the pathological processes that may be present in the neonatal patient.

The kidneys function to maintain fluid, electrolyte, and acid–base balance as well as to rid the body of nitrogenous and other waste products. Perinatal depression, prematurity, medical management for common neonatal conditions, and dehydration are only a few of the many factors placing the newborn at risk for renal compromise. Timely, accurate nursing assessment and intervention is of utmost priority to ensure an optimal outcome for both infants and their families.

This chapter outlines embryological development and anatomy, physiology, and assessment of the genitourinary (GU) system. It also describes various abnormalities and disease processes commonly identified in the neonatal period, including pathophysiology, risk factors, clinical manifestations, diagnosis, collaborative management, and prognosis.

EMBRYOLOGICAL DEVELOPMENT OF THE UROGENITAL SYSTEM

During the first weeks of gestation, the mesoderm is divided into three segments: lateral, intermediate, and paraxial. The intermediate mesoderm separates from the paraxial mesoderm and migrates ventrally as the nephrogenic cords located on either side of the primitive aorta. Cells on the dorsal end of the nephrogenic cords join to form the urogenital ridges from which components of both the urinary and genital structures are developed.

The Urinary System

The urinary system consists of the kidneys, ureters, urinary bladder, and the urethra. Development of the primary excretory organ begins around the fourth week of gestation with the production of fetal urine by week 10. At approximately 36 weeks, renal anatomic development is completed. Functional maturity increases after birth and continues until approximately 2 years of age.

Development of the kidneys occurs with the progressive formation of three nephric structures within the nephrogenic cord: the pronephros, the mesonephros, and the metanephros. The pronephros or primitive kidney develops during the first month of gestation and then gradually degenerates, thus contributing the duct system for the next developmental stage. The pronephros has no excretory function.

The second excretory organ to develop is the mesonephros. Mesonephric development begins at the caudal end of the pronephros during the fourth to sixth weeks of gestation. The mesonephros contains thin-walled glomeruli and functional tubules. Ultra-urine is produced by these mesonephric nephrons at 8 to 10 weeks. Mesonephric nephrons that are located more cranially along the nephrogenic cord begin to degenerate as those located more caudally are still developing. During this time, approximately the fourth week, the gonadal blastema begins to form in the genital ridge located on the medial aspect of each mesonephros, thus creating a urogenital ridge between the developing kidney and the genitals. As the mesonephric structure begins to degenerate in a caudal direction, it leaves a duct system for the following stage. In addition, the mesonephric duct eventually matures into the epididymis, vas deferens, and ejaculatory duct in the male or the vestigial Garner in the female. Thus, failure of the mesonephric duct to develop may result in anomalies in both the urinary and genital systems.

The third and final stage of kidney development, beginning in the fifth week of gestation, is the formation of the metanephros or definitive kidney. The metanephros develops from induction of the metanephrogenic blastema (metanephric mesoderm) by the ureteric bud. The ureteric bud, also called the metanephric diverticulum, is an outgrowth of the mesonephric duct, and the metanephrogenic blastema originates from the lower segment of the nephrogenic cord. As this stage progresses, the stalk of ureteric bud becomes the ureter. The development of the renal pelvis, major and minor calices, and, finally, the collecting tubes occurs through the continued elongating and branching of the cranial end of the ureteric bud. At the ends of the collecting tubules, the cells of the metanephric blastema clump and stimulate the formation of the glomerulus, proximal tubule, loop of Henle, and distal tubule,

which, eventually, empties into the collecting duct, thereby forming a nephron (Moore, Persaud, & Torchia, 2016).

To complete formation of the urinary system, a bladder and urethra are formed. The epithelium of the bladder and most of the urethra derive from the embryological hindgut. The expanded terminal end of the hindgut is the cloaca. The allantois, an outgrowth of the yolk sac, is attached to the ventral side of the cloaca. The urorectal septum creates a compartmentalized cloaca that consists of the anorectal canal and the urogenital sinus. With the exception of the bladder trigone—the area between the urethra and the ureters—the bladder arises from this urogenital sinus. The primitive structures regress, fibrose, or become part of the newly formed structures. The point of origin of the ureteric bud marks the point of insertion for the ureters. The ureters, formerly the metanephric ducts, then open bilaterally into the urinary bladder as the developing bladder reabsorbs the distal portions of the mesonephric ducts into its dorsal wall (trigone).

The allantois narrows into a fibrous band called the urachus that runs from the apex of the bladder to the umbilicus. Abnormalities of the urachus occur when it either remains patent or forms an urachal sinus. A patent urachus may occur in association with other anomalous conditions and may allow development of a functional kidney by alleviating the effects of urinary obstruction. An urachal sinus is usually an isolated anomaly and causes leakage of urine from the umbilical stump.

Urethral development in the male and female begins in the same manner. The urogenital sinus is visible at 6 weeks and consists of a narrow portion near the bladder, the pelvic urethra, and an expanded portion near the urogenital membrane (cloacal membrane), called the phallic urethra. Through several processes and stages, the phallic end of the urogenital sinus eventually becomes the bulbar and the penile urethra, and the pelvic urethra develops into the permanent urethra and vagina. Differentiation of the urethra in the male and female fetus can be detected by 12 to 14 weeks' gestation.

Initially, the kidneys are located within the pelvic region. They make a gradual ascent into their final location in the flank position or lumbothoracic area. Normal renal ascent is achieved as the result of caudal growth of the fetal spine, lengthening of the ureter, molding of the renal parenchyma, and fixation of the kidney to the retroperitoneum (Moore et al., 2016). Failure of normal ascent of the kidneys results in abnormalities such as horseshoe kidneys or pelvic kidneys. Blood supply to the ascending kidneys changes from lower arteries that gradually regress to arteries that arise from the aorta.

In utero, the placenta functions as the excretory organ for the fetus. Functional kidneys are, therefore, not necessary for fetal homeostasis. Consequently, pathological problems such as aplastic, hypoplastic, and otherwise nonfunctioning kidneys may not be detected until after birth. Fetal urination, swallowing, and breathing all impact amniotic fluid volume. Excretion of fetal urine contributes significantly to amniotic fluid volume, especially during the third trimester. A reduction in fetal urine excretion results in oligohydramnios. Failure of the fetus to swallow amniotic fluid due to gastrointestinal obstruction or central nervous system anomaly results in overaccumulation of amniotic fluid or polyhydramnios. Abnormalities in amniotic fluid volume can, therefore, signal pathology in various fetal organ systems.

A balance between genetic influences, cellular mediators, and the interaction of various molecular mechanisms is necessary for kidney development. Depending on the timing of development, insult or failure of the primitive structures to grow or to branch appropriately may result in a variety of uropathies, including dysplasia and renal agenesis.

PHYSIOLOGY OF KIDNEY FUNCTION

Kidney structure includes the cortex, the major and minor calices, and the renal pelvis (Figure 18.1). The kidney is divided into two sections: the outer renal cortex and the inner medulla. The kidney functions to regulate fluid and electrolyte balance and arterial blood pressure, as well as to excrete toxic and waste substances. These regulatory mechanisms are intimately tied to the formation of urine that involves three basic processes: ultrafiltration of plasma by the glomerulus, reabsorption of water and solutes from the ultrafiltrate, and secretion of certain solutes into the tubular fluid (Koeppen & Stanton, 2013).

The nephron is the functional unit of the kidney and is the site of urine formation. It consists of a glomerulus (Bowman's capsule and glomerular capillaries) and a renal tubule that has three sections: a proximal convoluted tubule, the loop of Henle, and a distal convoluted tubule (Figure 18.2). After urine is produced by the nephron, it drains into the minor and major calyces. From there, it drains into a single large cavity called the renal pelvis, then out through the ureter, and finally into the bladder.

Nephron formation (nephrogenesis) begins during the second month of gestation and is anatomically complete by approximately 35 weeks. Although anatomic formation may be complete, functional immaturity of the nephrons continues throughout infancy. At the completion of nephrogenesis, each kidney contains approximately 1 million nephrons. Nephrogenesis begins deep within the renal cortex near the medulla in the juxtamedullary region and continues outwardly (Koeppen & Stanton, 2013). The juxtamedullary nephrons differ from the superficial cortical nephrons in that their glomeruli are larger, the loop of Henle is longer, and the efferent arteriole forms a more complex vascular system. The less mature superficial cortical nephrons make up the majority of nephrons, whereas the more mature juxtamedullary nephrons account for a very small percentage of the total number. Altered renal function in the premature infant may, therefore, be caused by both anatomic and physiological immaturity.

RENAL BLOOD FLOW

Urine formation begins with blood flow. The pressure-driven process of ultrafiltration depends on optimal arterial pressure and is regulated by the dilation and constriction of afferent and efferent arterioles (Koeppen & Stanton, 2013). Adequate renal blood flow

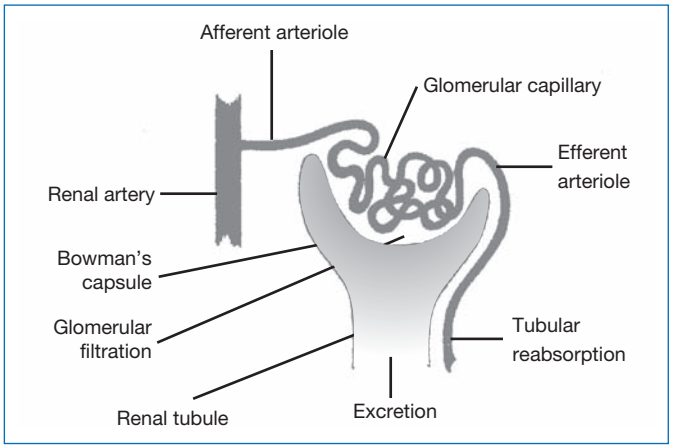

FIGURE 18.1 Glomerular apparatus.

is, therefore, essential to renal function. During the first 12 hours of life, 4% to 6% of the cardiac output goes to the kidney, which increases to 8% to 10% over the next few days. This is compared to the 25% of cardiac output that reaches the adult kidney. Renal blood flow not only provides oxygen and nutrients to the kidneys but also affects the rate of solute and water reabsorption by the proximal tubule, participates in the concentration and dilution of the urine, and delivers substrates for excretion in the urine.

The left and right renal arteries arise from the aorta. After entering the kidneys, they divide and branch several times to eventually give rise to the afferent arterioles. Each nephron receives one afferent arteriole that divides and forms the glomerulus. The distal ends of the glomerular capillaries merge to form the efferent arterioles that carry blood away from the glomerulus. The efferent arterioles divide to form the peritubular capillaries, which surround the tubular parts of the nephron in the renal cortex. Other vessels called the vasa recta also arise from the efferent arterioles to surround the tubular parts of the nephron in the renal medulla. The peritubular capillaries empty into the venous system and eventually leave the kidneys in the form of the renal vein. The fetus and infant have a decreased renal blood flow due to increased renal vascular resistance and decreased mean arterial pressure. Renal vascular resistance is elevated in the fetus because fetal renal function is required only for production of amniotic fluid (Blackburn, 2013). Renal blood flow increases with both advancing gestational and chronological age.

GLOMERULAR FILTRATION RATE

As blood flows into the kidney via the renal artery, it is directed into the afferent arteriole and carried into the glomerulus. The glomerulus consists of the glomerular capillaries and Bowman's capsule. Plasma driven through the glomerular capillaries is filtered through the filtration barrier, and the protein-free plasma, or ultrafiltrate, is forced into the Bowman's capsule or leaves via the efferent arteriole and enters into the renal vein. To produce ultrafiltrate, the glomerulus functions as a filtering site. Glomerular capillaries are lined with epithelial cells called podocytes, forming one of the layers of Bowman's capsule (see Figure 18.2). The endothelial cells of the glomerular capillaries are covered by a basement membrane and also surrounded by podocytes. The basement membrane, podocytes, and the endothelial cells of the glomerular capillaries form the filtration barrier. The epithelial cells of this filtration barrier express negatively charged glycoproteins and contain many small openings called fenestrations. The size of the fenestrations inhibits passage of large proteins, such as blood cells and platelets, but is highly permeable to the passage of water, small solutes, urea, and glucose. In addition, positively charged large proteins are repelled by the cationic cell membrane (Koeppen & Stanton, 2013).

The glomerular filtration rate (GFR) is the rate at which fluid is filtered through the glomerulus. Because it is equal to the sum of all filtration rates of all nephrons in both kidneys, the GFR reflects kidney function and a decrease in GFR signifies renal disease. Oncotic and hydrostatic pressures (Starling forces) drive the ultrafiltration process. Oncotic pressure is osmotic pressure generated by large proteins or colloids. Hydrostatic pressure is pressure exerted by fluids in equilibrium and depends on arterial pressure and vascular resistance (Koeppen & Stanton, 2013). Oncotic pressure in Bowman's space is very near zero because ultrafiltrate is nearly protein free (Dias, Sairam, & Kumarasiri, 2014). Filtration at this level is, therefore, driven by hydrostatic pressure across the glomerular capillaries. Hydrostatic pressure within Bowman's space

and glomerular oncotic pressure oppose glomerular hydrostatic pressure in the capillaries. The GFR is proportional to the sum of hydrostatic and oncotic pressures existing along the renal capillaries multiplied by the ultrafiltration coefficient. The difference between the permeability of the glomerular capillary and the glomerular surface area available for filtration is the ultrafiltration coefficient (Koeppen & Stanton, 2013). GFR is, therefore, affected by changes in arterial blood pressure, vascular resistance, concentration of plasma proteins, and glomerular capillary permeability. Alteration in the permeability of the glomerular capillaries may result from inherent damage to the capillary, thus altering the pore size or changing the electrical charge within the membrane. GFR may also be negatively affected by urinary system obstruction.

Fetal GFR is relatively low due to increased renal vascular resistance and decreased renal blood flow and then rapidly increases during the first few hours following birth. GFR increases with both advancing gestational and chronological age due to increased number and growth of the nephrons and reaches full-term levels by 32 to 35 weeks' gestation (Blackburn, 2013). In the preterm infant, functional maturation is determined by conceptional age, not by postnatal age. When corrected for body surface area, GFR is 10 mL/minute/1.73 m^2 at 28 weeks' gestation and rises to 30 mL/minute/1.73 m^2 at term. GFR does not rise due to an increase in the number of nephrons, but rather it is believed to reflect a decrease in vascular resistance and an increase in glomerular surface area (Luyckx & Brenner, 2010). Even in term infants, GFR is low compared to an older infant or child. This low GFR is adequate in normal circumstances, but in conditions such as sepsis, hypoxia, or the administration of nephrotoxic medications, the GFR may not meet the physiological needs of the infant. Medications administered prenatally can also have detrimental effects on fetal GFR and subsequent neonatal renal function. Examples of these drugs include prostaglandin inhibitors (indomethacin), nonsteroidal anti-inflammatories, diuretics, and antibiotics, especially aminoglycosides and angiotensin-converting enzyme inhibitors (Gubhaju, Sutherland, & Black, 2011).

Assessment of GFR is important in evaluating renal function. One method of assessing GFR is measurement of the renal clearance of a substance. Renal clearance represents a volume of plasma completely cleared of a substance by the kidneys over a specified period of time (Koeppen & Stanton, 2013). Various substances are used as markers for measuring GFR. These substances must have the following characteristics: (a) freely filter across the glomerulus into Bowman's space; (b) not be reabsorbed or secreted by the nephron; (c) not be metabolized or produced by the kidney; and (d) not alter GFR (Koeppen & Stanton, 2013). Several substances including cystatin C and inulin have been used as a marker of GFR (Abitbol et al., 2014). Creatinine, a by-product of muscle metabolism, also meets the marker criteria and is the most commonly used marker for estimating renal function in neonates; however, it may not be the best measure of GFR (Kastl, 2017). Because creatinine readily crosses the placenta, levels obtained during the first week reflect maternal levels (Filler, Guerrero-Kanan, & Alvarez-Elias, 2016; Kastl, 2017). After birth, the GFR in term infants increases as renal blood flow increases and vascular resistance decreases. This increase in function generally occurs over the first week of life and results in a drop in creatinine levels to nearly 0.4 mg/dL, depending on clinical status and gestational age. GFR does not increase as drastically until completion of nephrogenesis. Therefore, premature infants do not demonstrate the same decline in serum creatinine levels as infants born after 36 weeks' gestation (Kastl, 2017). Small increases in serum creatinine levels may indicate a significant decrease in GFR. Monitoring trends in serial creatinine levels may, therefore, render a more accurate evaluation of renal function.

Regulation of renal blood flow and, consequently, GFR is achieved by hormonal and sympathetic nervous system (SNS) influences. The renal vessels, including the afferent and efferent arterioles, are highly innervated by sympathetic nerve fibers. Mild stimulation of the SNS does not cause a change in renal vascular tone. However, under severe physiological stress such as that caused by significant fluid loss, activation of the renal sympathetic nerve fibers causes vasoconstriction of the renal arteries, which, in turn, decreases GFR.

Hormonal control is exerted mainly via activation of the renin–angiotensin–aldosterone system (RAS). The RAS plays a significant role in blood pressure regulation and sodium homeostasis and is found in the fetus, beginning at about 3 months' gestation. Renin is an enzyme found in high levels in the plasma and is produced and stored in specialized cells of the juxtaglomerular apparatus. Newborns have a significantly higher renin level than adults due to the neonate's altered GFR, increased vascular resistance, and decreased renal blood flow.

When renal blood flow is diminished due to decreased arterial pressure, the vessel walls of the afferent arterioles are less stretched and release of renin is stimulated. Release of renin causes production of angiotensin I from angiotensin, which is then converted by angiotensin-converting enzyme to angiotensin II. Angiotensin II stimulates secretion of aldosterone by the adrenal cortex. Aldosterone, in turn, triggers increased reabsorption of sodium and water, thereby increasing extracellular fluid volume and renal perfusion (Figure 18.3). The ultimate goal of the renin–angiotensin cycle is to maintain an adequate systemic blood flow to supply the body's vital organs (Tortora & Derrickson, 2017).

SECRETION AND REABSORPTION

The kidneys control fluid and electrolyte balance by reabsorption and secretion of sodium and water. The four segments of the nephron—the proximal tubule, loop of Henle, distal tubule, and the collecting duct—determine the composition and volume of urine.

Because nephron formation begins in the medullary area, the thin ascending portion of the nephron, which controls reabsorption, is not fully formed in the neonate. By birth, nephron formation has extended from the medullary to the juxtamedullary area. The descending portion of the tubular system, which controls urine secretion, is, therefore, more fully developed than the ascending segment at birth. Thus, a newborn's ability to concentrate urine is decreased because although urine secretion occurs readily, reabsorption is limited. Infants are, therefore, more likely to lose sodium, glucose, and other solutes in their urine. This process is further altered in preterm infants, resulting in possibly significant fluid and electrolyte disturbances.

Tubular reabsorption, secretion, and excretion are closely tied together and function to maintain internal homeostasis and regulate fluids and electrolytes. Tubular reabsorption is the process whereby substances from the tubular lumen move into the capillary system through simple diffusion and active transport. Many of the body's nutrients, electrolytes, and 99% of the filtered water are reabsorbed, thus achieving a balance for continued growth and normal physiological function. Simple diffusion involves movement of substances down a gradient, from an area of higher concentration to an area of lower concentration. Active transport requires energy derived directly from adenosine triphosphate because net movement of substances is against a gradient. Molecular structures may link together to piggyback, or carry one another, across the membrane. Sodium first undergoes simple diffusion across the tubular membrane and then is transported via active transport by the sodium pump into the interstitial fluid. Because

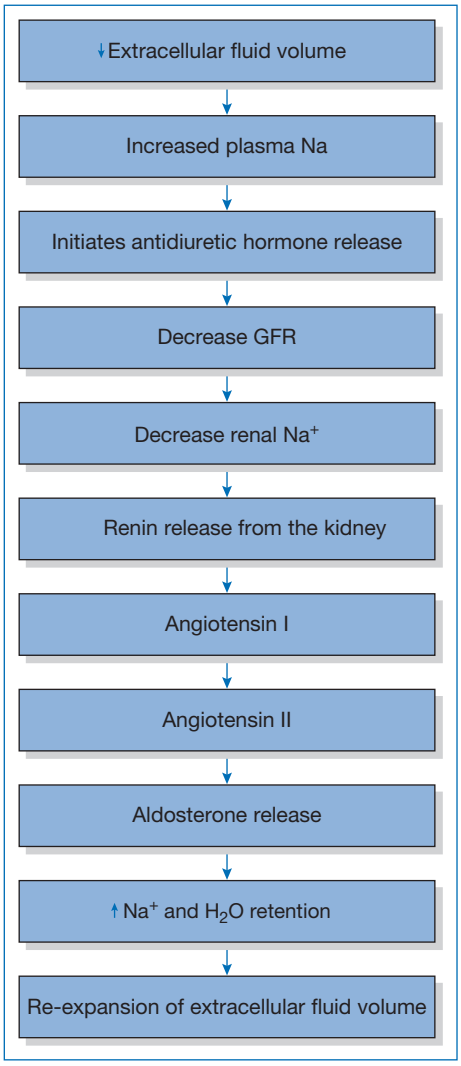

FIGURE 18.3 The renin–angiotensin–aldosterone regulation of extracellular fluid.

GFR, glomerular filtration rate.

sodium filtration depends on GFR, a higher GFR increases sodium reabsorption into the vascular space. If the extracellular fluid volume increases, sodium reabsorption is decreased.

Water follows sodium ions across the membrane and into the capillary bed. This type of transport of a second substance is called secondary active transport. Simple facilitated diffusion is similar to active transport in that a carrier substance is used, but the net movement is not against a gradient. Glucose is a substance that secondary active transport carries along with sodium across the membrane. Glucose is reabsorbed by the proximal tubules, thus appearing in the urine only when the renal threshold or the maximal tubular transport capacity has been exceeded or when the permeability of the filtering capillaries has been altered. Amino acids, water-soluble vitamins, albumin, and lactate are also transported in this manner.

Tubular secretion moves substances such as potassium and hydrogen from the epithelial lining of the tubules' capillaries into the interstitial fluid and, finally, into the tubular lumen. Tubular excretion is the process whereby substances enter the filtrate that will eventually exit the body as urine. Ions such as potassium, which are secreted in the distal tubule (a portion is also reabsorbed in the proximal tubule), find their way into the urine when the body has no need for higher concentration levels. The movement of hydrogen ions influences the excretion of potassium; therefore, metabolic acidosis and alkalosis affect the potassium level. **Quality and Safety: Hormones and drugs, especially diuretics, can also affect the movement of potassium with Aldactone causing potassium secretion and the thiazides resulting in potassium excretion.** Other filtrates present in the urine include urea, creatinine, and other ions not needed by the body.

ASSESSMENT OF THE GENITOURINARY SYSTEM

History

A thorough family history is imperative for all infants suspected of having a urogenital abnormality. Many urogenital problems have an inheritance pattern, suggesting a genetic predisposition. The history should focus on family members who have had a renal transplant or have undergone dialysis, those with a history of renal failure, and those with cystic kidney disease or anomalies of the GU system. A review of family history should also include fetal or neonatal deaths and the presence of individuals with external genitalia abnormalities, such as hypospadias, ambiguous genitalia, or undescended testicles. The prenatal history should be reviewed for antepartal factors associated with renal abnormalities, including oligohydramnios, an abnormal prenatal ultrasound, or perinatal depression.

The neonatal history should include the following questions:

1. Has the infant urinated, and, if so, how long following delivery? Normal voiding occurs within the first 24 hours of life. Care should be taken to note whether the infant voided in the delivery room.
2. Has the infant undergone any significant hypoxic episodes that may result in decreased renal blood flow?
3. Is the fluid intake sufficient relative to the infant's clinical status, gestational age, and immediate environment (radiant warmer or humidified isolette)? A radiant warmer can increase insensible water losses, thereby increasing fluid requirements.
4. Is the infant under treatment for jaundice? (Phototherapy can increase insensible water losses.)
5. Is the infant experiencing any bleeding or increased gastrointestinal losses from nasogastric suctioning, vomiting, diarrhea, or increased ostomy output?
6. What is the specific gravity of urine? (Normal range is 1.003–1.015.)
7. What is the infant's gestational and chronological age?
8. Has the infant received any nephrotoxic medications?
9. What is the infant's blood pressure? (Hypotension can indicate volume depletion, whereas hypertension [HTN] may be associated with an underlying renal abnormality.)

PHYSICAL ASSESSMENT

Physical examination should include inspection, palpation, and percussion. Auscultation is generally not useful in assessment of the renal system.

Inspection

Observation of the abdominal region is essential in infants suspected of having renal abnormalities. One should note the presence of abdominal distention, including whether the distention is localized to one side or is generalized. Any abdominal asymmetry is considered an abnormal finding. The presence of bladder distention should also be noted. Although mild abdominal

protuberance in the neonate may be normal due to the relative weakness of the abdominal musculature compared to infants who are several months older, an absence of muscle tone is characteristic of prune-belly syndrome. The umbilicus should be assessed for hernias and/or drainage. If possible, the urinary stream should be assessed. A continuous, straight stream is considered normal.

The genital and perineal area should be carefully inspected. Peritoneal tissue leading to the anal opening should be intact and smooth in appearance. Any abnormal openings, depressions, or swellings should be noted. The anus is normally located midline and can be tested for patency by gentle insertion of a gloved, well-lubricated small finger. Gentle stroking of the anal tissue and observation for anal sphincter constriction tests the anal wink, indicating adequate muscle tone.

Male infants require inspection of the skin covering the scrotum for color and the presence of rugae, edema, or ecchymosis. If the infant is full term, the scrotal sac should be full, and rugae should be present. The premature male infant exhibits a generally flaccid, smooth scrotal sac. The scrotum is generally darkly pigmented, without bluish discoloration that could denote disruption of circulation to the area, indicating the possible presence of a testicular torsion. An enlarged or edematous scrotum may accompany a hydrocele (a trapping of fluid in the tunica vaginalis) or may result from pressure during the birth process, especially during a breech delivery. If a hydrocele is suspected, transillumination of the scrotum with a good light source, such as a transilluminator or a flashlight, helps determine the presence of fluid. When transilluminated, fluid will allow light to pass through what appears as a highly lightened area.

Penile size, resting position, and position of the urinary meatus should also be assessed. An abnormally large or small penis may indicate a genital abnormality. A micropenis is suspected when the penis measures less than 2 to 2.5 cm in length and can be associated with renal, genital, and chromosomal abnormalities. Priapism, or a constantly erect penis, is also an abnormal finding. The urinary meatus should be located midline on the ventral portion of the glans penis. Dorsal or ventral placement of the meatus can occur anywhere along the shaft of the penis and is considered abnormal. A urinary meatus located on the dorsum of the penis is known as an epispadias and a hypospadias if the opening is displaced along the ventral penile surface. A hypospadias can be associated with a downward curvation, bowing, or chordee of the penis. The foreskin of the uncircumcised male may be gently retracted for accurate observation of meatal location and then returned to its unretracted state to avoid swelling and possible decreased penile circulation.

Female infants require inspection of the labia, clitoris, urinary meatus, and external vaginal orifice. The labia minora in the term infant should be well formed, and the labia majora should be present and extend beyond the labia minora. As gestational age decreases, the labia majora is smaller, and in premature infants, the labia minora may be larger than the labia majora. The labia may be darkly pigmented and is of no clinical significance. Because the labia may not be fully developed in premature infants, the clitoris in infants born preterm may appear prominent but, if normally sized, is considered normal. The urinary meatus should be patent and anterior to the vaginal orifice. The vagina should be inspected for patency, and any vaginal secretions should be noted. A white, milky vaginal secretion in the first few days of life, followed by pseudomenses or slight vaginal bleeding, is a normal finding. A hymenal tag may be present, usually disappearing within the first few weeks, and is considered a normal finding.

In both male and females, bruising and swelling of the genitalia may occur following a breech delivery. Ecchymosis and sometimes hematomas may also occur after traumatic delivery. These birth-related findings are transient and can be expected to resolve within several days. The inguinal areas should be assessed for the presence of an inguinal hernia. The genital and peritoneal regions must be observed to ensure that there is a clear differentiation of the sexes. If not, ambiguous genitalia must be considered (see Chapter 10, Endocrine System).

Palpitation

This portion of the physical examination may be stressful to the infant and thus is best left until the end of the examination. Place the infant in the supine position with the knees and hips flexed and provide a means of non-nutritive sucking for the infant. This position generally places the infant at ease and facilitates relaxation of the abdominal muscles. The abdomen is then gently palpated with a gradual downward movement, anteriorly to posteriorly. To palpate the kidneys, place the fingers of one hand along the flank, while the thumb palpates the abdomen. This allows the examiner to trap the kidney's pole between the fingers and the thumb (ballottement). Deep palpitation is required to manually assess the kidneys and is, therefore, reserved only for infants suspected of having a GU or renal abnormality. The kidneys are only reliably palpated in the first 1 to 2 days of life (Tappero & Honeyfield, 2019).

In males, palpate the scrotal sac for each testis and cord. If the testis is absent, palpate along the canal to assess its location. The scrotal sac may be palpated by gently pressing the tissue between two fingers, one on the anterior surface and the other on the posterior surface. Gentle movement of the fingers upward over the scrotum until the testes are detected bilaterally indicates whether one or both testes are descended and their location in relationship to the internal ring in the inguinal canal. Until 28 weeks' gestation, the testes are abdominal organs, and between 28 and 30 weeks, they begin to descend into the inguinal canal. The cremasteric reflex, recoil of the testes toward the inguinal canal, may be elicited by gentle stroking of the upper thigh or scrotal sac.

Percussion

If bladder distention is palpated or observed, percussion should be performed. This technique is useful in determining whether the area is fluid filled or a solid mass. If the bladder is filled with fluid, percussion will invoke a somewhat tympanic sound, while a dull sound will be noted if the mass is solid. Percussion may also be used over the entire abdominal region. Examination of the abdomen and gastrointestinal system is discussed in depth in Chapter 8, Gastrointestinal System.

Related Findings

All infants should be inspected for general characteristics suggesting renal abnormalities. Severe oligohydramnios sequence facies (flattened, beaklike nose; wide-set eyes; micrognathia; disproportionately large ears; and short neck) accompanied by abnormal positioning of the hands and feet and pulmonary hypoplasia are associated with oligohydramnios and may indicate the presence of a renal disorder. Since genetic syndromes commonly have associated renal abnormalities, one should assess for characteristics consistent with the presence of genetic abnormalities. A single umbilical artery is present in up to 1% of newborns (Luo et al., 2017). **Quality and Safety:** **Historically, the presence of a single umbilical artery was thought to be strongly associated with renal abnormalities, and therefore, a renal ultrasound was recommended. Recent evidence has suggested that the association is not as strong as previously thought and that an ultrasound may only be indicated in infants with other symptoms of renal disease** (de Boom et al., 2010). The ears should be assessed for

TABLE 18.1

SYNDROMES ASSOCIATED WITH THE DEVELOPMENT OF UROGENITAL DISORDERS

Syndromes	Renal Component	Genital Component
Severe oligohydramnios sequence	Renal agenesis	Absence of vas deferens, seminal vesicle, upper vagina, uterus
Meckel's syndrome	Polycystic kidneys	Ambiguous genitalia Hypoplastic phallus Cryptorchidism
Trisomy 21	Cystic kidneys and other renal anomalies	Hypoplastic penis and scrotum Cryptorchidism
Trisomy 18	Dysplastic renal system	Hypoplastic clitoris and labia minora Cryptorchidism
Turner's syndrome	Horseshoe kidney	Infantile genitalia Duplications of the collecting system
Prune-belly syndrome Urinary tract dysplasia	Bladder and ureter dilation	Patent urachus Cryptorchidism
Errors of metabolism	Renal tubular dysfunction	Galactosemia Tyrosinemia Glycogen storage (von Gierke's) disease
Adrenogenital syndrome	Masculinization of the female clitoral hypertrophy	Incomplete masculinization of the male Hypospadias Hypoplastic penis Cryptorchidism

abnormalities since preauricular tags have been associated with urinary tract abnormalities. Meningomyelocele and other neural tube defects may cause decreased or absent bladder innervation, resulting in a neurogenic bladder and bladder distention. If untreated, the associated urinary stasis may result in a urinary tract infection (UTI). Syndromes associated with renal and genital problems are listed in Table 18.1.

Urine Collection

Urine collection is a relatively simple procedure in the neonate, and several adhesive-backed collection bags are currently available. When placing urine collection bags, care should be taken to not include the rectum or the scrotum within the opening of the bag. The penis should not be left in urine because infection and skin irritation may occur. To avoid skin irritation when using adhesive-backed collection bags, care should be taken to maintain skin integrity. Alternative collection systems can be used if accurate measurement of urine output is not needed. Cotton balls can be placed inside diapers to catch a small specimen for dipstick analysis or for measurement of specific gravity. Many institutions now use super absorbent disposable diapers, which can potentially alter the result of urine tests. Nursing research is needed to evaluate the accuracy of specific laboratory tests when using these newer products.

When sterile urine specimens are required for culture, a suprapubic bladder tap or urethral catheterization must be performed. Performance of a suprapubic tap requires minimal equipment and time. The lower abdomen is prepared with an antimicrobial solution and allowed to dry. If the infant has voided within the previous hour, the attempt should be delayed until the infant's bladder is full. If severe dehydration, abdominal congenital anomalies, inguinal hernias, or distention are present, a suprapubic tap may be contraindicated. Nonpharmacological and/or pharmacological pain relief should be provided. The procedure is usually performed with a 3-mL syringe and a 23- to 25-gauge straight needle. The needle is placed midline, 1 to 1.5 cm above the symphysis pubis, and is inserted perpendicularly or at a slight angle, pointing toward the head. Entry into the bladder is determined when resistance decreases as the needle is inserted. A slight traction on the plunger facilitates aspiration of urine into the syringe. If no urine is obtained on the first attempt, a second attempt should be delayed until sufficient urine buildup has occurred. At the completion of the procedure, pressure should be applied over the puncture site until all evidence of bleeding has ceased.

Emergency Alert: Suprapubic aspiration can result in complications, including uterine and bowel perforation, trauma to other portions of the renal system, and infection. The procedure is not recommended for neonates with clotting disorders or disseminated intravascular coagulation. Urethral catheterization may also be performed to obtain sterile urine specimens. After prepping the area with an antimicrobial solution, a 3.5- or 5-French feeding tube or urinary catheter is coated with lubricant and inserted into the urethra until urine returns. Discarding the initial 1 to 2 mL of urine obtained may increase the accuracy of the culture results. Because bagged specimens have a significant risk of contamination, they are not recommended for Gram stain or culture.

Urinalysis

One of the first steps in a urogenital workup is a urinalysis. Variables normally assessed in a urinalysis include color, pH, specific gravity, white blood cells, blood, and protein. Urinalysis includes gross assessment as well as dipstick and microscopic evaluation. The urine is most often straw colored, but this may be altered by the type and amount of solutes. Dipstick testing of urine can provide a wide range of information. This test requires that one to two drops of urine be placed on the dipstick, or the stick may be dipped into a specimen of urine. The results are generally obtained within 30 seconds to 1 minute; however, the exact timing required is based on the manufacturer's suggested procedure and can be found in either the instruction manual or on the dipstick bottle itself. In addition to pH, specific gravity, protein, and blood, the dipstick test may also assess the presence of leukocytes, nitrites, glucose, bilirubin, and ketones in the urine. The presence of leukocytes and nitrites can be indicative of a UTI.

Renal regulation of acid–base balance has previously been discussed. Urinary pH values range from 4.5 to 8 and reflect the kidney's attempt to maintain acid–base balance. The newborn initially excretes alkalotic urine with a pH of approximately 6. Urine pH values in the newborn should be evaluated in relation to the serum bicarbonate values. Production of alkaline urine with documented metabolic acidosis may indicate renal pathology.

Specific gravity indicates the kidney's ability to concentrate and dilute urine, and normal levels typically range from 1.001 to 1.015. Since infants have a decreased ability to concentrate urine, specific gravity measurement in the newborn can be misleading. High specific gravities can be an indication of either dehydration or high solute excretion. Excretion of glucose and protein in the urine may artificially increase the specific gravity in the newborn. Urine osmolality or the number of solute particles dissolved in a given volume of solution is a more accurate measure.

Urine Chemistries

Urine chemistries can be helpful in determining fluid and electrolyte balance when evaluated in comparison to serum electrolyte levels. Sodium excretion is very high in the fetus and premature infant but tends to decrease with increasing gestational age. While the term infant conserves renal sodium and renal sodium loss is small, sodium loss in the premature infant can be very high, necessitating correction in intravascular fluids or feedings. The increased sodium loss in premature infants is related to an impaired reabsorption of sodium in the renal tubules as well as unresponsiveness to aldosterone.

Potassium is freely filtered by the glomerulus, but urinary potassium levels are low because the majority of filtered potassium is reabsorbed by the proximal tubule and, to a lesser extent, the loop of Henle. Urinary potassium levels reflect the amount secreted by the collecting tubule. As a result, increased potassium load can significantly increase serum potassium levels. Hyperkalemia can be a life-threatening situation and is defined as a potassium level greater than 6 mEq/L. Infants who are extremely low birth weight (<1,000 g) are at a higher risk of hyperkalemia due to a reduced GFR, acidosis, and an immature tubular response to aldosterone.

Blood Urea Nitrogen and Creatinine

Evaluation of blood urea nitrogen (BUN) and creatinine levels is essential when assessing renal function. Creatinine is a breakdown product of creatinine phosphate in the muscles. It is freely filtered by the glomerulus, and creatinine levels are the most common indicator of GFR (Boer, de Rijke, Hop, Carnsberg, & Dorresteijn, 2010). Creatinine levels at birth are relatively high and reflect maternal levels, gestational age, and the infant's GFR. The level may temporarily increase on day 1, but then begins to decrease over the first few weeks of life (Boer et al., 2010). The more immature the infant, the higher the initial creatinine level and the longer it takes to reach normal levels. Serial levels are necessary to accurately evaluate renal function. Although these indices are not absolute indicators of long-term renal dysfunction, they can be used to identify and treat acute problems. During the first few days of life, BUN levels should not be greater than 20 mg/dL. Elevated BUN levels can result from significant dehydration, ingestion of high-protein loads, and renal dysfunction. Table 18.2 provides a summary of blood and urine chemistries in both term and preterm infants.

Urine Culture

Urine culture in the newborn is used to assess for UTI. UTIs are common in the infant and can occur in association with urinary tract deformities, due to sepsis, or when organisms have been introduced via invasive procedures. Either in-and-out catheterization or suprapubic tap to maintain the sterility of the specimen should be used to obtain urine cultures.

RADIOLOGICAL EVALUATION

Radiological examination includes a variety of tests available for determining anatomic and physiological function.

TABLE 18.2

DIFFERENCES IN RENAL FUNCTION BETWEEN FULL-TERM AND PRETERM INFANTS

	Preterm	Full-Term
Creatinine clearance 1 week after birth (mL/minute/1.73 m^2)	11 ± 5 (GA 25–28 weeks) 15 ± 6 (GA 29–34 weeks)	46 ± 15
Plasma creatinine 1 week after birth (mg/dL)	1.4 ± 0.8 (GA 25–28 weeks)	0.5 ± 0.1
Maximum urine osmolality (mOsm/kg H_2O)	400–700	600–900
Proteinuria (mg/m^2/day)	86–377	68–309
Plasma bicarbonate (mEq/L)	19.5 ± 2.9	21.0 ± 1.8
Mean fractional excretion of sodium (%)	4 (GA ≤30 weeks)	≤2

GA, gestational age.

Source: Modified from Springate, J. E., Fildes, R. D., & Feld, L. G. (1987). Assessment of renal function in newborn infants. *Pediatrics in Review, 9*(2), 51–56. doi:10.1542/pir.9-2-51

Renal Ultrasonography

One of the safest and most useful tests to evaluate for the presence of renal anomalies is ultrasonography. Ultrasound is readily available, is noninvasive and inexpensive, and can detect most structural renal abnormalities. The two-dimensional mode and Doppler imaging are the usual techniques. The two-dimensional mode may be used to determine kidney structure, and Doppler imaging provides information relative to blood flow in the renal arteries and veins. Ultrasonography is useful in identifying renal obstruction, hydronephrosis, the presence of renal calculi, and, in some cases, advanced parenchymal disease.

Prenatal Ultrasound

Currently, the majority of pregnant women undergo prenatal ultrasounds between 16 and 20 weeks' gestation. Seventy percent of renal and urinary tract anomalies are diagnosed during prenatal ultrasound (Dias et al., 2014). Prenatal ultrasound is proficient in providing information regarding amniotic fluid volume, degree of urinary tract obstruction, as well as the presence of hydronephrosis. The presence of abnormally sized kidneys, renal cysts, hydronephrosis, abnormal bladder size, and oligohydramnios suggests significant renal or urinary tract abnormality. Amniotic fluid is predominantly produced by the kidneys, and anhydramnios or severe oligohydramnios may be indicative of severe kidney disease (Dias et al., 2014). Normal amniotic fluid levels are critical for normal lung development, and severe oligohydramnios can result in pulmonary hypoplasia.

Prenatal diagnosis of renal abnormalities provides an opportunity for family counseling and, if necessary, allows the family time

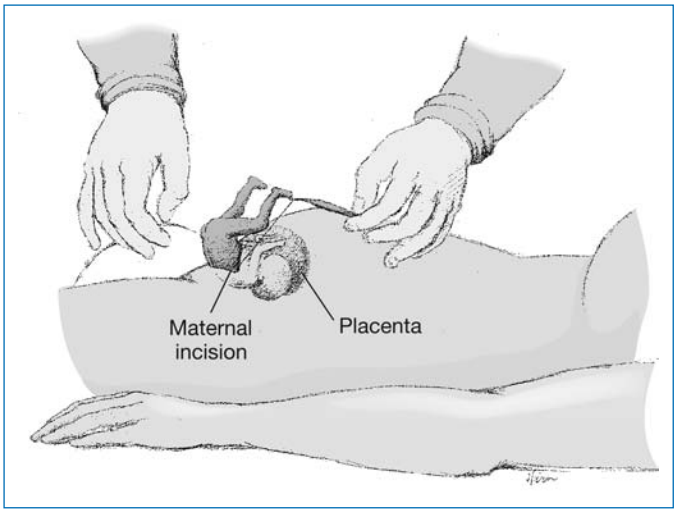

FIGURE 18.4 Fetal surgery to prevent hydronephrosis.

to make treatment decisions, including elective termination if the anomaly is incompatible with life. It also allows maternal transfer prior to a tertiary care center so that the infant can be provided optimal care in the delivery room and immediately following delivery. Because of prenatal diagnosis, treatment of neonatal renal disease may be initiated prior to the onset of symptoms, potentially improving long-term prognosis. Prenatal diagnosis of renal abnormalities can cause significant family stress, and families require honest, accurate information. To become a source of this information, nurses require an understanding of the disease process and treatment options for renal abnormalities.

Prenatal ultrasound also provides an opportunity for in utero treatment of certain disorders. Placement of a vesicoamniotic shunt (a shunt placed in the bladder to drain urine into the amniotic fluid) can be used to increase amniotic fluid volume and reduce the complications of oligohydramnios (Figure 18.4; Clayton & Brock, 2018). The goals of in utero shunting include restoration of adequate amniotic fluid volume for lung development and preservation of renal function by relieving obstruction. This procedure is associated with varied success, and complications include dislodgement, premature labor, urinary ascites, and chorioamnionitis (R. K. Morris et al., 2015; Nassr et al., 2017).

Voiding Cystourethrogram

During a voiding cystourethrogram (VCUG), a urinary catheter is placed into the bladder, contrast material is instilled, and fluoroscopy is then used to monitor bladder filling and voiding mechanisms and to assess for the presence of vesicoureteral reflux (VUR; Choi, Cheon, Kim, & Kim, 2016). VCUGs are primarily used to assess for the presence of VUR but can also assess bladder and urethral function and anatomy.

Renal Scintigraphy With Dimercaptosuccinic Acid Scan

This test is considered the gold standard for assessment of renal parenchyma and is usually performed to evaluate renal function and assess for renal damage. It involves intravenous (IV) administration of an actively labeled substance (radioisotope) radioactive isotope. The most commonly used radioisotope is technetium-99m mercaptoacetyltriglycine (^{99m}Tc-MAG-3). The radioactive isotope is taken up by the renal parenchyma to identify regions of decreased update representing inflammation or renal scarring. It can also be used to visualize kidney mass as well as ureter and bladder outline. In the premature infant, contrast material should only be used when absolutely necessary, since the hyperosmolarity of the solution can lead to further renal compromise.

Diuretic Renography

A diuretic renography is another radionuclide test that is used to differentiate between obstructive and nonobstructive uropathies and to assess renal function. A radioisotope injection is administered, followed 15 to 30 minutes later by a diuretic injection. The diuretic facilitates the movement of the radioisotope through the renal system, and a gamma computer tracks the isotope's movement. If urinary obstruction is present, the isotope's progress is slowed or impeded and is shown as retention of the radioactive substance. If dilation exists along the renal system, urine is retained at the ureteropelvic junction (UPJ) until overflow occurs with diuretic action. Stretching of the muscle fibers at this point causes strong contractions, release of urine, and rapid movement of the isotope with a sharp, immediate decline in isotope concentration. In a normal kidney, the isotope takes about 25 minutes to clear the system.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) provide high-resolution cross-sectional imaging and may be useful to provide additional information in the setting of complex urological abnormalities (Garcia-Roig, Grattan-Smith, Arlen, Smith, & Kirsch, 2016). In addition, fetal MRI is becoming more accepted as a way to more precisely characterize GU abnormalities prior to birth (Tubre & Gatti, 2015).

MANAGEMENT

Fluid, Electrolytes, and Nutrition

When renal failure is suspected, serum electrolytes, phosphorus, and calcium levels should be monitored as frequently as clinically indicated to prevent derangement. Fluids should be carefully managed relative to the clinical presentation and response to therapy.

Abnormalities in fluid status, including both dehydration and overhydration, are common and must be carefully monitored. Nursing management involves the ongoing assessment and reporting of signs and symptoms consistent with abnormalities in hydration. Daily or twice-daily weights may be required for determination of excessive fluid retention or loss. Accurate intake and output must be measured, and urine specific gravity should be frequently monitored. The presence of edema due to fluid overload can be assessed by observing for the presence of periorbital edema and edema of the hands, feet, labia, and scrotum. Pitting should be determined by gentle depression of a fingertip into the suspected edematous site.

Hyponatremia is common and is usually related to fluid overload and increased antidiuretic hormone (ADH) production (Jetton & Sorenson, 2017). A sodium level less than 120 mEq/L can result in seizures and must be treated with sodium replacement therapy. **Quality and Safety: Careful monitoring of fluid status and restricting fluid intake to insensible water loss plus urinary output is imperative to prevent hyponatremia in infants with severe oliguria.**

Due to oliguria or anuria, hyperkalemia is also a potential complication of renal failure, and maintenance of appropriate potassium levels is imperative.

Emergency Alert: If hyperkalemia is associated with ECG changes, it may result in a medical emergency; careful cardiac monitoring is essential to detect any abnormal rhythms or patterns resulting from alterations in potassium levels (Bonilla-Felix, 2017).

Potassium should not be added to parenteral fluids until an appropriate urine output has been established. The goals of hyperkalemia management are to decrease myocardial excitability, enhance cellular potassium uptake, and facilitate potassium excretion. Administration of IV calcium gluconate aids in decreasing myocardial excitability. Cellular uptake of potassium can often be achieved through combined administration of glucose and insulin as well as administration of sodium bicarbonate alone (1 mEq/kg). These measures are the only temporary solutions to the problem since they do not remove the excess potassium from the body. Exchange transfusions and administration of Kayexalate can facilitate potassium excretion. The administration of a cation-exchange resin, such as Kayexalate, binds the serum potassium and actively removes it from the body (Bonilla-Felix, 2017). Each gram per kilogram administered will decrease the potassium level by 1 mEq/L. Since the mechanism of action is exchange of a sodium ion for a potassium ion, hypernatremia, fluid overload, and congestive heart failure are potential side effects of Kayexalate. Administration of Kayexalate is not an immediate solution for hyperkalemia since it takes several hours to take effect. If the hyperkalemia is severe or if conventional therapies are unsuccessful, dialysis may be necessary.

Because of decreased excretion, hyperphosphatemia may also occur with renal disease, causing severe hypocalcemia and even tetany. Aluminum hydroxide is a treatment option by binding phosphorus in the intestines, but dialysis is often indicated for treatment of severe hyperphosphatemia. A low-phosphorus formula such as Similac PM 60/40 (Ross Laboratories, Columbus, OH) or spinal muscle atrophy (SMA; Wyeth, Madison, NJ) may be indicated in infants receiving enteral nutrition.

Hypocalcemia is common and, if symptomatic, can be treated with calcium supplements. Close nursing observation is necessary during IV administration since rapid administration can precipitate cardiac arrest. Vitamin D supplementation is a useful adjunct for correction of calcium levels through facilitation of intestinal calcium absorption during enteral feedings. Metabolic acidosis often occurs in conjunction with renal disease due to decreased secretion and increased production of hydrogen ions. Sodium bicarbonate is indicated if the pH falls to less than 7.2.

Growth and nutrition may be compromised due to the necessary fluid and protein restriction necessitating meticulous attention to nutrition and fluid status. A positive nutritional status positively affects both the short- and long-term outcomes of infants with renal disorders. If fluid restriction is necessary, attempts should be made to increase the total caloric consumption without increasing the overall fluid volume. The overall goal of nutritional therapy is to preserve a positive nitrogen balance while avoiding increases in nitrogenous waste products and increased BUN levels. Protein intake should be determined by overall caloric intake and BUN levels, and recommendations usually include 1 to 2 g/kg/day (Zaritsky & Warady, 2014).

Skin Management

Impaired skin integrity is common, especially in the presence of severe edema. The infant's position should be changed every 2 hours to decrease the effects of dependent edema and to improve circulation. The skin around any operative site should be inspected with every dressing change for signs of irritation or infection and should be kept clean and dry to prevent skin breakdown and infection.

Respiratory Management

Due to oligohydramnios, respiratory compromise is common in infants with alterations in urinary elimination. During fetal life, insufficient amniotic fluid is linked to decreased development of the respiratory tree (see discussion on severe oligohydramnios sequence's syndrome). Varying degrees of lung hypoplasia may exist, resulting in potentially significant respiratory distress.

Before extensive therapy is initiated for the treatment of renal anomalies, careful evaluation of respiratory status should be performed (see Chapter 6, Respiratory System). Measures to improve renal function may not be considered if respiratory capacity is insufficient to support life.

General Preoperative Management

If surgical intervention is indicated, preoperative care is directed toward achieving and maintaining fluid and electrolyte balance and ensuring hemodynamic stability. Ongoing assessment for signs of a UTI, including poor feeding, temperature instability, cyanosis, and other subtle signs of infection, is necessary. Surgery should be delayed until the infant is free from any possible infection including UTIs.

General Postoperative Management

Postoperatively, nursing management is again focused on careful assessment and monitoring of fluid and electrolyte status as well as the hemodynamic system. Vital signs including blood pressure, pulse, and respiration should be monitored every 2 to 4 hours after the initial post-op period. Accurate measurement of fluid intake and output is critical. Dressings should be inspected for bloody drainage or secretions. Initially, a small amount of bleeding at the site is common, but prolonged or heavy bleeding should be reported to the medical team. Depending on the overall clinical status of the infant, feedings can usually be resumed once bowel sounds can be auscultated and the nasogastric tube has been removed.

If renal function is at risk due to a blockage at the level of the ureter, surgical placement of a nephrostomy tube may be indicated (Hwang et al., 2018). Generally, nephrostomy tubes are considered only for severe bilateral obstruction with renal failure or if there is evidence of renal insufficiency in a severely obstructed unilateral kidney (Lang, Allaei, Robinson, Reid, & Zinn, 2015). Because the renal system is highly vascularized, the chance of bleeding and infection is increased. After insertion of a nephrostomy tube, pink-tinged urine or even urine with visible bloody streaks is common. Because they are located within the renal pelvis, these tubes should not be irrigated. The tubes should be connected to a closed drainage system to maintain sterility, and a clean dressing surrounding the tube should be used to maintain the position and to protect the underlying skin. Upon removal, leakage of urine at the site for up to 48 hours is considered normal.

Parental Support

Parental response to a critically ill infant will vary and must be addressed individually. Consenting to a major surgical procedure on their infant so early in life may be very difficult. The parents must be given accurate information regarding their infant's prognosis and should be encouraged to express their concerns. Use of an interdisciplinary team is essential. Collaboration among the neonatologist, pediatric urologist, nurse, clergy, and social worker will help parents adjust to this frightening situation. If the infant's clinical status is terminal, early identification and involvement of their support network, including family, friends, and clergy, can assist the parents in coping with the reality that their child may not survive. In order for the family's needs to be met, the bedside nurse must anticipate their needs and respond appropriately (Purdy, Craig, & Zeanah, 2015).

The general principles of collaborative management have been outlined. The remainder of the chapter addresses the most common GU neonatal problems.

URINARY TRACT INFECTIONS

Pathophysiology

UTIs are common in infants and are defined as infection of the kidney and/or the bladder. Infection occurring in the kidney is called pyelonephritis, whereas infection of the bladder is cystitis. The presence of a UTI results in acute morbidity in the neonatal population and, if not properly treated, can result in long-term sequelae, including decreased renal function, renal scarring, and HTN. The presence of a UTI can also be a sign of an underlying renal abnormality (Arshad & Seed, 2015).

Risk Factors

The incidence of UTIs is 7% to 15% in infants less than 30 days old, and the risk is even higher in infants born premature or who are critically ill (Bonadio & Maida, 2014). UTIs are more common in male infants, potentially due to an increased risk of UTI in uncircumcised males (B. J. Morris & Wiswell, 2013). Traditionally, it was thought that UTIs were strongly associated with the presence of VUR, but recent evidence has refuted this assumption. The risk of a UTI is increased in infants with a neurogenic bladder that is associated with neural tube defects, including meningomyelocele, and occurs when the bladder lacks innervation and, therefore, fails to completely empty.

Clinical Manifestations

During the first 1 to 2 months of life, clinical manifestations of UTIs are often nonspecific and subtle and include temperature instability, poor feeding, cyanosis, abdominal distention, poor weight gain, hepatomegaly, jaundice, and fever (Arshad & Seed, 2015). A urine dipstick is often positive for protein, blood, nitrites, or leukocytes (Joseph & Gattineni, 2016). The presence of a UTI may also be discovered during a general sepsis evaluation.

Diagnosis

Initial examination of the infant suspected of having a UTI includes a thorough family and perinatal history. Any positive familial history of pyelonephritis or nephritis as well as maternal infections should be noted. Neonatal procedures, including suprapubic bladder taps and bladder catheterization, should be noted along with the dates these procedures were performed in order to estimate the incubation time for possible infection. Infants with signs of a UTI may have nonspecific inflammatory markers, including an elevated or decreased white blood cell count, a left shift on complete band count, and an elevated C-reactive protein (CRP). A urinalysis or dipstick positive for either leukocytes or nitrites should be considered evidence of a UTI until urine culture results are obtained. The presence of protein and blood in the urine suggests a UTI but is not conclusive.

A urine Gram stain and culture should be obtained using either suprapubic aspiration or sterile bladder catheterization. Bagged urine specimens should never be used for culture purposes due to the high likelihood of contamination (Roberts et al., 2011). False-positive culture results obtained from bagged specimens can lead to misdiagnosis and inappropriate treatment. Any bacteria obtained from a suprapubic aspiration must be considered diagnostic, whereas urine obtained via catheterization can have up to 10^5 CFUs (colony-forming units) before a UTI is diagnosed. Because of the strong possibility of systemic infection, a blood culture should also be obtained. All Gram stains and cultures should be obtained prior to the initiation of antibiotic therapy, allowing appropriate diagnosis and identification of pathogens (Roberts et al., 2011).

Prognosis

With prompt diagnosis and treatment, the prognosis is generally excellent for isolated UTIs. If left untreated, the potential for serious complications, including severe damage to the renal system, exists, including renal scarring, decreased renal function, and HTN (Stein et al., 2015). The prognosis of infants with underlying renal abnormalities is dependent on the severity and type of abnormality.

Collaborative Management

Prompt treatment is imperative to prevent complications, including renal scarring, which can lead to HTN or permanent kidney failure. Empiric broad-spectrum IV antibiotic therapy should be initiated following completion of the diagnostic workup and continued for 7 to 14 days IV (Roberts et al., 2011). Following identification of the infective organism on culture and specification of sensitivities, antibiotic coverage may be adjusted. A repeat urine culture should be obtained 48 to 72 hours following initiation of treatment. The majority of UTIs are caused by *Escherichia coli*; however, *Klebsiella*, *Pseudomonas*, *Proteus*, *Enterococcus*, *Staphylococcus*, and *Candida* are becoming more common as causative agents in the NICU (Arshad & Seed, 2015). UTIs commonly occur in conjunction with systemic sepsis, and it may be difficult to determine whether the UTI is a result of sepsis or is the underlying cause.

Historically, infants diagnosed with a UTI underwent a VCUG to assess for VUR because of a presumed association between VUR and UTIs. Evidence now exists that the risk of recurrent UTI is not significantly affected by VUR, and the American Academy of Pediatrics (AAP) currently recommends that a VCUG not be performed following the first UTI unless the renal ultrasound indicates the presence of abnormalities, including hydronephrosis, renal scarring, severe VUR, or obstructive uropathy (Flannery et al., 2017; Roberts et al., 2011). A VCUG is also indicated if the infant is affected by subsequent UTIs. A renal ultrasound is recommended following all UTIs. It is a safe and easy procedure that may provide important information regarding an underlying renal abnormality (Roberts et al., 2011). Controversy exists concerning the necessity of prescribing prophylactic antibiotic therapy to all infants until the presence of reflux has been eliminated. Prophylactic antibiotics do not completely prevent future UTIs or the scarring associated with reflux, and the risk of subsequent UTIs is not increased without prophylactic antibiotics (Roberts et al., 2011).

Nursing Management

Nurses play a key role in monitoring infants in the NICU for symptoms of UTIs. When an infant exhibits symptoms or has other signs including the presence of leukocytes, nitrites, blood, or protein in the urine, these should be reported to the medical team for further evaluation. If a VCUG is performed, it is important for nurses to appreciate that this procedure may be uncomfortable to the infant and stressful to the family. Nonpharmacological interventions, such as sucrose nipples, swaddling, and non-nutritive sucking, should be provided, and while pharmacological pain interventions are rarely required, they should be administered if the infant's pain scores are elevated. Discharge instructions for infants who have been diagnosed with a UTI should include signs and symptoms of a UTI, and parents should be instructed to seek medical care immediately if symptoms occur (Roberts et al., 2011).

CIRCUMCISION

Circumcision is removal of the prepuce from the glans of the penis. Although the function of the prepuce is not entirely understood, it is probably involved in protection of the glans. Circumcision is

one of the most commonly performed procedures in the United States, and approximately 89% of neonates are circumcised (Introcaso, Xu, Kilmarx, Zaidi, & Markowitz, 2013). There are currently three commonly utilized methods of circumcision: the Gomco clamp, the Plastibell device, and the Mogen clamp. The method utilized is generally dependent on individual preference and familiarity.

Until 1989, the AAP recommended against routine circumcision based on lack of medical indication for the procedure. In 1989, a multidisciplinary Task Force on Circumcision established by the AAP summarized the pros and cons of circumcision but did not make a specific recommendation regarding the necessity of routine circumcision (Schoen et al., 1989). In 1999, this same task force again summarized the existing scientific evidence, stating that although potential benefits to circumcision existed, there were insufficient data to recommend routine circumcision. They recommended that parents be provided with accurate and unbiased information and allowed to make the decision whether or not to circumcise their child (Lannon et al., 2012). The World Health Organization (WHO) takes a more proactive stance, stating that circumcision should be considered an effective intervention of HIV prevention in areas with heterosexual HIV epidemics and a low rate of male circumcision (WHO, n.d.).

Males who are not circumcised as neonates are at increased risk of infection of the prepuce (posthitis) or glans (balanitis) or both (balanoposthitis) and obstruction of the urethra (phimosis; B. J. Morris et al., 2017). Uncircumcised infants have a 9.9 times higher risk of UTI, and the lifetime UTI incidence increases from 8.8% to 32.1% in uncircumcised males (B. J. Morris & Wiswell, 2013). This increased risk is thought to be due to the higher periurethral colonization of bacteria in uncircumcised males that can be introduced into the urethral opening.

Circumcision is also associated with long-term benefits, including a decreased risk of HIV, and in the United States, it is estimated that routine neonatal circumcision would decrease the rate by 2,500/year (Lei et al., 2015; Nelson, 2015; Sharma et al., 2018). In addition, the risk of human papillomavirus may be decreased by 43% (Albero, Castellsague, Giuliano, & Bosch, 2012). Circumcision has also been associated with a reduced risk of penile cancer, probably due to a decrease in the incidence of phimosis (Larke, Thomas, dos Santos Silva, & Weiss, 2011). However, the American Cancer Society states that due to the low risk of penile cancer among uncircumcised males in the United States, circumcision should not be recommended only to prevent penile cancer (American Cancer Society, 2017).

Complications of circumcision are rare, occurring in less than 5% of cases (El Bcheraoui et al., 2014). Most complications are minor and include bleeding, pain, inadequate skin removal, and mild infection. Bleeding is by far the most common complication, occurring in 1% of infants undergoing circumcision (Krill, Palmer, & Palmer, 2011). A hematological workup is warranted in patients who have persistent or significant bleeding associated with the procedure. More serious complications, including amputation of the glans, glandular necrosis, and meatal stenosis, are rare (Krill et al., 2011). Complications occur most often when the wrong-sized equipment is used or when the clinician performing the procedure is inexperienced or untrained. Although the complication rate of circumcision is higher in older individuals, some suggest that parents are providing consent for what may be considered a nonessential procedure and perhaps the procedure should be delayed until the child reaches adolescence and can make an independent and informed decision.

It is well known that performing circumcision without analgesia produces significant pain and physiological stress, underscoring the need for appropriate procedural analgesia, which is recommended by the AAP. The use of a dorsal penile nerve block, a ring block, and eutectic mixture of local anesthetics (EMLA) have all been shown to decrease the pain associated with circumcision, with the dorsal penile nerve block being found most effective in pain control (O'Conner-Von & Turner, 2013). Effective adjuncts to nerve blocks include non-nutritive sucking, sucrose nipples, and padded chairs; these therapies should be provided in addition to more invasive pain relief.

Nursing Management

Nursing care following circumcision includes assessment for symptoms of bleeding every 30 minutes for at least 2 hours. Assessment and documentation of the first void following circumcision are also necessary to evaluate for urinary obstruction related to penile injury or edema. Petroleum gauze should be applied to the circumcision site and should be changed frequently to protect the site and prevent bleeding. Parent education prior to discharge is necessary and should include care of the site as well as potential complications requiring medical care. Parents should be told that normal bathing is safe and be provided instructions regarding the petroleum-based dressing. Parents should also be advised to seek medical care if the child presents with pain, fever, lethargy, separation of the edges of the skin, unusual swelling or bleeding, and difficulty with urination.

ACUTE RENAL FAILURE

Pathophysiology

Acute renal failure (ARF) is associated with a significant increase in both the mortality and the morbidity of infants in the NICU. ARF occurs when the GFR abruptly decreases or completely ceases, leading to impairment in fluid and electrolyte regulation and acid–base homeostasis (Jetton & Askenazi, 2014). ARF can be either oligoanuric or nonoliguric. Oligoanuric renal failure is suspected when urinary output falls below 1 mL/kg/hour and serum creatinine levels rise to greater than 1.5 mg/dL. Nonoliguric renal failure occurs in 30% of cases and has an elevated creatinine level, but urine output is either normal or elevated. Other indicators of ARF include a serum creatinine level that rises by 0.3 mg/dL within the first 48 hours or rises 50% or higher above baseline (Jetton & Askenazi, 2014; Selewski et al., 2015).

ARF can be classified as prerenal, intrinsic, or postrenal. Prerenal failure is by far the most common, accounting for 75% to 80% of cases, and is caused by inadequate perfusion to a normal kidney (Nada, Bonachea, & Askenazi, 2017). Decreased perfusion may be caused by increased fluid losses from hemorrhage, increased insensible water loss, third spacing, or by decreased renal blood flow due to congestive heart failure, hypotension, or hypoxia (Nada et al., 2017). Persistent hypoxia may lead to shunting of blood away from the kidneys toward the more critical organs of the body, causing renal hypoperfusion. Failure to adequately recognize and treat prerenal failure can result in permanent kidney damage.

Intrinsic renal failure results from damage to the renal parenchyma and can occur due to progression of either prerenal or postrenal failure, infection, renal vein thrombosis (RVT), or nephrotoxicity from medications such as aminoglycosides, indomethacin, and amphotericin B (Girardi et al., 2017; Nada et al., 2017; Selewski et al., 2015). Acute tubular necrosis (ATN) is the most common cause of intrinsic renal failure and is a renal tubular cellular injury due to severe hypoxia, dehydration, sepsis, or blood loss (Nada et al., 2017). Other causes of intrinsic renal failure include structural abnormalities of the kidney, including renal

dysplasia and polycystic or multicystic kidney disease (MKD; Nada et al., 2017).

Postrenal failure is caused by obstruction of the urinary tract with resultant disruption in antegrade urine flow (Nada et al., 2017). Posterior urethral valves (PUVs), UPJ and ureterovesical junction obstruction, prune-belly syndrome, and neurogenic bladder can cause obstruction. Back flow of urine into the kidney pelvis can result in hydronephrosis and subsequent damage to the renal parenchyma.

Risk Factors

Acute kidney injury is common in neonates and is estimated to occur in 24% to 56% of neonates admitted to the NICU (Lee et al., 2017). This estimate may not accurately reflect the true incidence since cases of nonoliguric renal failure are often not included. Any condition that interferes with normal renal function can cause acute injury (Table 18.3). Asphyxia is one of the most common causes of ARF, with 30% to 56% of affected infants having ARF (Chock, Frymoyer, Yeh, & Van Meurs, 2018). Severity of the asphyxia correlates with both the incidence and the severity of ARF, and the risk increases during hypothermic therapy. ARF is also common in very-low-birth-weight infants, with the most premature infants being the most susceptible to injury (Lee et al., 2017).

Clinical Manifestations

Acute renal injury should be suspected in all critically ill infants in the NICU, especially those with underlying risk factors for ARF. Cardinal symptoms of ARF include urine output less than 1 mL/kg/hour and an elevated creatinine level. However, oliguria is not always present since infants with nonoliguric renal failure may have a normal or high urine output. The infant may also appear edematous due to fluid overload resulting from a decreased urinary output and be hypertensive from fluid overload or an increased secretion of renin and aldosterone from the damaged kidney. Physical examination may reveal a flank mass, abnormal genitalia, or the presence of other associated congenital anomalies.

Serum electrolytes will show an elevated BUN and creatinine level and, possibly, hyperphosphatemia, hyponatremia, acidosis, and hypocalcemia. Hematuria and proteinuria on urine dipstick and urinalysis are also common signs of intrinsic renal failure (Joseph & Gattineni, 2016). A urine to plasma osmolality ratio of 1:1 or less is also indicative of renal failure. Renal compromise can be detected in utero through evaluation of fetal urine samples. The maximum fetal urine electrolyte levels considered within normal limits are sodium, 100 mEq/L; chloride, 90 mEq/L; and osmolality, 210 mOsm/kg. When these levels are elevated, renal failure is suspected.

TABLE 18.3

MAJOR CAUSES OF ACUTE RENAL FAILURE IN THE NEWBORN

Prerenal Failure	Intrinsic Renal Failure	Postrenal Failure
Systemic hypovolemia	Acute tubular necrosis	Congenital malformations
Fetal/neonatal hemorrhage	Congenital malformations	Imperforate anus
Septic shock	Bilateral agenesis	Urethral stricture
Necrotizing enterocolitis	Renal dysplasia	
Polycystic kidney disease	Posterior urethral valves	
Dehydration		Urethral diverticulum
Renal hypoperfusion	Glomerular immaturity	Primary vesicoureteral reflux
Perinatal asphyxia	Infection Congenital syphilis	
Congestive heart failure	Toxoplasmosis	Ureterocele Megacystis megaureter
Cardiac surgery	Pyelonephritis	
Respiratory distress syndrome	Renal vascular Renal artery thrombosis	Eagle–Barrett syndrome (prune-belly syndrome)
Pharmacological	Renal venous thrombosis

Diagnosis

ARF is often a manifestation of other underlying disease processes, and diagnosis is aimed at both determining the presence of ARF and identifying the causative element. The suspected contributing process determines specific diagnostic testing.

A careful prenatal, perinatal, and postnatal history is necessary when evaluating an infant with symptoms of renal failure. A family history and prenatal history, including prenatal ultrasound results and amniotic fluid measurements, should be evaluated. Information should be collected regarding a history of perinatal depression, conditions associated with decreased renal blood flow, and administration of nephrotoxic medications.

To differentiate between prerenal and intrinsic renal failure, a fluid challenge of 10 to 20 mg/kg of an IV isotonic solution may be administered (Nada et al., 2017). A urine output of at least 1 mL/kg/hour within 2 hours of the fluid infusion strongly suggests a prerenal cause for the renal failure. The use of a diuretic following the fluid challenge may be necessary if urine output does not immediately increase. A fractional excretion of sodium (FeNa) and a renal failure index may be calculated to further differentiate between prerenal and intrinsic renal failure. A FeNa greater than 3% and a renal failure index greater than 3 suggest a prerenal etiology. Unfortunately, both of these indices are only accurate after 48 hours following delivery, suggesting a need for alternative mechanisms for acute kidney injury within the first 48 hours of life. Urinary biomarkers are under investigation and may be more specific markers for renal tubular damage.

Postrenal failure originating in the lower urinary system can be diagnosed by a positive urinary output following placement of a urinary catheter. A renal ultrasound is indicated to evaluate the etiology of both intrinsic and postrenal failure. Other diagnostic testing is indicated by individual clinical manifestations and suspected underlying etiology of the renal failure.

Prognosis

The prognosis of ARF is related to both the severity of the underlying disease and the ability to treat the underlying problem. The presence of ARF is an independent risk factor for infant mortality and is associated with both short- and long-term complications (Harer, Pope, Conaway, & Charlton, 2017; Maqsood, Fung, Chowdhary, Raina, & Mhanna, 2017). At least 40% of infants diagnosed with ARF experience residual renal dysfunction and/or HTN, and a long-term follow-up is necessary.

Collaborative Management

Early recognition and treatment of ARF may prevent further renal failure and improve outcome, and therefore, the overall treatment goal is to prevent long-term complications of ARF. ARF is treated symptomatically until a definitive cause is determined to guide more specific treatment. Increasing renal perfusion through administration of increased intravascular fluids and, possibly, administration of low-dose dopamine treats prerenal failure.

In infants with intrinsic renal failure, fluid administration is limited to replacement of insensible water losses, other fluid losses, and urine output. Accurate calculation of fluid intake, electrolytes, and urine output is vital to prevent fluid overload and subsequent HTN, edema, and hyponatremia. Hyponatremia can occur because of fluid overload due to oliguria and increased renal sodium losses in infants with nonoliguric renal failure (Misurac, 2017; Nada et al., 2017). Although treatment with fluid restriction is usually sufficient, if the infant is symptomatic or the serum sodium level is less than 120 mEq/L, correction with 3% hypertonic 5 mL/kg over 4 to 5 hours may be necessary (Nada et al., 2017). Hyponatremia unresponsive to treatment may require dialysis.

Since the kidney excretes excess phosphorus, hyperphosphatemia can occur in infants with renal failure. Treatment includes phosphorus restriction, use of low-phosphate formula, and administration of oral calcium carbonate, which binds phosphate and prevents absorption (Nada et al., 2017). Hypocalcemia is also common and may require additional calcium supplementation.

The kidney excretes potassium; therefore, infants with intrinsic renal failure are at significant risk of hyperkalemia. Due to the possibility of cardiac rhythm abnormalities, hyperkalemia can be life-threatening, and thus, potassium intake should be significantly limited or eliminated and the serum level carefully monitored (Nada et al., 2017). Fresh blood should be used for transfusions since older blood is more likely to contain hemolyzed cells, with a resultant elevation in potassium. Treatment of hyperkalemia includes administration of sodium bicarbonate and a combination of insulin and dextrose to drive potassium from the intracellular space into the extracellular space, thereby reducing the serum level of potassium. Administration of IV calcium can be used to protect the heart against arrhythmias but does not reduce the serum potassium level. Kayexalate can be administered rectally to increase elimination of potassium through the intestinal tract. Kayexalate may be ineffective in infants less than 29 weeks' gestation and may be contraindicated due to a possible increased risk of necrotizing enterocolitis (NEC). Uncontrolled hyperkalemia is the most common reason that dialysis is necessary.

Since the kidneys excrete excess hydrogen from the body, metabolic acidosis is common in infants with intrinsic renal failure. Treatment with either additional sodium acetate in IV fluids or administration of sodium bicarbonate orally or parenterally may be necessary (Coulthard, 2016). Sodium bicarbonate should be administered with caution due to its hypertonic nature and possibility of increasing the risk of intraventricular hemorrhage in premature infants.

Due to decreased production and release of erythropoietin from the affected kidney, anemia is a potential complication of renal failure. Careful monitoring of the hematocrit is essential, and treatment with exogenous erythropoietin or packed red blood cell transfusion may be necessary (Coulthard, 2016).

HTN secondary to fluid overload or increased renin secretion from the damaged kidney is common and may require treatment with sodium and fluid restriction. Antihypertensive agents, such as hydralazine, nicardipine, and nitroprusside, may be required if the HTN is severe and/or uncontrollable (Misurac, 2017).

Because many medications are eliminated through the kidney, certain drugs including aminoglycosides, penicillins, cephalosporins, theophylline, indomethacin, tolazoline, amphotericin, and magnesium should be used with caution and levels carefully monitored (Hanna, Askenazi, & Selewski, 2016).

Adequate nutrition is critically important to prevent catabolism and malnutrition but is challenging due to the necessary protein and fluid restriction. Because of their decreased sodium potassium and phosphorous loads, infants receiving enteral nutrition may benefit from feedings of breast milk, Similac PM 60/40, or SMA. Infants with intrinsic renal failure are unable to excrete the by-products of protein breakdown with subsequent elevation in BUN and ammonia levels. Protein administration is thereby generally limited to 1 to 2 g/kg/day.

Emergency Alert: If the infant's condition continues to deteriorate and high BUN and creatinine levels coupled with increasing ammonia levels are present, dialysis may be necessary. Dialysis is a process that removes solutes by diffusion from across a semipermeable membrane (Rees, 2017). Dialysis is generally indicated when maximal medical therapy has failed, and specific recommendations include hyperkalemia, severe hyponatremia, acidosis, hypocalcemia, hyperphosphatemia, volume overload, and malnutrition (Nada et al., 2017; Rees, 2017; Selewski et al., 2015). Although survival of infants requiring dialysis has increased over the past several decades, it remains challenging in neonates (Coulthard, 2016).

Currently, two types of dialysis are used in neonatal patients: peritoneal dialysis and hemofiltration. Peritoneal dialysis is simple, less invasive, is associated with improved hemodynamic tolerance, and is currently the most common type of dialysis performed in neonates (Misurac, 2017; Nada et al., 2017; Selewski et al., 2015). During peritoneal dialysis, hyperosmolar dialysate is infused into the peritoneal cavity through a surgically placed Silastic Tenckhoff catheter, and following dialysis, the fluid is drained from the cavity. Depending on the need for solute and fluid removal, cycle time, dwell time, volume, and the osmolar concentration of the fluid can be adjusted.

Hemofiltration is used when peritoneal dialysis is contraindicated, such as in infants with NEC or those who have undergone abdominal surgery (Selewski et al., 2015). Hemofiltration is a continuous filtration process and includes continuous arteriovenous and continuous venovenous hemofiltration. Continuous arteriovenous hemofiltration (CAVM) involves cannulation of both an artery and a vein. Blood is removed via the artery driven across a filter and replaced via the vein. Continuous venovenous hemofiltration involves either cannulation of two veins or placement of a double-lumen venous line, and a pump is used to draw blood into the filtration circuit.

Nursing Management

Accurate calculation of fluid intake and output is vital to prevent fluid overload and its associated HTN, hyponatremia, and edema (Nada et al., 2017). Frequent monitoring of electrolytes is essential to assess for abnormalities, including hyponatremia (Selewski et al., 2015), which, if severe, can result in seizures, and hyperkalemia, which may produce life-threatening cardiac arrhythmias. Careful monitoring for cardiac arrhythmias using bedside EKG monitoring in infants with intrinsic renal failure at risk for hyperkalemia is necessary. Vital signs, activity level, and color should be frequently assessed to ensure that subtle changes indicating anemia are promptly detected. Infants with renal failure are prone to infection due to multiple invasive procedures and their extended hospitalization and, therefore, should be monitored for signs of infection and any abnormality reported to ensure timely diagnosis and treatment.

Nursing responsibilities for infants on dialysis include monitoring the equipment, monitoring the cycles if performed manually, performing clotting studies, and administration of heparin and other drugs via the dialysis apparatus. Catheter care includes maintenance of aseptic technique, prevention of hemorrhage and clotting, and observation of the insertion site for signs of infection or dislodgment. The infant should be observed for signs and symptoms of chemical imbalances during the entire dialysis procedure. Accurate measurement of fluid intake and output and electrolyte levels is critical. Fluid shifts affecting blood pressure and electrolyte balance can occur rapidly, causing cardiac arrhythmias, muscle spasms, seizures, and shock.

SEVERE OLIGOHYDRAMNIOS SEQUENCE (FORMALLY POTTERS)

Pathophysiology

Severe oligohydramnios sequence occurs in approximately 1 in 10,000 births with an increased incidence in males. Defects associated with this syndrome can be due to bilateral renal agenesis resulting when the ureteric bud fails to divide and develop, culminating in complete absence of the kidney (Phua & Ho, 2016). The etiology can also include completely dysfunctional kidneys due to autosomal recessive polycystic kidney disease (ARPKD), dysplastic kidneys, renal hypoplasia, and obstructive uropathies. The developing fetus continuously swallows amniotic fluid, which is absorbed by the gastrointestinal system and is then secreted into the amniotic cavity by the kidney. When there is little to no urinary output, severe oligohydramnios occurs, resulting in the deformities seen in severe oligohydramnios sequence. An adequate amount of amniotic fluid is also necessary for normal pulmonary development. In the presence of severe oligohydramnios, normal pulmonary development fails to occur, resulting in development of hypoplastic lungs.

Diagnosis

Infants are often born premature, small for gestational age, and in the breech position. Many affected fetuses are stillborn. The effect of severe oligohydramnios on the facies includes low-set, malformed ears and micrognathia, "senile" appearance, wrinkled skin, parrot-beak nose, and wide-set eyes with epicanthal folds. Depending on the degree of oligohydramnios, variable degrees of respiratory distress due to pulmonary hypoplasia are present. Contractures of the limbs due to intrauterine compression are common.

Severe oligohydramnios sequence is readily identifiable on direct observation because of its characteristic features. Prenatal history includes severe oligohydramnios and bilateral renal agenesis or other renal disorders. Regardless of prenatal ultrasound results, an abdominal ultrasound following birth is indicated to confirm the diagnosis.

Collaborative Management

Severe oligohydramnios sequence is almost universally fatal due to pulmonary hypoplasia and subsequent respiratory failure. Due to the irreversible pulmonary hypoplasia, treatment does not include renal transplantation or long-term dialysis.

Assisting the family to cope during and after the death of their infant is the primary aspect of nursing care of infants with severe oligohydramnios sequence. The nurse should encourage parents to visit and hold their infant. Support from pastoral services or social work is imperative during this difficult time.

UNILATERAL RENAL APLASIA

Pathophysiology

When one of the ureteric buds fails to form in utero, unilateral renal aplasia, or the absence of one kidney, occurs. The incidence of unilateral renal aplasia may be as high as 1 in 500 births and is often associated with other structural defects, such as VACTERL association (vertebral anomalies, tracheoesophageal atresia, esophageal atresia, renal agenesis, renal dysplasia, and limb defects), caudal regression syndrome, and chromosomal abnormalities. This condition may often go undetected in the newborn period and may be an incidental finding later in life.

Clinical Manifestations

If the unaffected kidney is normal, infants with unilateral renal aplasia are often asymptomatic (Davidovits, Cleper, Eizenberg, Hocherman, & Mashiach, 2017). Unfortunately, the contralateral kidney is often abnormal, and findings of VUR, UPJ obstruction, renal dysplasia, and ureterocele are common. When the contralateral kidney is abnormal, symptoms are directly related to the type of renal abnormality. If function of the remaining kidney is significantly decreased, the infant may exhibit signs of renal failure. Diagnosis centers on confirmation of the presence of a single kidney and investigation of the contralateral kidney for abnormalities. This is best accomplished by renal ultrasonography with future testing being determined by results of the ultrasound.

Collaborative Management

If kidney function is not compromised, no nursing care beyond normal newborn care is usually necessary. Information regarding the nursing care and treatment of the specific disorders affecting the contralateral kidney is contained in the appropriate section. The prognosis for infants diagnosed with unilateral renal atresia is excellent if the contralateral kidney is normal. If the remaining kidney is abnormal, the prognosis depends on the specific disease process.

CYSTIC KIDNEY DISEASE

Cystic disease of the kidney occurs when normal kidney tissue is replaced with nonfunctioning cysts. These cysts may occur unilaterally or bilaterally, and the amount of cystic formation within each kidney determines the severity of the disease. Severely affected kidneys often have an associated ureteral agenesis. Cystic kidney disease includes polycystic kidney disease and MKD.

POLYCYSTIC KIDNEY DISEASE

Pathophysiology

Polycystic kidney disease is a bilateral process involving micro- or macroscopic cysts distributed throughout the renal parenchyma (Dell, 2011). There are two types of polycystic kidney disease: autosomal dominant polycystic kidney disease (ADPKD) and ARPKD. ADPKD rarely presents in the neonatal period, with symptoms presenting in the fourth to fifth decades of life. In contrast, ARPKD presents in the neonatal period with enlarged kidneys and replacement of the kidney parenchyma with nonfunctional cysts (Figure 18.5). The pelvis, calyces, and ureter are all normal (Baum, 2015). Liver involvement, including hepatic fibrosis, is nearly universal, but symptoms rarely occur in the neonatal period (Hoyer, 2015).

FIGURE 18.5 Gross specimen showing polycystic kidney disease.

Source: Jnah, A. J., & Trembath, A. N. (Eds.). (2019). *Fetal and neonatal physiology for the advanced practice nurse.* New York, NY: Springer Publishing Company.

Risk Factors

The incidence of ARPKD is 1 in 10,000 to 1 in 40,000 (Dell, 2011; Mao, Francis-West, & Irvine, 2015). The majority present as a sporadic anomaly, but an association with other syndromes has been reported. The genetic cause of ARPKD is mutations in the *PKHD1* gene located on chromosome 6p21 (Mao et al., 2015).

Clinical Manifestations

Symptoms include bilateral abdominal masses and HTN. Respiratory distress may also be present due to pressure from the enlarged kidneys on the diaphragm or from pulmonary hypoplasia due to oligohydramnios (Hoyer, 2015).

Diagnosis

ARPKD may be diagnosed on prenatal ultrasound showing enlarged kidneys with increased echodensity. Postnatal diagnosis is through ultrasound findings of small cysts in the collecting ducts. After discussion with the family, a positive family history for ARPKD is often discovered.

Prognosis

Six to thirty percent of affected infants will die in the neonatal period, usually as a result of respiratory failure from pulmonary hypoplasia (Dell, 2011; Mao et al., 2015; Phua & Ho, 2016). In those who survive the neonatal period, over 80% are alive at 10 years (Marlais et al., 2016). An additional close to 60% of infants will eventually advance to end-stage renal disease, requiring dialysis and renal transplantation. Hepatic complications are common and include portal HTN and biliary disease (Dell, 2011).

Collaborative Management

Treatment of ARPKD is mainly supportive and includes treatment of renal failure, ventilatory support if significant respiratory distress is present, and treatment for HTN. HTN associated with ARPKD may be difficult to control, requiring treatment with fluid restriction and antihypertensive medications (Marlais et al., 2016). Nephrectomy may be indicated if severe respiratory distress occurs due to pressure on the diaphragm and/or lungs from the enlarged kidney (Misurac, 2017).

MULTICYSTIC KIDNEY DISEASE

Pathophysiology

MKD is characterized by a collection of different-sized noncommunicating cysts with a complete lack of renal function due to early obstruction of the ureter leading to kidney maldevelopment (Baum, 2015). MKD is generally a unilateral disease; however, if both the kidneys are affected, the prognosis is grim due to respiratory failure from pulmonary hypoplasia.

Risk Factors

MKD has an incidence of 4.3 in 10,000 (Winding et al., 2014).

Clinical Manifestations and Diagnosis

The majority of cases are diagnosed via antenatal ultrasound (Winding et al., 2014). If not diagnosed prenatally, most infants present with a palpable flank mass. Postnatal diagnosis is through renal ultrasound, indicating multiple noncommunicating renal cysts with no normal renal parenchyma or renal pelvis (Sarhan et al., 2014). A radionuclide renal scan will indicate a complete lack of renal function of the affected kidney. VUR and UPJ obstruction frequently occur in the contralateral kidney, requiring careful evaluation via ultrasound and VCUG (Tiryaki et al., 2013). The contralateral kidney is at risk for decreased function both in the neonatal period and childhood.

Collaborate Management

Historically, management included nephrectomy of the affected kidney to confirm diagnosis and prevent HTN and renal malignancy. It is now known that spontaneous involution of the multicystic kidney generally occurs and that only a minimal risk of either HTN or malignancy exists (Chiappinelli, Savanelli, Farina, & Settimi, 2011). Spontaneous involution of the multicystic kidney occurs in 33% of cases, and therefore, conservative treatment is often recommended (Tiryaki et al., 2013). Follow-up care includes clinical and ultrasound assessment every 6 months for the first 2 years and yearly afterward until complete involution of the kidney occurs (Chiappinelli et al., 2011). Proponents of prophylactic nephrectomy argue that frequent follow-up is burdensome to both the family and child and that more cost is incurred than with early removal of the kidney (Tiryaki et al., 2013). Since long-term dysfunction in the remaining kidney is common, careful long-term evaluation for renal function is warranted.

PRUNE-BELLY SYNDROME (EAGLE–BARRETT SYNDROME)

Pathophysiology

Prune-belly syndrome consists of a triad of anomalies, including lack of appropriate abdominal musculature, undescended testicles, and urinary tract malformations (Figure 18.6; Garcia-Roig et al., 2016; Misurac, 2017). Associated urinary abnormalities include an enlarged, poorly functioning bladder; VUR; and urethral obstruction. The ureters may be tortuous and severely dilated, and the kidneys may be dysplastic due to urinary tract obstruction with reflux of urine into the kidneys. Other associated abnormalities include orthopedic, cardiovascular, and respiratory anomalies as well as imperforate anus and patent urachus (Hassett, Smith, & Holland, 2012; Seidel, Arlen, Smith, & Kirsch, 2015).

Two theories exist concerning the etiology of prune-belly syndrome. The first suggests that in utero urethral obstruction results

FIGURE 18.6 A neonate with prune-belly syndrome.
Source: From Clark, D. (2000). *Atlas of neonatology.* Philadelphia, PA: Saunders.

in a back flow of urine into the bladder, leading to severe bladder dilation. This extreme dilation places pressure on the abdominal muscles with subsequent abnormal abdominal wall muscle development (Herman & Siegel, 2009). The second and most prevalent theory is that a generalized mesodermal abnormality occurs during the fourth to 10th weeks of fetal development. During this time, the bladder is taking shape and is being separated from the allantois, and formation of the abdominal wall is occurring. The abnormal mesodermal development leads to the triad of defects seen with prune-belly syndrome (Misurac, 2017).

Risk Factors

Prune-belly syndrome predominantly affects males and only rarely occurs in females. It is 20 times more common in males and has an incidence of approximately 4 in 100,000 live births (Lloyd et al., 2013).

Clinical Manifestations

If the abdominal muscles are severely weakened, the abdominal region may appear wrinkled, much like a prune's surface. Due to the lack of abdominal musculature, there may be visible bowel loops and observable spleen and liver. The abdomen will feel flaccid, and there will be a lack of muscle tone. A large distended bladder and large kidneys will be present on palpitation. Although the spleen is rarely palpable in neonates, one can often feel the spleen in infants with prune-belly syndrome is due to lack of abdominal muscle tone. The liver may also be easily palpable, with more than 1 to 3 cm of liver appreciated even if no hepatomegaly is present. Bilateral cryptorchidism is nearly universally present in males (Seidel et al., 2015). Infants with pulmonary hypoplasia due to oligohydramnios may present with varying degrees of respiratory distress, and those with cardiac anomalies may have symptoms of congenital heart disease.

Diagnosis

A diagnosis of prune-belly syndrome can be made as early as 13 weeks' gestation on prenatal ultrasound (Papantoniou et al., 2010). Oligohydramnios may be present if fetal renal function is compromised. The presence of a distended bladder, dilated ureters, large kidneys, and an abnormal abdominal wall on prenatal ultrasound is highly suggestive of prune-belly syndrome. Following birth, the diagnosis of prune-belly syndrome is generally obvious upon initial examination. A postnatal ultrasound will indicate bladder and urethra distension, hydroureter, and hydronephrosis. Determination of renal function is necessary, and an electrolyte panel including creatinine and BUN levels should be obtained. Urinary output and fluid status must be meticulously monitored. Following stabilization, a VCUG is generally indicated to assess for VUR, and a radionuclide renal scan may be scheduled to determine the degree of renal function. MRI may be useful in further identifying anatomical and functional abnormalities (Garcia-Roig et al., 2016).

Woodard classified patients with prune-belly syndrome into three groups. The first group accounts for 20% of cases and presents with severe renal dysplasia and pulmonary hypoplasia and has a mortality rate of nearly 100%. The second group accounts for 40% of patients and presents with significant urinary tract abnormalities but adequate renal function. Future renal compromise may occur due to renal obstruction or infection. The third group, accounting for 40% of patients, presents with mild urinary tract abnormalities and normal kidney function (Woodard, 1978).

Prognosis

The prognosis of prune-belly syndrome is directly related to the severity of any underlying renal dysfunction, whether there is pulmonary hypoplasia, and the presence of other associated anomalies (Seidel et al., 2015). The mortality rate is 10% to 20%, and another 25% to 39% will develop chronic renal dysfunction, potentially requiring ultimate dialysis and transplantation (Seidel et al., 2015).

Collaborative Management

This triadic anomaly generally results in severe urinary tract complications. The bladder is usually extremely distended and has a large postvoid residual often requiring bladder decompression for prevention of stasis and resultant reflux of urine into the kidney. Bladder decompression generally requires bladder catheterization, and an urethrotomy may be required if urethral obstruction is present. If urinary stasis results in UTIs, a vesicostomy may be indicated (Seidel et al., 2015). Other urinary tract correction is dependent on the type and severity of the underlying abnormalities.

The main goal of therapy is preservation of existing kidney function. Urinary stasis, reflux, and infection can potentially lead to progressive deterioration in renal function. Careful monitoring and prompt diagnosis and treatment are necessary to preserve existing renal function. In infants with decreased renal function, careful attention to fluid and electrolyte balance, removal of wastes, and adequate nutrition for growth and development is required. Prophylactic antibiotics are usually recommended to decrease renal damage from UTIs.

The prenatal placement of a vesicoamniotic shunt may be considered in the presence of oligohydramnios, a large distended bladder, and severe hydronephrosis when there is evidence of functioning kidneys. This procedure has been successful in decreasing

the degree of oligohydramnios and its associated complications and improving subsequent renal function (Leeners, Sauer, Schefels, Cotarelo, & Funk, 2000).

Muscle tone has been shown to improve with time, but abdominoplasty may be performed to improve the appearance of the abdomen and has been shown to increase self-esteem and improve abdominal strength (Seidel et al., 2015). The resultant improvement in abdominal strength may also decrease constipation associated with an inability to perform the necessary Valsalva maneuver required for intestinal evacuation. Strengthening the abdominal muscles may also decrease the number of respiratory infections occurring due to lack of abdominal support and an inability to produce an effective cough as well as to improve the child's posture.

Undescended testes are present in males affected with prune-belly syndrome, and orchiopexy is generally recommended prior to 6 months of age to avoid potential future testicular cancer; however, it is often delayed for 1 year to allow repair in conjunction with urinary tract reconstruction (American Urological Association guidelines; Kolon et al., 2014). Some recommend a nonoperative approach unless significant renal compromise is present, whereas others feel early urinary reconstruction to eliminate urinary stasis, correct reflux, and improve bladder drainage is necessary. Early urinary reconstruction, bilateral orchiopexy, and abdominoplasty may be associated with improved results (Seidel et al., 2015).

Nursing Management

If bladder distention and urinary retention continue when the infant is ready for discharge, parents should be taught to empty the infant's bladder by intermittent catheterization. Parents must also be educated regarding the signs and symptoms of a UTI, such as increased irritability with urination, temperature instability, increase or decrease in urine output, and cloudy or foul-smelling urine. They must understand the importance of early detection and intervention to prevent long-term renal compromise. If a vesicostomy or other urinary diversion procedure has been performed, parents will need specific discharge instructions regarding care of the device.

Consideration of parental feelings concerning the physical appearance of their infant is mandatory. Because American culture places significant value on an individual's appearance, it may be difficult for parents to accept the loss of their "perfect" infant. Significant parental support from social and pastoral services may be necessary. To increase parent–infant interaction, nurses should attempt to include the family as much as possible in the daily care of their infant. Infants diagnosed with prune-belly syndrome often require frequent hospitalizations and several operative procedures, and it is necessary to prepare families for the long-term needs of their infant (Arlen et al., 2016).

EXSTROPHY OF THE BLADDER

Pathophysiology

Exstrophy of the bladder is a rare but severe congenital defect where the anterior abdominal wall fails to close at the point of the bladder (O'Kelly, Keefe, Herschorn, & Lorenzo, 2018). It is theorized that the defect occurs due to an overgrowth of the cloacal membrane, which disrupts closure of the abdominal wall. Timing of its rupture determines the severity of the defect. Exstrophy of the bladder is the most common condition in a spectrum of anomalies ranging from simple epispadias to classic bladder exstrophy (O'Kelly et al., 2018).

Risk Factors

The incidence of this defect is 1 in 30,000 to 1 in 50,000 live births, with males being affected more often than females (Siffel et al., 2011). It is most often an isolated malformation, and infants born weighing less than 1,500 g may be at higher risk (Reinfeldt Engberg, Mantel, Fossum, & Nordenskjold, 2016).

Clinical Manifestations

In classic bladder exstrophy, the bladder region appears open or uncovered, and the posterior wall of the bladder is exposed. Implantation of the ureters may be visible as urine continues to pass from the orifices. A concomitant defect exists in the genitalia, and males present with epispadias with a short, flat, and angulated penis. In the female, the labia do not meet in the midline, and there is a divided clitoris (Pierre, Borer, Phelps, & Chow, 2014). Exstrophy of the bladder is generally not associated with other anomalies, and the kidneys are generally normal. Prolapse of the rectum may also be evident prior to surgical correction. Failure of the pubic bones to meet anteriorly causes the hips to rotate outward (Pierre et al., 2014). Cloacal exstrophy is the most severe expression in this spectrum of anomalies and presents with all the features of classic bladder exstrophy along with an omphalocele, imperforate anus, spinal defects, and UPJ obstruction (Pierre et al., 2014). Neural tube defects and spinal dysraphisms are also commonly present.

Diagnosis

Prenatal ultrasound may suggest the presence of bladder exstrophy. However, a definitive prenatal diagnosis can only be made in approximately 25% of cases. Diagnosis often does not occur until after birth when the defect is obvious on visual inspection (Goyal, Fishwick, Hurrell, Cervellione, & Dickson, 2012; Figure 18.7).

Prognosis

Prognosis is generally favorable with most children leading nearly normal lives. Long-term complications include incontinence as well as sexual and fertility problems.

FIGURE 18.7 An infant with exstrophy of the bladder.
Source: From Clark, D. (2000). *Atlas of neonatology*. Philadelphia, PA: Saunders.

Collaborative Management

Treatment goals for infants with exstrophy of the bladder include successful bladder and abdominal wall closure, urinary continence, preservation of the upper urinary tract, and normal-appearing genitalia. Prior to or immediately following delivery, the infant should be transported to a tertiary care facility experienced with care of the infant with this defect (Inouye et al., 2018). Because bladder exstrophy exposes the urinary tract to the environment, careful attention to prevention of infection is essential both before and after surgical correction. Broad-spectrum antibiotic therapy is initiated prior to surgery and continued for at least 7 days. Because wound dehiscence is often caused by infection, strict observation of aseptic technique and aggressive management of infection are mandatory.

Repair may be accomplished in a single stage where the bladder is closed, the bladder neck is reconstructed, and the epispadias is repaired, usually around 6 weeks of life (O'Kelly et al., 2018). Repair may also be staged where there is a delay of epispadias repair and bladder neck reconstruction (O'Kelly et al., 2018). A suprapubic catheter and bilateral ureteral stents may be placed during surgery to allow drainage of urine while the bladder heals. The infant may be immobilized for several weeks following surgery with traction to facilitate wound healing. VUR is common but can generally be managed conservatively (O'Kelly et al., 2018). Due to the increased risk of future pregnancies being affected, genetic counseling is indicated (Suzuki et al., 2017).

Nursing Management

Immediately following birth, the exposed bladder should be covered with plastic wrap or a similar material to protect it from injury until closure is complete. The area should also be protected by avoiding gauze due to the possibility of becoming dry and adhering to the tissue, using a tie instead of a clamp for umbilical care, changing dressings as needed to prevent skin irritation, and using humidified incubators to prevent excess drying. Diapers should be kept folded well below the defect, to not only protect the area from irritation but to prevent wound infection.

RENAL VEIN THROMBOSIS

Pathophysiology

RVT is a rare occurrence in the neonate, potentially resulting in renal failure, renal atrophy, and HTN (Kraft, Brandao, & Navarro, 2011). The thrombus may be unilateral or bilateral and often extends into the inferior vena cava (IVC).

Risk Factors

RVT occurs in approximately 0.5 of 1,000 admissions to the NICU. Although the presence of an umbilical catheter is a risk factor, the majority of RVTs are non–catheter related, and the exact etiology is often unknown (Kraft et al., 2011). Up to 80% of affected infants have one or more risk factors, including male gender, hyperviscosity and polycythemia, perinatal asphyxia, maternal diabetes, prematurity, dehydration, and infection (Bidadi, Nageswara Rao, Kaur, Khan, & Rodriguez, 2016; Joseph & Gattineni, 2016). Most risk factors are thought to be related to an associated decreased kidney perfusion leading to vasoconstriction and a subsequent decreased venous blood flow and thrombosis. Neonates are at a higher risk for RVT than older children due to a low renal perfusion pressure, decreased levels of natural anticoagulants, and lower levels of fibrinolytic components (Resontoc & Yap, 2016).

Up to 50% of affected infants have inherited prothrombotic risk factors, including hypercoagulation disorders such as protein C deficiency, homocystinuria, and Factor V Leiden (Resontoc & Yap, 2016).

Clinical Manifestations

The mean age of onset is 3 days, with 7.3% of RVTs presenting in utero, 67% within the first 3 days following delivery, and 26% later than 3 days of life (Kraft et al., 2011). RVT often occurs in critically ill infants and may be incidentally discovered when the infant is imaged for other reasons. The classic triad of symptoms include a palpable flank mass, hematuria, and thrombocytopenia; however, only 13% to 22% of infants actually present with all three symptoms (Winyard et al., 2006). However, the majority of infants present with at least one of the three symptoms (Resontoc & Yap, 2016). Other clinical manifestations include symptoms of decreased renal function, including decreased urinary output, elevated creatinine, and anemia (Brandao, Simpson, & Lau, 2011; Resontoc & Yap, 2016).

Diagnosis

Diagnosis is through Doppler ultrasound showing an enlarged kidney. It also provides information regarding renal blood flow and may reveal the presence of a thrombosis located in the renal vein (Joseph & Gattineni, 2016; Resontoc & Yap, 2016). A radionuclide renal scan may be performed to assess function of the affected kidney. Since RVTs may not present with the typical triad of symptoms (flank mass, hematuria, and thrombocytopenia), a high degree of suspicion is necessary to increase the likelihood of prompt diagnosis and appropriate treatment.

Prognosis

Prognosis is dependent on the extent of the thrombus and on whether the lesion is unilateral or bilateral. Although the mortality rate is relatively low (5%) and often related to the underlying critical nature of the infant rather than the RVT, the risk of both acute and chronic complications is significant (Brandao et al., 2011). Acute complications include adrenal hemorrhage, thromboemboli, and pulmonary embolism. HTN, renal atrophy, and chronic renal failure, including end-stage renal disease, are long-term complications (Bidadi et al., 2016; Kraft et al., 2011). HTN occurs in 19% to 22% of survivors and may require nephrectomy if severe (Lau et al., 2007). Chronic renal insufficiency occurs in up to 71% of affected infants, with 3% of infants ultimately experiencing end-stage renal failure (Lau et al., 2007).

Collaborative Management

Treatment is dependent on the severity of the RVT, whether it is unilateral or bilateral, and the presence of impaired renal function (Resontoc & Yap, 2016). Currently, no specific guidelines exist for RVT treatment, and therapy varies between institutions and individual clinicians. Therapy may include supportive care; degradation of the clot with urokinase, streptokinase, or tissue plasminogen activator; or anticoagulation with low-molecular-weight heparin (Resontoc & Yap, 2016). If signs of renal failure occur, careful monitoring of fluid and electrolyte status is necessary as well as treatment of any HTN. In cases of severe renal failure, dialysis may be required. Due to the association of RVT with anticoagulant deficiencies, the infant will require a diagnostic workup for these disorders (Joseph & Gattineni, 2016). All infants will require long-term monitoring for HTN, renal atrophy, and chronic renal insufficiency.

Nursing Management

Nurses are essential for successful evaluation and treatment of RVT. They are often the first clinician to recognize the presence

of risk factors and clinical manifestations, and it is, therefore, necessary for nurses to have a strong knowledge base concerning RVTs. Careful monitoring for HTN is necessary as well as following dipstick urine analysis for hematuria and proteinuria. Strict monitoring of input and output as well as electrolyte status is also necessary. The use of thrombolytic agents or heparin requires careful monitoring of coagulation status, and extreme caution is warranted when using these agents in very-low-birth-weight infants due to the risk of intraventricular hemorrhage.

HYDRONEPHROSIS

Pathophysiology

Hydronephrosis is the accumulation of urine within the renal pelvis and calices to the point of overdistention. If left untreated, this buildup of fluid can cause irreversible kidney damage. Hydronephrosis can be caused by obstruction of urine flow at the UPJ, the ureterovesical valve, or the urethrovesical valve. Nonobstructive abnormalities such as VUR and prune-belly syndrome can also cause hydronephrosis. Secondary etiologies include obstruction such as kidney stones or tumors (Yang, Hou, Niu, & Wang, 2010). The severity of hydronephrosis is classified from grade I to grade V depending on the diameter of the renal pelvis.

Clinical Manifestations

Hydronephrosis is usually detected during a prenatal ultrasound. If the hydronephrosis is severe and bilateral, oligohydramnios may also be present. If diagnosis is delayed until after birth, hydronephrosis may present as a large, smooth, solid, palpable abdominal mass in the region of the kidney. Since the presence of an abdominal mass can signify many disease processes, including cystic kidney disease, urogenital tumors, and RVT, determination of the mass's etiology is essential.

Depending on the amount of functioning kidney, infants with hydronephrosis may have a decreased or normal urine output. When only one kidney is involved, urine output may be normal because a single kidney is sufficient for adequate removal of water and waste. Severe bilateral hydronephrosis may present with signs and symptoms of kidney failure, including a low or nonexistent urine output as well as a high creatinine and BUN level. Infants born with bilateral severe hydronephrosis may also exhibit features consistent with severe oligohydramnios sequence syndrome, including pulmonary hypoplasia due to the presence of oligohydramnios. Since UTIs may be associated with hydronephrosis, infants may present with signs of an UTI, including fever, subtle signs of sepsis, hematuria, proteinuria, and the presence of white blood cells on urinalysis (Joseph & Gattineni, 2016).

Diagnosis

Hydronephrosis is most commonly diagnosed on prenatal ultrasound and can be detected as early as 12 weeks' gestation by the presence of a dilated renal pelvis (Nguyen et al., 2010). Hydronephrosis is the most common renal abnormality detected prenatally and is present in 2.3% of all pregnancies (Ek, Lidefeldt, & Varricio, 2007).

The first diagnostic study indicated in infants suspected of having hydronephrosis or who have hydronephrosis on prenatal ultrasound is a renal ultrasound. In clinically stable infants, the ultrasound should be delayed until the infant is 3 to 4 days old, since the newly born infant's relative dehydration may mask the presence of hydronephrosis (Choi et al., 2016). If bilateral hydronephrosis, unilateral severe hydronephrosis, or possible PUVs exist, an ultrasound should be performed within 1 to 2 days (Nguyen et al., 2010). A VCUG is recommended to assess for the presence of reflux if the hydronephrosis is moderate or severe (Nguyen et al., 2010). Although administration of prophylactic antibiotics for prevention of UTI is somewhat controversial, many clinicians will prescribe until the presence of reflux has been excluded.

Prognosis

Prognosis depends on the underlying causative factor, the severity, and the presence of any permanent renal damage. Outcome ranges from complete resolution to end-stage renal disease requiring dialysis and renal transplant. Most cases of hydronephrosis occur without significant obstruction and can be managed conservatively without surgery (Di Renzo et al., 2015). Complications of hydronephrosis include HTN, UTI, and progressive renal damage (Oliveira, Oliveira, & Mak, 2016). Hydronephrosis secondary to VUR generally spontaneously resolves. Antenatally diagnosed hydronephrosis can indicate obstruction or other serious abnormalities, but can also represent a transient developmental change that may spontaneously resolve prior to birth. Even if resolved, postnatal imaging is required for at least 6 weeks (Choi et al., 2016).

Collaborative Management

Preservation of renal function is the main goal of treatment, and treatment is dependent on the severity of the hydronephrosis. Mild-to-moderate hydronephrosis is usually managed conservatively with close ultrasound monitoring. A VCUG is generally indicated to evaluate for VUR (Choi et al., 2016). Although severe hydronephrosis is initially managed with conservative treatment, some cases will ultimately require pyeloplasty due to deteriorating renal function. When reflux is present, prophylactic antibiotics are often prescribed for UTI prophylaxis.

When severe hydronephrosis is prenatally diagnosed, vesicoamniotic shunting (placement of a catheter into the bladder to drain urine) may be performed to reduce oligohydramnios and its associated complications as well as to sustain kidney function. After birth, definitive surgery is necessary to correct the obstructive defect or to provide a diversion for urine flow (Tubre & Gatti, 2015).

Nursing Management

Careful assessment is imperative in infants diagnosed with hydronephrosis. Vital signs, including blood pressure, must be monitored at least every 4 hours and more frequently if unstable. Monitoring blood pressure is especially important since HTN is a common complication in infants with severe hydronephrosis. Fluid and electrolyte status, including serum creatinine and BUN, must also be carefully monitored. Fluid intake and output should be recorded at least every 2 to 4 hours.

OBSTRUCTIVE UROPATHY

Pathophysiology

When obstruction occurs in the urinary tract, changes referred to as obstructive uropathy can occur. Obstruction to urinary flow can cause reflux of urine into the kidney, with resultant hydronephrosis and irreversible kidney damage (Misurac, 2017). Urinary obstruction can be unilateral or bilateral and can occur at the ureterovesical junction, the UPJ, or due to PUVs (Figure 18.8). The most common cause of urinary obstruction is UPJ obstruction. UPJ obstruction occurs due to obstruction of urinary flow from the pelvis of the kidney into the ureter and is caused by stenosis of the

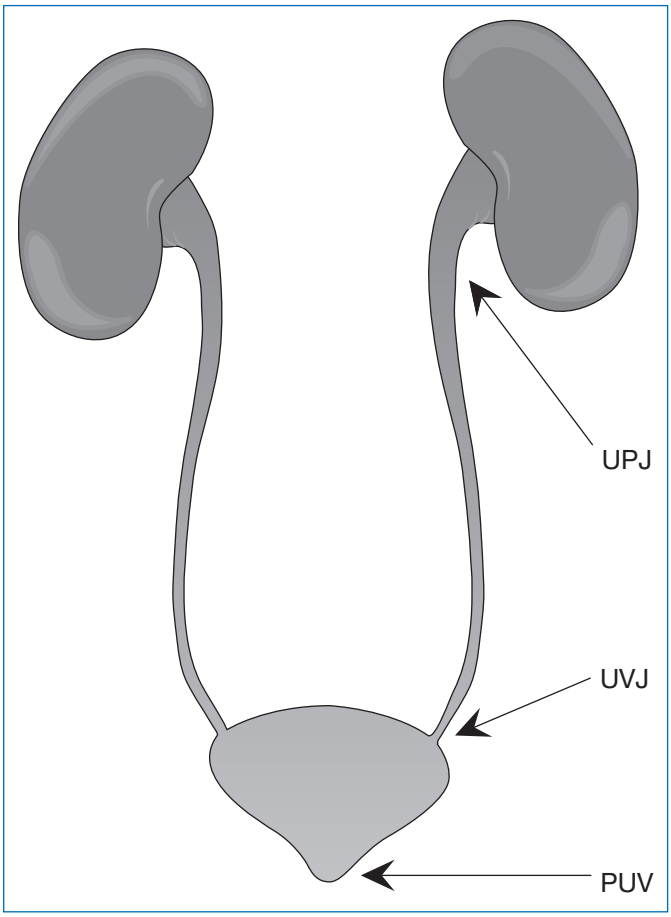

FIGURE 18.8 Location of most common sites of congenital urinary tract obstruction.

PUVs, posterior urethral valves; UPJ, ureteropelvic junction; UVJ, ureterovesical junction.

Source: From Chevalier, R. L. (2004). Perinatal obstructive nephropathy. *Seminars in Perinatology, 28*, 124–131. doi:10.1053/j.semperi.2003.11.009

ureter and/or its associated valves or by an insertion anomaly of the ureter (Choi et al., 2016). Ureterovesical junction obstruction is caused by obstruction of flow from the ureter into the bladder.

Risk Factors

UPJ obstruction is the most common cause of obstructive uropathy, with an incidence of 1 in 2,000, and is increased in males (Epelman et al., 2012). Information concerning PUVs may be found in the later section of this chapter.

Clinical Manifestations

Signs of urinary tract obstruction include symptoms of a UTI, or, if significant hydronephrosis is present, an abdominal mass may be appreciated. Severe, bilateral obstruction can also be associated with symptoms of renal failure.

Diagnosis

Urinary tract obstruction can be diagnosed on prenatal ultrasound as early as 16 to 17 weeks' gestation with evidence of hydronephrosis (Oliveira et al., 2016). Ultrasound findings range from mild hydronephrosis to extreme obstruction with oligohydramnios.

Postnatal diagnosis is via renal ultrasound and, although controversial, may be followed by a VCUG to assess for reflux (Weitz & Schmidt, 2017). A radionuclide renal scan is also recommended to assess renal function.

Prognosis

Obstructive uropathy can result in chronic renal failure and is a common cause of pediatric kidney transplantations if bilateral (Misurac, 2017).

Collaborative Management

Treatment depends on the severity of the obstruction and on whether the obstruction is unilateral or bilateral. If mild, conservative management is appropriate with frequent renal assessment. Prophylactic antibiotics may be indicated to prevent UTIs and the possibility of associated renal damage.

Surgical intervention may be indicated to relieve the obstruction. Insertion of a urinary diversion, such as a pyelostomy tube inserted into the renal pelvis, may be indicated (Hwang et al., 2018). Significant diuresis may follow urinary diversion, and thus, meticulous monitoring of fluid and electrolytes and replacement of losses are critical to avoid dehydration. Long-term follow-up is essential for the early detection of chronic renal problems (Tubre & Gatti, 2015).

Prenatal treatment, including insertion of a vesicoamniotic shunt, may be indicated if severe obstruction is present to increase the amniotic fluid volume and decrease the potential for renal failure. Complications of this procedure include shunt displacement and clogging of the shunt.

POSTERIOR URETHRAL VALVES

Pathophysiology

PUVs are the most common cause of urinary tract obstruction and cause severe obstruction uropathy, often resulting in end-stage renal failure (Odeh, Noone, Bowlin, Braga, & Lorenzo, 2016). PUV occurs when urine is obstructed at the level of the bladder outlet due to the presence of enlarged valves. Severity ranges from mild obstruction to severe disease, with obstructive uropathy and massive hydronephrosis. Urinary obstruction can increase pressure in the bladder and upper urinary tract, resulting in abnormal bladder function and renal injury (Casella, Tomaszewski, & Ost, 2012).

Risk Factors

PUV is a rare disease occurring exclusively in males with an incidence of 1 in 3,000 to 1 in 8,000 live births (Yohannes & Hanna, 2002). The specific etiology is unknown. Other associated urinary tract anomalies including VUR are common (Kibar, Ashley, Roth, Frimberger, & Kropp, 2011).

Clinical Manifestations

Neonatal symptoms of PUV include a palpable bladder, anuria or oliguria, a weak urinary stream, urosepsis, and urinary ascites (Kibar et al., 2011). If severe oligohydramnios is present prenatally, respiratory symptoms due to pulmonary hypoplasia may be present.

Diagnosis

PUVs are often diagnosed on prenatal ultrasound with the presence of bilateral hydronephrosis, a distended bladder, a dilated posterior urethra, and a thickened bladder wall (Casella et al., 2012). Following delivery, an ultrasound is required to evaluate the presence and degree of hydronephrosis, the presence of bladder wall thickening, and the general health of the kidneys. However, the gold standard for diagnosis is through a VCUG, showing a dilated posterior urethra, a trabeculated bladder, VUR, and sometimes

visualization of the enlarged valve leaflets. Renal scintigraphy for evaluation of renal function is usually deferred for approximately 4 weeks following birth to allow maturation of developing kidneys (Nasir, Ameh, Abdur-Rahman, Adeniran, & Abraham, 2011).

Prognosis

The diagnosis of PUVs is associated with significant long-term morbidity, which is dependent on the amount of renal damage caused by the PUVs (Caione & Nappo, 2011). In all, 13% to 42% of infants diagnosed with PUV will progress to end-stage renal disease, often requiring dialysis and/or renal transplantation (Caione & Nappo, 2011; Odeh et al., 2016). Bladder dysfunction in childhood is common, including bladder overactivity, resulting in urgency, urge incontinence, and nocturnal enuresis. The bladder can also become overdistended and overcompliant, causing ineffective bladder emptying and possibly requiring intermittent catheterization. Urethral strictures are also a possible complication occurring later in childhood (Caione & Nappo, 2011).

Collaborative Management

The initial treatment of PUVs is immediate urinary diversion with either bladder catheterization or suprapubic diversion to relieve the obstruction and reduce the pressure on the urinary tract to maintain normal bladder and kidney function (Misurac, 2017). Due to the increased risk of long-term complications, suprapubic diversion is only performed if bladder catheterization is impossible or if early correction of the defect is impossible because of the infant's small size or if the urethra is too small, precluding insertion of the endoscope for valve ablation. The infant may also require stabilization, including administration of IV fluids, correction of electrolyte or acid–base abnormalities, and antibiotics to prevent infection. Mechanical ventilation may be required if pulmonary hypoplasia is present. Definitive treatment of PUVs is transurethral endoscopic ablation (rupture) of the enlarged valves (Caione & Nappo, 2011). Prophylactic antibiotics are often required to prevent UTIs and subsequent renal injury, and long-term follow-up is essential to monitor bladder and renal function.

Unfortunately, prenatal treatment is difficult to perform and has not been shown to improve the mortality or morbidity of infants with PUV (R. K. Morris, Malin, Khan, & Kilby, 2010). In cases of oligohydramnios-associated pulmonary hypoplasia, some clinicians favor prenatal treatment with urinary diversion to increase the amniotic fluid level (R. K. Morris et al., 2010). In the future, prenatal valve ablation may be possible, thereby avoiding the renal and urinary tract damage that often occurs early in gestation prior to diagnosis of the defect (Casella et al., 2012).

Nursing Management

Immediately following delivery, the bladder should be catheterized under sterile conditions using a small 5- or 6-French feeding tube to allow passage through the constricted urethra. **Quality and Safety: Use of balloon catheters are contraindicated due to the possibility of bladder spasms.** Parents should be educated regarding the necessity of close postdischarge follow-up to ensure early detection of chronic renal disease and bladder dysfunction.

HYDROCELE

Pathophysiology

A hydrocele, the collection of fluid in the scrotal sac, is a common occurrence in the neonate (Lao, Fitzgibbons, & Cusick, 2012). The fluid originates from the peritoneal cavity, which communicates with the scrotum through a patent processus vaginalis. The only difference between the presence of a hydrocele and an inguinal hernia is the size of the processus vaginalis (Basta, Courtier, Phelps, Copp, & MacKenzie, 2015). If the processus vaginalis is small, only fluid can move into the scrotum, resulting in a hydrocele. Larger passageways may allow escape of a bowel segment into the scrotum, resulting in an inguinal hernia.

Risk Factors

The risk of a patent processus vaginalis is elevated with increased abdominal pressure secondary to a ventriculoperitoneal shunt or high ventilatory pressures and prematurity.

Clinical Manifestations

Clinical manifestations include the presence of painless scrotal swelling that is readily transilluminated.

Diagnosis

The most critical aspect of diagnosis is differentiating whether scrotal swelling is due to the presence of a hydrocele or the more serious diagnosis of either an inguinal hernia or testicular torsion. Upon palpation, inguinal hernias are generally reducible whereas hydroceles are not. When transilluminated, the hydrocele will show a fluid-filled scrotum, whereas an inguinal hernia will appear as a solid mass. If the examiner encounters loops of intestine near the vas deferens or the ductus deferens within the scrotal sac, an inguinal hernia is present. Ultrasound may also assist in differentiation (Basta et al., 2015).

Collaborative Management

Treatment for hydroceles is rarely indicated; the majority will spontaneously resolve within 1 to 2 years due to closure of the processus vaginalis (Basta et al., 2015). Indications for surgical correction generally include failure to resolve within the first year of life, although some surgeons will wait 2 years if there are no complications. Surgery entails drainage of fluid from the scrotal sac and closure of the processus vaginalis (Lao et al., 2012). Until resolution of the hydrocele, the infant should be closely monitored for signs of intestinal herniation. If an inguinal hernia is suspected, surgical intervention is indicated.

Nursing Management

Parents should be taught the signs of intestinal herniation and incarceration and the need for prompt medical attention if symptoms occur. These signs include the presence of a lump in the groin (this lump is especially noticeable when the infant is crying) and increased irritability. Careful attention must be paid to skin care of the edematous scrotum to avoid irritation and breakdown.

INGUINAL HERNIA

Pathophysiology

An inguinal hernia occurs when the intestines descend into either the inguinal canal or the scrotum through an open processus vaginalis (Lao et al., 2012; Figure 18.9). During fetal life, as the testes descend into the scrotum, they bring a small part of the peritoneum that is the processus vaginalis (Lao et al., 2012). When the processus vaginalis is open, fluid or intestines can pass through the opening, resulting in either a hydrocele or an inguinal hernia. The presence of a hydrocele or inguinal hernia is dependent on the size of the opening. The processus vaginalis becomes obliterated between 38 and 48 weeks of gestational age.

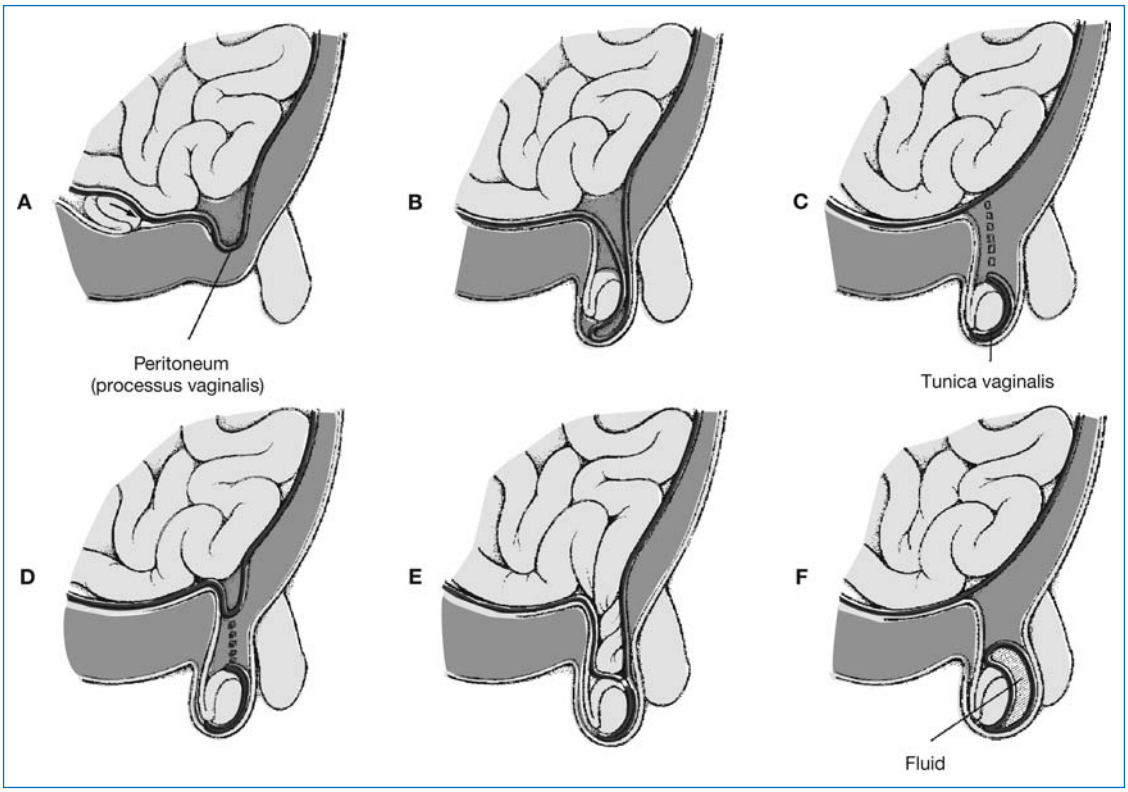

FIGURE 18.9 Development of inguinal hernias. (A and B) Prenatal migration of processus vaginalis. (C) Normal. (D) Partially obliterated processus vaginalis. (E) Hernia. (F) Hydrocele.

Source: From Hockenberry, M. J., Wilson, D., Winkelstein, M. L., & Wong, D. L. (2003). *Wong's nursing care of infants and children* (7th ed., p. 478). St. Louis, MO: Mosby.

Risk Factors

Due to the presence of an open processus vaginalis during fetal life, the incidence of inguinal hernias is inversely related to gestational age and birth weight. The incidence is also more prevalent in male infants (Youn et al., 2018). Sixty percent of inguinal hernias occur in the right and 15% are bilateral (Lao et al., 2012). Additional risk factors include cystic fibrosis, congenital hip dysplasia, the presence of a ventriculoperitoneal shunt, and abdominal wall defects.

Prognosis

The most severe complication of inguinal hernia is an incarcerated hernia with subsequent intestinal necrosis. The highest risk of incarceration occurs in early infancy, and the risk of incarceration in premature infants is up to 31% (Youn et al., 2018). When inguinal hernias are surgically repaired prior to incarceration, complications are rare. Reoccurrence after surgical repair can occur especially in infants born premature (Youn et al., 2018).

Clinical Manifestations

The most common clinical manifestation of an inguinal hernia is the presence of an inguinal bulge or mass as the omentum of the small intestine slides through the open processus vaginalis (Cavaliere, 2019). Crying or increased abdominal pressure often causes the inguinal hernia to appear more prominent. When a hernia is reducible, the intestine can be gently manipulated back into the abdomen cavity.

Diagnosis

The most important component of diagnosis is determining whether the mass is an inguinal hernia or other scrotal mass, including a hydrocele or testicular torsion. If the scrotum can be transilluminated, the mass may be either a hydrocele or an inguinal hernia (Cavaliere, 2019). Testicular torsion should be suspected if the scrotum contains a hard, solid mass. This is a surgical emergency and must be immediately reported to the surgical team. If it is not possible to distinguish between an inguinal hernia and a hydrocele, a rectal examination, while palpating the scrotum simultaneously, may reveal whether an intestinal loop is present in the scrotal sac rather than a fluid-filled hydrocele. The use of ultrasound may also prove helpful in differentiating between the two processes.

Collaborative Management

Inguinal hernias should be reduced daily and as needed by applying gentle pressure to assess for incarceration of the hernia. An incarcerated hernia occurs when the intestines are caught within the processus vaginalis. Symptoms of incarcerated hernias include inability to reduce, vomiting, a firm tense mass, inconsolable crying, and abdominal distention. When incarceration occurs, circulation is compromised and intestinal necrosis is possible, necessitating an immediate surgical consult.

If the inguinal hernia is nonreducible, advanced attempts for reduction are often attempted. After the infant is well sedated and placed in the Trendelenburg position, ice packs are placed on the hernia to reduce intestinal edema. If gentle reduction is successful, surgery may be delayed for 24 to 48 hours. Surgery for incarcerated hernias includes reduction of hernia and, if necrotic bowel is present, resection of the affected intestine.

Because of the high risk of incarceration, it is generally recommended that surgical repair of inguinal hernias should be performed as soon as possible. Surgery may be delayed in premature

infants due to the technical difficulty of operating and an increased risk of complications, including testicular atrophy and recurrent hernia. Exact timing of surgical intervention in the premature infant is controversial; however, many surgeons will correct the defect prior to discharge from the hospital (Gulack et al., 2018). Surgery may be performed either through an open procedure or through laparoscopic surgery (Ho, Ihn, Koo, Chang, & Oh, 2018). Surgical correction involves separation of the hernia sac from surrounding structures (Youn et al., 2018). The contralateral side may be explored to detect a patent process or a nonclinically evident hernia (Youn et al., 2018). Whether or not to explore the contralateral side is controversial. The goal of this exploration is to avoid future inguinal hernias, thereby reducing the risk of a second surgery and possible incarceration. However, it also increases the risk of infection, pain, and the cost of surgery. The risk of complications associated with surgical correction of inguinal hernias is generally low; however, premature infants are at high risk for postoperative apnea and should be monitored for at least 24 hours following surgery. Apnea following surgery may be decreased with the use of spinal anesthesia.

Nursing Management

Reduction of all inguinal hernias should take place daily, and an inability to reduce the hernia should immediately be reported to the medical and surgical team. The postoperative course is similar following open procedures or laparotomy and includes observation for apnea and adherence to aseptic technique with regard to suture line maintenance. The infant should be placed in a side-lying or supine position with the head turned to the side to prevent disruption of the suture line. Operative dressings should be observed for any drainage and bleeding, kept dry, and underlying skin should be regularly inspected for irritation and breakdown. Pain should be assessed every 4 hours, and appropriate pain management should be provided when indicated. Since discharge is often 24 hours after surgery, parents need to be instructed on proper surgical site and dressing care.

TESTICULAR TORSION

Pathophysiology

Torsion of the testicle occurs when the testis and coverings twist inside the scrotum, compromising blood flow, frequently resulting in a nonviable testicle (Basta et al., 2015).

Risk Factors

The incidence of testicular torsion is 6.1 per 100,000 (John, Kooner, Mathew, Ahmed, & Kenny, 2008). Although it is most often unilateral, bilateral torsion can unfortunately occur, resulting in complete lack of testicular development (Nandi & Murphy, 2011). Risk factors include vaginal delivery, prolonged labor, gestational diabetes, macrosomia, and breech delivery, and it appears that fetal stress and mechanical factors may be the contributing factors.

Prognosis

An 8.96% salvage rate for testicular torsion in the neonatal population has been reported. This may increase to 21.7% if surgery is emergent. Unfortunately, salvage of antenatally occurring torsion is extremely rare (Nandi & Murphy, 2011).

Clinical Manifestations

Testicular torsion presents with unilateral acute pain and scrotal swelling. The scrotum is firm to the touch, tender, and often discolored. The abdomen may be significantly discolored and be either plethoric or cyanotic. The clinical presentation of testicular torsion is similar to other scrotal abnormalities, such as hydrocele, inguinal hernia, and trauma; however, it can often be distinguished due to the presence of scrotal discoloration and an inability to be transilluminated. Information related to testicular blood flow can be obtained via the use of color Doppler ultrasound. Because of the emergent need for surgical intervention, the diagnosis of testicular torsion must be considered in all infants presenting with scrotal swelling.

Collaborative Management

Treatment of acute testicular torsion is immediate surgery to untwist the testicle and restore blood supply. Timing of the intervention is critical, and a delay in surgical intervention of 4 to 6 hours following initiation of symptoms offers little to no chance of testicular survival. If the torsion occurs antenatally, the chance for testicular survival is nearly nonexistent, and surgical intervention may be futile (Basta et al., 2015). The most important determinant in the decision to perform surgery is the appearance of the scrotum in the delivery room. If the scrotum appears normal initially and then becomes acutely painful, swollen, and discolored, immediate surgery is indicated in an attempt to salvage the testicle. If the scrotum appears blue, hard, and painless immediately after birth, the torsion occurred prenatally and the testicle has already become necrotic.

Controversy exists regarding the treatment of antenatally occurring testicular torsion. Some advocate conservative treatment with regular ultrasound examination to monitor for testicular atrophy. Others suggest contralateral orchiopexy is necessary to prevent the possibility of torsion and subsequent necrosis of both testes (Nandi & Murphy, 2011).

Nursing Management

The focus of nursing care is on keeping the infant as comfortable and quiet as possible. The abdominal girth should be measured every 4 hours to assess for distention. The infant should be positioned supine with head turned to the side or in a side-lying position to avoid excessive pressure on the abdominal and scrotal areas.

If surgery is required, nursing care is centered on the stability of the vital signs and prevention of infection. The suture line is generally small but still requires aseptic technique. The site should be assessed for edema, drainage, or discoloration.

NEPHROBLASTOMA (WILMS' TUMOR)

Pathophysiology

Wilms' tumor (nephroblastoma) is a well-encapsulated heterogeneous malignant tumor of the kidney. It is thought to be due to persistent nephrogenic embryological cells that fail to develop appropriately. Wilms' tumor is associated with other anomalies, including aniridia (lack of development or absence of the iris), GU tract anomalies, and Beckwith–Wiedemann syndrome (Style et al., 2018).

Risk Factors

The incidence of Wilms' tumor in neonates is rare, with the incidence increasing as the infant ages. It can be detected prenatally (Toussi, Granberg, & Gargollo, 2018). Wilms' tumor is generally a sporadic condition, but 1% of those affected have a family history of the disease (Powis, 2010; van den Heuvel-Eibrink et al., 2017).

Clinical Manifestations

The typical presentation of Wilms' tumor is a unilateral smooth, solid abdominal or flank mass that does not cross the midline in an otherwise well-appearing infant (Powis, 2010). Microscopic hematuria may be present, and HTN may occur if associated renal artery stenosis or increased renin secretion is present (Leclair et al., 2005).

Diagnosis

Prenatal diagnosis is uncommon, and most are diagnosed after birth (Toussi et al., 2018). Prenatally, Wilms' tumor is associated with an increased risk of fetal distress, hydrops, and prematurity (Leclair et al., 2005). Postnatally, the initial diagnostic procedure is an abdominal ultrasound to determine the origin of the abdominal mass. Either CT or MRI generally follows the ultrasound to make a definitive diagnosis and to determine the cancer stage (Powis, 2010). Biopsies are usually unnecessary in infants under 6 months of age.

Prognosis

Prognosis is related to the stage of disease and size of the tumor. Children younger than 2 years generally have a very favorable prognosis, but the risk of complications is higher in neonates (Toussi et al., 2018).

Collaborative Management

Because of the possibility that the encapsulated tumor may rupture and seed other areas of the body, repeated abdominal examinations should be avoided. Treatment of unilateral Wilms' tumor generally includes only nephroureterectomy in the neonate. If the tumor is bilateral, if shrinkage is necessary prior to removal, or if metastasis has occurred, chemotherapy may be required (van den Heuvel-Eibrink et al., 2017). **Quality and Safety: The diagnosis of cancer in a young infant can be devastating to the family. Clear, easy-to-understand information related to treatment and prognosis is required to assist parents to have realistic expectations related to their infant's diagnosis.**

SUMMARY

The infant with a GU abnormality presents unique challenges to the neonatal care team. Although aberrations in the genital system are not life-threatening, their appearance can be traumatic for parents. Urinary tract pathology, on the other hand, can result in emergent life-threatening events at any age. Renal abnormality and diseases manifesting in the neonatal period can have lifelong consequences. The neonatal nurse must be able to accurately assess and respond to alterations in renal function. Astute nursing care of the infant and parents is paramount to optimal management and outcome. The neonatal nurse is in the position to be the first member of the healthcare team to detect minor changes in neonatal physiological functions that may signify onset of significant compromise. To do this, the neonatal nurse must have knowledge of normal and abnormal renal and urinary tract physiology and pathophysiology. Parental support is another aspect of nursing care that is of major importance when caring for the infant with GU conditions. Timely assessment of parental coping mechanisms, alterations in parent–infant attachment, and evaluation of the parents' response to teaching provide vital information that will ultimately affect the infant's overall well-being.

CASE STUDY

■ **Identification of the Problem.** Infant with an average urinary output of 0.4 mL/kg/hour for the past 24 hours.

■ **Assessment: History and Physical Examination.** The child is a 3-day-old, 900-g, 28-week of gestational age infant born to a 28-year-old gravida 1, para 0 mother. Blood type is A+, and all serologies including Venereal Disease Research Laboratory (VDRL), HbsAg, GC, and HIV are negative. The mother received good prenatal care during this pregnancy. No smoking, drug, or alcohol use reported. Delivery was via cesarean birth due to placental abruption at 28 weeks' gestation. No antibiotics or prenatal steroids were administered prior to delivery. Infant required intubation at delivery because of apnea and low heart rate. Apgar scores were 4 at 1 minute and 8 at 5 minutes. Infant was transferred to the Level 3 NICU. His problems included the following:

- Fluid, electrolytes, and nutrition: He is currently on minimal enteral feedings of 1 mL every 12 hours and tolerating these well; his total fluid volume is 120 mL/kg/day of total parenteral nutrition.
- Respiratory: He received two doses of surfactant for a chest radiograph consistent with hyaline membrane disease; he remains intubated on moderate ventilatory settings.
- Cardiovascular: Infant has had several episodes of hypotension that have resolved spontaneously without treatment; heart rate is 175; current blood pressure has a mean arterial pressure of 28.
- Infectious disease; receiving ampicillin and gentamicin for suspected sepsis; no culture-proven sepsis.
- Hematologic: Hematocrit is 35%; under phototherapy for hyperbilirubinemia.
- Neurologic: A cranial ultrasound has been ordered for 1 week of life.
- Social: Parents are married; this is their first child; they are appropriately concerned and have been updated at the bedside daily.

■ **Physical Assessment**

- GENERAL: no obvious anomalies noted
- HEENT: anterior fontanelle soft and flat; eyes clear without drainage, red reflex present; pupils equally reactive to light; nares patent bilaterally; no clefts or abnormalities of mouth noted; ear canals patent bilaterally
- CHEST AND LUNGS: heart rate regular without murmur; pulses equal in all four extremities; quiet precordium; capillary refill time is 2 seconds; lungs equal with fine crackles bilaterally
- ABDOMEN: soft and nondistended; positive bowel sounds auscultated in all four quadrants; no masses felt; umbilical cord normal; liver felt 2 cm below right intercostal margin
- GU: normal female infant; genitalia appropriate for gestational age
- SKELETAL: moves all extremities well; no obvious anomalies noted
- NEUROLOGIC: all reflexes present; tone appropriate for gestational age

■ **Differential Diagnoses.** The differential diagnosis of oliguria in this infant includes:

- Prerenal failure associated with decreased renal blood due to low systemic blood pressure or inadequate fluid intake
- Intrinsic renal failure due to the administration of nephrotoxic medications (gentamicin) or ATN due to perinatal depression related to the placental abruption as evidenced by the low Apgar scores
- Postrenal obstruction due to a neurogenic bladder related to fentanyl administration

■ **Diagnostic Tests.** Palpate the abdomen for the presence of a distended bladder and perform an in-and-out catheterization.

- Electrolytes: sodium 148; potassium 3.5; creatinine 0.4; BUN 10
- Weight is 780 g
- Gentamicin trough is 0.4 mg/L
- Urine specific gravity is 1,020, no protein, blood, or WBCs are present in the urine

The next step should be administration of 10 to 20 mL/kg of normal saline via IV. Use of a diuretic after the fluid challenge may be necessary if urine output does not increase immediately after the fluid challenge.

■ **Working Diagnosis.** The bladder is not distended. No urine is obtained via in-and-out catheterization, thus ruling out postrenal failure.

Physical assessment is imperative for lack of abdominal masses that would possibly indicate an enlarged kidney and associated intrinsic renal failure. Tachycardia is present, possibly indicating mild dehydration. A borderline mean arterial pressure may indicate decreased intravascular volume or decreased systemic blood flow.

Infant has lost 120 g over the past 3 days.

Gentamicin level is normal and does not support the presence of intrinsic renal failure.

The sodium level and specific gravity are elevated, which are both consistent with prerenal failure.

The creatinine and BUN levels are normal. If elevated, they would support a diagnosis of intrinsic renal failure.

There is no blood or protein in the urine. The presence of these substances would also support a diagnosis of intrinsic renal failure.

The administration of a fluid challenge produced a urine output of over 1 mL/kg/hour, thus indicating a diagnosis of prerenal failure.

No other workup, such as a renal ultrasound, would be indicated at this time.

■ **Development of Management Plan.** Ensure administration of an adequate fluid volume by increasing fluid volume appropriately to ensure a urine output over 1 mL/kg/hour. Compensate for fluid losses due to insensible water losses, including losses from phototherapy.

Low-dose dopamine may increase renal blood flow.

Ensure appropriate renal blood flow by increasing mean arterial pressure. If increase in fluid volume does not increase blood pressure sufficiently, inotropes such as higher dose dopamine or dobutamine may be administered.

■ **Implementation and Evaluation of Effectiveness**

Monitor skin turgor and fontanelles for signs of dehydration.

- Monitor serum electrolytes closely to ensure normalization of sodium levels
- Monitor vital signs every 3 to 4 hours to ensure normalization of blood pressure and heart rate
- Carefully monitor intake and output to ensure that infant is receiving adequate volume to result in a urine output of over 1 mL/kg/hour
- Daily or twice-daily weights
- Monitor specific gravity to ensure resolution to a normal range

EVIDENCE-BASED PRACTICE BOX

UTIs are common in infants and are defined as infection of the kidney and/or the bladder. They are estimated to occur in 0.1% to 2% of all newborns and in 20% of preterm and critically ill infants. UTIs can increase morbidity and, if not properly treated, can result in decreased renal function, renal scarring, and hypertension (Arshad & Seed, 2015). Treatment of UTIs consists of antibiotic therapy, and traditionally due to concerns of VUR, a VCUG and prophylactic antibiotic therapy were recommended in all infants diagnosed with a UTI. Unfortunately, a VCUG is not a benign procedure and is associated with both infant pain and family stress.

Evidence now exists that the risk of recurrent UTI is not significantly affected by VUR, and the AAP currently recommends that a VCUG not be performed following the first UTI unless the renal ultrasound indicates abnormalities including hydronephrosis, renal scarring, severe VUR, or obstructive uropathy (Roberts et al., 2011). A meta-analysis of six studies including data on 1,091 infants indicated no benefit in providing prophylactic antibiotics to prevent future UTIs in infants with grades I to IV VUR, and there was insufficient data regarding use in infants with grade V VUR (Roberts et al., 2011). Furthermore, it is estimated that only 1% of infants diagnosed with a UTI has grade V VUR (Roberts et al., 2011). Therefore, the use of a VCUG or prophylactic antibiotic therapy is not recommended following an initial UTI (Roberts et al., 2011). If an infant is diagnosed with subsequent UTIs, a VCUG is required at that time (Roberts et al., 2011).

CHAPTER 19

Fluids, Electrolytes, and Acid–Base Balance

Shreyas Arya and Vivek Narendran

INTRODUCTION

The maintenance of fluid, electrolytes, and acid–base balance are vital components of neonatal care. This is particularly true for very low birth weight (VLBW) infants, as they require parenteral fluids for prolonged periods and have unique limitations related to their immature kidneys and skin. Rapid maturational changes in various organs and fluid shifts that occur after birth confound the issue further. Critically ill newborns are at additional risk for morbidity and mortality due to fluid and electrolyte imbalance.

WATER

Physiology. Water is the main component of the human body. It is distributed both inside and outside the cells. Thus, the total body water (TBW) is a sum of intracellular water (ICW) and extracellular water (ECW). ICW is the total amount of water in all the body's cells. ECW is the total amount of water outside the cells, which includes the water in the interstitial space and in the intravascular space (plasma).

The distribution of TBW between intracellular and extracellular spaces depends on the relative concentration of solutes (relative osmolality). The total number of solute particles in solution determines the osmolality of a solution. Osmolality values are expressed in osmoles or milliosmoles per kilogram of water (Osm/kg or mOsm/kg). Cell membranes are completely permeable to water but not to most solutes; hence, water shifts from one compartment to the other until equilibrium is established between the osmolalities on both sides of the membrane. The osmolality of intracellular and extracellular spaces, therefore, is equal, although the composition of ICW is vastly different from that of ECW; for example, sodium (Na^+) is the major extracellular cation, whereas potassium (K^+) is the main intracellular cation. In each compartment, the main solute acts to keep water within the compartment:

- The volume of the intracellular compartment is maintained mainly by potassium salts and is regulated by the Na^+/K^+ cellular pump.
- The volume of the extracellular compartment is maintained mainly by sodium salts and is regulated by the kidneys.
- The volume of the intravascular compartment is maintained mainly by the colloidal osmotic pressure of plasma proteins and is regulated by the endocrine system and the kidneys.

Changes in Water Distribution. In the first trimester of gestation, TBW constitutes more than 90% of the body weight; however, its relative contribution to body weight declines as the fetus matures. TBW decreases to 80% at 32 weeks' gestation, 78% at 40 weeks' gestation, and approximately 60% to 65% at the end of the first year of life. The ratio of ECW to ICW also changes with growth. ECW declines from approximately 60% of body weight in the second trimester to about 45% at term. Correspondingly, ICW increases from about 25% of body weight in the second trimester to approximately 33% at term. Thus, the decrease in TBW as the infant matures is attributed largely to the decrease in ECW compartment (Figure 19.1).

Superimposed on the gradual contraction of ECW that occurs as the fetus approaches term is an acute expansion of ECW that occurs at birth. This is due to (a) placental transfusion, (b) reabsorption of lung fluid, and (c) shift of water and electrolytes from the intracellular to the extracellular space (Baumgart & Costarino, 2000). The newborn at birth is, therefore, in a state of excess extracellular fluid, a condition that is particularly prominent in preterm infants (TBW and ECW are greater at lower gestational ages). After the first 24 to 48 hours of life, the infant undergoes a diuresis phase. This results in the loss of excess ECW and is termed as physiologic weight loss (5%–10% in term infants and up to 15% in very preterm infants). Any disruptions in this normal transition can lead to imbalances in fluid and electrolyte homeostasis, leading to morbidity. For example, in preterm infants, iatrogenic administration of large amounts of fluids can potentially increase the risk of a symptomatic patent ductus arteriosus (PDA; Bell, Warburton, Stonestreet, & Oh, 1980), necrotizing enterocolitis (NEC; Bell, Warburton, Stonestreet, & Oh, 1979), and bronchopulmonary dysplasia (BPD; Van Marter, Leviton, Allred, Pagano, & Kuban, 1990).

Water Balance and Requirements. Water balance in neonates is under the direct control of antidiuretic hormone (ADH), which is also known as vasopressin. ADH is secreted by the hypothalamus when the serum osmolality is greater than 285 mOsm/kg or there is intravascular volume depletion. It regulates intravascular volume by changing water permeability of the collecting ducts in the kidneys. A mature adult kidney can concentrate urine

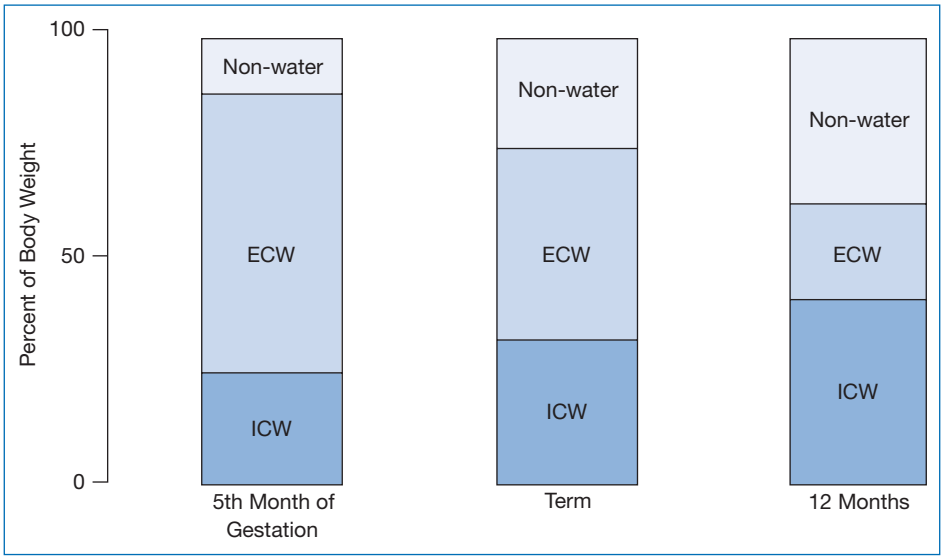

FIGURE 19.1 Changes in body water distribution. Note the relative decrease in ECW compartment.
ECW, extracellular water; ICW, intracellular water.

up to a maximum of 1,500 mOsm/kg or dilute to a minimum of 50 mOsm/kg based on the body's fluid status. However, this concentrating ability is remarkably diminished in neonates. A term neonate can maximally concentrate urine up to 800 mOsm/kg and a preterm neonate to only 600 mOsm/kg. This inability to sufficiently concentrate urine, proportionate to the demands of the body, predisposes neonates to a significant risk for water and electrolyte imbalances.

Maintaining optimal water and electrolyte composition depends on anticipating water losses and replacement with pertinent maintenance fluids. Table 19.1 highlights factors that impact water loss in neonates. Maintenance fluids are defined as the amount of water and electrolytes required to maintain a patient in a neutral water balance. These include replacement of urine, gastrointestinal losses, and insensible water loss (IWL). Preterm infants are particularly susceptible to water imbalances due to immature renal function, very high IWL through the skin and respiratory tract, higher body surface area to body mass ratio, and acuity of illness (Baumgart & Costarino, 2000). Table 19.2 provides approximate requirements for the maintenance fluids (mL/kg/day) for infants up to a week of life. However, further titrations are made by assessing the clinical status of the patient and accounting for factors that might increase or decrease fluid loss. For example, phototherapy increases IWL, whereas the use of double-walled and humidified incubators reduces IWL. However, the use of newer devices for phototherapy combined with modern incubators has significantly decreased their effects on IWL (Maisels & McDonagh, 2008).

Postnatal Adaptations. Most preterm infants follow a distinctive postnatal pattern of diuresis consisting of three phases: (a) the prediuretic phase, (b) the diuretic phase, and (c) the homeostatic phase (Lorenz, Kleinman, Ahmed, & Markarian, 1995). The *prediuretic phase* occurs in the first 24 to 48 hours of life wherein the glomerular filtration rate (GFR), urinary output (UOP), and sodium and potassium excretion are all very low. Water is lost mainly by IWL. The total fluid requirement is calculated to account mainly for the IWL (Tables 19.1 and 19.2) and supplementation with sodium, chloride, or potassium is not done. As very preterm infants have significant skin (transepidermal) water losses, they are predisposed to hemoconcentration and hypernatremia even in the prediuretic phase.

TABLE 19.1
FACTORS AFFECTING WATER LOSS IN NEONATES

Increasing Water Loss	Decreasing Water Loss
Water Loss From the Skin	
Low gestational age	High humidity in incubator
Radiant warmer	Double-walled incubator
Hyperthermia	Plastic heat shield
Skin breakdown	
Phototherapy	
Congenital defects (e.g., gastroschisis)	
Water Loss From the Respiratory Tract	
Tachypnea	Use of humidified gas
Inadequate humidification	
Renal Water Loss	
Diuretic agents (e.g., furosemide)	Renal failure
Osmotic diuresis (hyperglycemia, mannitol)	Inappropriate secretion of antidiuretic hormone
Congenital adrenal hyperplasia	Congestive heart failure

The *diuretic phase* usually begins on day 2 to 5 of life when the UOP, sodium, and potassium excretion increases abruptly. This phase seems to be triggered by the atrial natriuretic peptide (ANP),

TABLE 19.2

APPROXIMATE MAINTENANCE REQUIREMENTS OF NEWBORNS IN THE FIRST WEEK OF LIFE

	Birth Weight			
Time Period	**<750 g**	**750–1,000 g**	**1,001–1,500 g**	**>1,500 g**
First 48 hours	100–200	80–150	60–100	60–80
Day 3–7	120–200	100–150	80–150	100–150

Note: Amounts are given as mL/kg/day.

TABLE 19.3

ELECTROLYTE CONTENT OF BODY FLUIDS

Fluid	Sodium (mmol/L)	Potassium (mmol/L)	Chloride (mmol/L)
Stomach	20–80	5–20	100–150
Small intestine	100–140	5–15	90–120
Bile	120–140	5–15	90–120
Ileostomy	45–135	3–15	20–120
Diarrheal stool	10–90	10–80	10–110

Source: With permission from Martin, R. J., Fanaroff, A. A., & Walsh, M. C. (Eds.). (2015). *Fanaroff and Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (10th ed.). Philadelphia, PA: Saunders.

which is released by myocardial cells in response to atrial stretching or filling. This occurs due to the physiologic decrease in pulmonary vascular resistance after birth that leads to increased venous return to the left atrium and the release of ANP. This ANP in turn causes increased natriuresis (Modi, 2003). In this phase, water intake is adjusted to maintain a normal serum sodium concentration and to maintain total weight loss below 10% in term and below 15% in preterm infants. Sodium and potassium supplementation is also started.

In the *homeostatic phase*, which follows the diuretic phase, UOP stabilizes. The goal of fluid and electrolyte intake in this phase is to maintain water and electrolyte balance and to provide nutrition for adequate growth. Infants normally grow at a rate of 10 to 20 g/kg/day. Because three quarters of this new body mass is fluid, the total fluids given to an infant should provide a net positive balance of 10 to 15 mL/kg/day.

Pathologic Fluid and Electrolyte Losses. Certain clinical conditions predispose infants to pathologic fluid and electrolyte loss. Commonly encountered situations in the neonatal intensive care unit (NICU) include loss of gastric fluid due to Replogle tube placement or vomiting, loss of enteric fluids due to an ostomy, and fluid and electrolyte losses in stools. Table 19.3 highlights the electrolyte concentration of different body fluids and can be used to estimate the specific losses and for calculating adequate replacement.

ELECTROLYTES

Sodium. Sodium is the main extracellular cation accounting for more than 90% of the solutes in the extracellular space. It is absorbed in both the small intestine and the colon, the largest amount being absorbed in the jejunum. Sodium absorption involves several mechanisms:

- Passive absorption along with glucose, secondary to the flow of water
- Active absorption, uncoupled with glucose, involving the Na^+/K^+ pump
- Active absorption in exchange for hydrogen ions (H^+)

The overall process is very efficient. The kidneys excrete sodium, which is first filtered by the glomeruli and later reabsorbed throughout the tubules and the collecting ducts. Most of the sodium is absorbed with chloride (Cl^-), with lesser amounts absorbed in exchange with K^+ or H^+. Under normal circumstances, 96% to 99% of filtered sodium is reabsorbed. The main factors regulating sodium resorption are the oncotic and hydrostatic pressures in the peritubular capillaries of the kidneys. The mineralocorticoid aldosterone is also critical in maintaining sodium levels. When there is volume depletion, aldosterone is secreted by the renin–angiotensin–aldosterone system in the juxtaglomerular cells of the kidney. Under the influence of this steroid hormone, there is sodium and water absorption in exchange for K^+ and H^+. Although ADH does not affect the excretion of sodium directly, it can influence the serum sodium concentration indirectly as it regulates the excretion and resorption of free water.

Emergency Alert: Both hypernatremia and hyponatremia in preterm infants have been associated with adverse neurologic outcomes at 2 years of age. Additionally, the risk appears to be directly proportional to the magnitude of the variation in serum sodium levels during the NICU stay (Baraton et al., 2009).

The sodium concentration in human milk is 12 to 20 mEq/L. The recommendation for growing preterm infants is 3 to 5 mEq/kg/day (Tsang, Lucas, Uauy, & Zlotkin, 2005). Because of their high urinary loss of sodium, VLBW infants (those weighing <1,500 g) may temporarily require up to 8 mEq/kg/day by the end of the first week of life. Thereafter, urinary losses in these infants decrease. The normal serum sodium concentration ranges from 130 to 150 mEq/L.

Disorders of sodium balance are listed in Box 19.1.

Hyponatremia. Hyponatremia is defined as a serum sodium level below 130 mEq/L. There are three major mechanisms for this:

- Increased sodium loss
- Inadequate sodium intake
- Inability to excrete excess water (dilution effect)

Box 19.1

DISORDERS OF SODIUM BALANCE

Hyponatremia

- VLBW infant-fed unfortified human milk or standard term formula
- Perinatal asphyxia
- Renal failure, congestive heart failure
- SIADH (RDS, IVH, pneumothorax)
- Diuretics
- Sodium losses through the gut
- Hypotonic fluid administered to mother during labor
- Adrenal insufficiency (congenital adrenal hyperplasia)

Hypernatremia

- Dehydration (vomiting, diarrhea, IWL through immature skin)
- Diabetes insipidus (central and nephrogenic)
- Osmotic diuresis (hyperglycemia, mannitol)
- Overhydration (excessive administration of sodium-containing fluids)
- Medication errors

IVH, intraventricular hemorrhage; IWL, insensible water loss; RDS, respiratory distress syndrome; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; VLBW, very low birth weight.

It is therefore important to first delineate the etiology of hyponatremia and assess volume status prior to instituting therapy. For example, an infant with hyponatremia due to inability to excrete water because of acute kidney injury requires fluid restriction, while an infant with excessive urinary or stool water and sodium losses requires fluid replacement.

Increased Sodium Loss and Inadequate Intake. This is most commonly seen after the first week of life in growing VLBW infants, fed either human milk or standard term formulas. These infants can have a negative sodium balance in the first weeks of life because of an inadequate sodium intake and transient unresponsiveness of the renal tubules to aldosterone (Baumgart & Costarino, 2000). VLBW infants may require up to 8 mEq/kg/day or higher to maintain a positive sodium balance. Usually, the lower the gestational age, the higher the sodium intake needed.

Abnormalities in either the production of aldosterone (congenital adrenal hyperplasia) or the renal responsiveness to aldosterone (pseudohypoaldosteronism) can also lead to increased sodium losses and hyponatremia. Variable degrees of hyperkalemia and metabolic acidosis are associated with the previously noted disorders due to the influence of aldosterone on K^+ and H^+ excretion.

Extrarenal losses of sodium occur with vomiting and diarrhea. Loop diuretics like furosemide are notorious for causing hyponatremia.

Inability to Excrete Excess Water. In neonates, hyponatremia due to retention of water (dilution) occurs after an acute kidney injury leading to decreased GFR. This is seen after perinatal asphyxia or following nephrotoxic drug therapy. Another mechanism at play during perinatal asphyxia is the increased secretion of ADH (syndrome of inappropriate secretion of antidiuretic hormone, or SIADH). Severe respiratory distress syndrome (RDS), intraventricular hemorrhage (IVH), and pneumothorax can also predispose newborns to hyponatremia due to SIADH.

Hyponatremia can also be iatrogenic secondary to excessive administration of hypotonic fluids to the mother during labor, feeding diluted formula, or following resuscitation with hypotonic fluids. Whenever the serum sodium concentration decreases, serum osmolality declines, causing water to move into cells. This phenomenon also occurs in the brain cells, causing signs and symptoms characteristic of hyponatremia. Vomiting, lethargy, and apnea may occur with various degrees of hyponatremia. Seizures and coma are not seen unless the serum sodium concentration falls below 115 mEq/L.

Treatment is directed both at the underlying disorder and volume replacement with sodium chloride (NaCl)–containing solutions. The amount of sodium needed is calculated using this standard formula:

$$\begin{aligned}&\text{Total sodium required (mEq)}\\&\quad = 0.6 \times \text{Weight (kg)}\\&\qquad \times (\text{Desired serum } Na^+ - \text{Observed serum } Na^+)\end{aligned}$$

Quality and Safety: This correction is done slowly over several hours. The rate of correction should not exceed 10 to 12 mEq/L/day (or 0.5 mEq/L/hour). The target is a serum sodium concentration of about 135 mEq/L. Rapid correction of hyponatremia puts the infant at risk for a condition known as central pontine myelinolysis.

This general rule has two exceptions:

- In presence of overt or impending shock, normal saline should be given intravenously and rapidly at 10 to 20 mL/kg over 20 to 30 minutes; treatment is repeated until arterial blood pressure is normal.
- If hyponatremic seizures are diagnosed, hypertonic saline (3%) should be infused. These seizures usually abate with correction in serum sodium concentration of 3 to 5 mEq/L. Care must be taken to avoid overcorrection.

Hypernatremia. Hypernatremia is defined as a serum sodium level over 150 mEq/L. It is also caused by three major mechanisms:

- Increased loss of free water (renal or extrarenal)
- Decreased water replacement
- Excess sodium intake

Whenever hypernatremia occurs, the serum osmolality increases, leading to water moving out of the cells into the extracellular space to achieve an osmotic equilibrium between intracellular and extracellular fluid. This attempt to equilibrate results in volume depletion of the intracellular space. To counteract this phenomenon, brain cells (neurons) have the unique ability to generate new solutes called idiogenic osmoles. These are substances (amino acids, polyols, trimethylamines) synthesized by the brain cells as a protective response to serum hyperosmolality. Idiogenic osmoles are produced and catabolized slowly and hence are effective only if hyperosmolality does not develop too rapidly. For this reason, correction of hypernatremia with hypotonic solutions should not be performed rapidly as cerebral edema can occur due to movement of water into brain cells.

Increased Loss of Free Water and Decreased Replacement. This is referred to as hypernatremia with dehydration. Water loss in a neonate can occur through the immature skin, kidneys, or the gastrointestinal tract. Hypernatremia due to excess IWL through the immature skin is particularly pronounced in VLBW infants. The magnitude of these losses is inversely related to gestational age. In these infants, weight, UOP, serum sodium level, and glucose concentrations should be monitored closely. Adequate fluid replacement and sodium restriction during the first 3 to 5 days of life may prevent hypernatremia. IWL is minimized with the use of double-walled incubators with a high relative humidity.

Excessive renal water loss occurs when an increased amount of solute such as glucose needs to be excreted (osmotic diuresis) or secondary to diabetes insipidus (DI). DI is caused by either decreased production of ADH by the hypothalamus (central DI) or by renal unresponsiveness to ADH (nephrogenic DI). In both these conditions, the infant presents with hypernatremia, polyuria, decreased feeding, and poor growth. These infants frequently require periodic fluid replacements to compensate for ongoing renal losses. Water loss similarly may occur from the gastrointestinal tract following vomiting, diarrhea, or increased ostomy output.

Quality and Safety: Hypernatremia with dehydration must be corrected slowly to avoid cerebral edema. Intravascular volume should be restored relatively quickly with isotonic fluids, but water deficits should be corrected slowly with administration of hypotonic fluids. As a general rule, serum sodium should not decrease by more than 0.5 mEq/kg/hour (or 10–12 mEq/kg/day).

Excessive Sodium Administration. This is referred to as hypernatremia with overhydration. Excessive sodium administration can be caused inadvertently by administration of certain medications like gentamicin, heparin, calcium gluconate, sodium bicarbonate, sodium chloride flushes, and fluids to keep central lines patent (Bhatia, 2006). VLBW infants are particularly at risk from these "large" sodium loads. Treatment of this iatrogenic form of hypernatremia involves sodium restriction.

Potassium. Potassium is the main intracellular cation. Its concentration in cells is maintained by the membrane Na^+/K^+ pump, and it is involved in the regulation of cell membrane potential. Small variations in serum potassium concentration have significant effects, particularly on the myocardial cells.

Dietary potassium is mainly absorbed in the small intestine by passive absorption, and is actively secreted in the colon. The kidneys excrete potassium, and most filtered potassium is reabsorbed in the proximal tubule. Potassium is then secreted by the distal tubules in exchange for sodium in a process regulated by aldosterone. Hence, preterm infants with BPD that require chronic diuretic therapy (most diuretics are natriuretic) often need replacement with oral potassium chloride (KCl) to correct their electrolyte imbalance. The potassium requirement for both preterm and full-term infants is 2 to 3 mEq/kg/day. The normal serum concentration is 3.5 to 5 mEq/L.

Disorders of potassium balance are listed in Box 19.2.

Box 19.2

DISORDERS OF POTASSIUM BALANCE

Hypokalemia

- Renal losses: chronic diuretics, renal tubular acidosis, Bartter's syndrome
- Inadequate potassium intake
- Gastrointestinal losses: vomiting, diarrhea, nasogastric aspiration, ostomy output

Hyperkalemia

- Hemolyzed blood sample
- Excessive intake
- Impaired excretion: renal failure, congenital adrenal hyperplasia, pseudohypoaldosteronism
- Potassium-sparing diuretics
- Metabolic acidosis

Hypokalemia. Hypokalemia is defined as a serum potassium level below 3.5 mEq/L. It can be caused by increased renal losses (diuretics, renal tubular acidosis [RTA], and Bartter's syndrome), increased gastrointestinal losses (diarrhea, vomiting, continuous nasogastric aspiration, and ostomy output), or inadequate intake. The use of potassium-sparing diuretics may decrease the incidence of hypokalemia in the NICU.

Hypokalemia manifests through its effects on muscle cells. Although abdominal distention, diminished bowel motility, weakness, and lethargy are described, the cardiac effects are of much greater concern. An electrocardiogram (EKG) is a better measure of serious toxicity than the serum potassium concentration. **Emergency Alert: EKG changes associated with hypokalemia include a depressed ST segment, a flattened T wave, and a prominent U wave. A prolonged P-R interval, widening QRS complex, and various arrhythmias may follow, if untreated.**

Treatment involves potassium replacement. KCl should be given very slowly (<0.3 mEq/kg/hour) with frequent serum and EKG monitoring. Rapid intravenous (IV) administration of potassium may in itself cause fatal arrhythmias.

Hyperkalemia. Hyperkalemia is defined as a serum potassium level over 6.5 mEq/L. It can be caused by an excessive intake of potassium, impaired excretion (renal failure, congenital adrenal hyperplasia, and pseudohypoaldosteronism), or with severe metabolic acidosis (increased movement of potassium from the intracellular to the extracellular space). Factitious hyperkalemia may be associated with hemolysis (breakdown of red blood cells) and must be ruled out. Hyperkalemia occurs in approximately 50% of infants whose birth weight is less than 1,000 g, and is thought to occur due to decreased activity of the Na^+/K^+ pump. Thus, potassium should not be added to IV fluids in the first few days of life until good UOP is established. Cardiac toxicity is a serious complication of hyperkalemia and is better reflected by EKG changes than by the serum concentration. The typical EKG sequence is peaked or "tented" T waves, disappearance of P waves, and a widening QRS complex, which fuses with the T wave to form a sine wave. Ventricular fibrillation and cardiac arrest may follow if the serum potassium level remains untreated.

Treatment is directed at the underlying disorder. All potassium-containing fluids and supplements should be stopped immediately. Management of hyperkalemia with EKG changes includes the following:

- 10% calcium gluconate (100–200 mg/kg/dose, IV) is given to counteract the effects of hyperkalemia on the myocardium cells (*stabilizing the myocardial membrane against arrhythmias*). It does not decrease the serum potassium concentration.
- Sodium bicarbonate (1–2 mEq/kg, IV) is given to raise the blood pH and consequently increase potassium influx into cells.
- Nebulized beta-agonist agent (albuterol) is administered to increase intracellular uptake of potassium.
- Infusion of glucose and insulin is done, at a ratio of 4 g of glucose to 1 U of insulin, to increase intracellular uptake of potassium.
- Loop diuretics (furosemide; 1 mg/kg, IV) are given to increase renal excretion of potassium.
- Potassium-binding resin, Kayexalate (1 g/kg, by rectum or by mouth), is given to increase intestinal excretion.

Most of these measures are transient, as they do not decrease total body potassium but just move it intracellularly. Hence, if the serum potassium continues to rise and exceeds 8 mEq/L, peritoneal dialysis or exchange blood transfusions, using a mixture of washed red blood cells and fresh frozen plasma, may be necessary.

Chloride. Chloride is the main inorganic anion in the extracellular fluid, and together with sodium is responsible for maintaining plasma volume. Chloride is typically administered with Na^+ or K^+

Box 19.3

DISORDERS OF CHLORIDE BALANCE

Hypochloremia

- Decreased intake: older soy-based formulas
- Increased gastrointestinal losses: vomiting (pyloric stenosis), continuous gastric aspiration
- Congenital chloride diarrhea
- Increased renal losses: diuretics, Bartter's syndrome

Hyperchloremia

- Increased bicarbonate losses: renal tubular acidosis
- Excessive administration (with NaCl: absolute or relative)
- Hypertonic dehydration (apparent hyperchloremia)

as either NaCl or KCl in diet or in intravenous fluids. Intestinal absorption is passive in the jejunum and occurs secondary to sodium absorption. In the ileum and colon, chloride is actively absorbed in exchange for bicarbonate (HCO_3^-). Normally, only minimal amounts of chloride are lost in the feces. Similar to sodium, it is filtered by the glomeruli and reabsorbed throughout the tubules and collecting ducts. Normally, 99% of the filtered chloride is reabsorbed.

Chloride resorption is inversely related to bicarbonate resorption; hence, their serum concentrations are also inversely correlated, which keeps the total anion concentration (Cl^- and HCO_3^-) constant and maintains electrical neutrality. For this reason, although chloride has no buffer effect, it plays an important part in the acid–base regulation. When chloride is retained in the body, the serum bicarbonate level declines and metabolic acidosis follows. When chloride is lost from the body, the serum bicarbonate level rises and metabolic alkalosis ensues.

The recommended oral intake for preterm infants is 105 to 177 mg/kg/day (Agostoni et al., 2010). Normal serum chloride concentrations are 90 to 112 mEq/L in full-term infants and 100 to 115 mEq/L in preterm infants.

Disorders of chloride balance are listed in Box 19.3.

Hypochloremia. Hypochloremia is defined as a serum chloride level below 90 mEq/L and is caused by either a diminished intake or increased loss of chloride (gastrointestinal or renal). Clinical manifestations include metabolic alkalosis, hypokalemia, and, when chronic, failure to thrive.

Insufficient intake has been reported with soy formulas due to their low chloride content. The diagnosis of insufficient intake is based on the dietary history and the absence of urinary chloride, which indicates a normal ability to retain chloride to compensate for the low intake. Chloride losses independent of sodium and potassium may occur from prolonged vomiting in the form of hydrochloric acid (HCl) in pyloric stenosis or continuous aspiration of gastric contents via nasogastric tubes (e.g., in NEC).

Congenital chloride diarrhea is a rare disorder of severe diarrhea, beginning at birth, caused by impairment of the active Cl^-/HCO_3^- transport system in the ileum and colon. It is caused by a mutation in the *SLC26A3* gene responsible for encoding the exchange transporter in the intestine. However, these infants usually have normal electrolyte absorption in the jejunum. Analysis of stools shows an acidic pH and a greatly increased chloride concentration (>90 mmol/L; Elrefae, Elhassanien, & Alghiaty, 2013). Diarrhea is caused by the osmotic effect of excess chloride, which then leads to metabolic alkalosis and hypokalemia. The urine chloride is also decreased. Treatment involves lifelong supplementation and replacement of appropriate electrolytes. Other treatments include proton pump inhibitors and oral butyrate.

The most common cause of increased renal loss of chloride is diuretic therapy. **Quality and Safety: Chronic administration of furosemide, used often in the management of BPD, may cause chloride deficiency with secondary metabolic alkalosis.** Alkalosis, in turn, causes compensatory hypoventilation and an increase in the partial pressure of carbon dioxide (P_{CO_2}) in blood. This clinical picture can simulate pulmonary edema; however, the treatment should not be additional diuretic therapy but rather correction of the underlying hypochloremia.

Metabolic alkalosis with hypochloremia, hypokalemia, and hypercalciuria due to increased renal loss of chloride is the characteristic feature of Bartter's syndrome. These infants also have failure to thrive and episodes of dehydration. It is caused by a mutation in the Na^+-K^+-Cl^- cotransporter and is inherited in an autosomal recessive pattern. Elevated prostaglandin E concentrations are observed in the urine. Replacement with NaCl and KCl, maintenance of intravascular volume, and indomethacin (a prostaglandin antagonist) are the mainstays of treatment (Rodriguez-Soriano, 1998).

Hyperchloremia. Hyperchloremia is defined as a serum chloride level over 115 mEq/L. It is caused by either bicarbonate depletion or by excessive chloride intake and is commonly associated with metabolic acidosis. Diarrhea is the most common cause of hyperchloremic metabolic acidosis, as chloride is absorbed with sodium, and bicarbonate is excreted with potassium in the intestine.

Emergency Alert: Increased loss of bicarbonate occurs with RTA (type II or proximal type). In this condition, the renal threshold for bicarbonate drops and absorption of bicarbonate does not occur until the serum levels drop approximately below 15 mEq/L. The result is a hyperchloremic metabolic acidosis. The condition is often self-limited, as the proximal tubular length increases and function matures. The diagnosis is based on demonstrating a renal bicarbonate reabsorption threshold that is lower than normal.

Hyperchloremia may follow excessive administration of NaCl. Overtreatment with NaCl may be absolute, as in accidental errors in administration, or relative, as in renal failure where the excretion is impaired. Finally, apparent hyperchloremia, together with increased serum concentrations of other electrolytes, can occur with dehydration when there is a water deficit in relation to solute.

Calcium and Phosphorus. Calcium (Ca) is the most abundant mineral in the human body and is an essential component of the skeleton. It plays an important role in muscle contraction, neural transmission, and blood coagulation. Phosphorus (P) is equally essential for bone mineralization. About 80% of phosphorus is present in the bones and the remaining 20% is incorporated into energy storage molecules as adenosine triphosphate (ATP), which is essential for cell metabolism.

In the third trimester, the placental accretion of calcium is about 100 to 130 mg/kg/day and that of phosphorus is 60 to 70 mg/kg/day. In preterm babies, unfortified human milk fails to provide comparable levels of mineral retention, predisposing these infants to relative osteopenia known as metabolic bone disease of prematurity (Abrams, 2013).

Recommendations for enteral intake in preterm infants are 120 to 140 mg/kg/day of calcium and 60 to 90 mg/kg/day of phosphorus (Agostoni et al., 2010). With parenteral nutrition, a calcium intake of 60 to 80 mg/kg/day and a phosphorus intake of 45 to 60 mg/kg/day is recommended (Tsang et al., 2005). **Quality and Safety: To avoid precipitation in the parenteral solution,**

the calcium concentration should be maintained between 500 and 600 mg/L (12.5–15 mmol/L), and the phosphorus concentration should be maintained between 390 and 470 mg/L (12.5–15 mmol/L).

Calcium. Calcium transport in the intestine occurs by both passive and active processes. Active intestinal transport involves carriers called calcium-binding proteins. Vitamin D in its active form, 1, 25-dihydroxyvitamin D or calcitriol, is essential for the active process. Parathyroid hormone (PTH) is involved in the production of 1,25-dihydroxyvitamin D. Vitamin D deficiency and intestinal malabsorption due to any cause can impair calcium transport. **Quality and Safety: Corticosteroids diminish calcium absorption by inhibiting its transfer in the intestinal mucosa. Similarly, anticonvulsants can inhibit intestinal transfer of calcium (phenytoin) and interfere with vitamin D metabolism (phenobarbital and phenytoin).**

Calcium is present in the serum in three forms: ionized (50%), bound to proteins—mainly albumin (40%), and complexed with organic and inorganic compounds (10%). The ionized calcium is the only biologically active form. The calcium bound to albumin serves as a reserve. Therefore, measuring the ionized calcium level is more clinically relevant than the total serum calcium concentration. The affinity of calcium to albumin is increased by metabolic alkalosis and decreased by acidosis. In addition, with every 1 g/dL decrease in serum albumin, the total serum calcium decreases by 0.8 mg/dL but the ionized calcium remains unchanged. The serum calcium concentration is maintained within narrow limits by the action of PTH, 1,25-dihydroxyvitamin D, and calcitonin. PTH and 1,25-dihydroxyvitamin D increase the serum calcium level, while calcitonin reduces it. PTH secretion is driven by the serum ionized calcium concentration via the calcium-sensing receptors in the parathyroid cells.

The kidneys excrete calcium and filtered calcium is reabsorbed in most segments of the renal tubules. PTH increases tubular resorption of calcium, whereas calcitonin increases calcium excretion.

Disorders of calcium balance are listed in Box 19.4.

Box 19.4

DISORDERS OF CALCIUM BALANCE

Hypocalcemia

- *Early*
  - Preterm infant
  - Infant of diabetic mother
  - Perinatal asphyxia
  - Maternal anticonvulsant therapy
- *Late*
  - Hyperphosphatemia (increased dietary intake, renal failure)
  - Cow milk–based feeding
  - Hypomagnesemia
  - Hypoparathyroidism
  - Vitamin D deficiency

Hypercalcemia

- Excessive administration of calcium or vitamin D (or both)
- Hypophosphatasia
- Subcutaneous fat necrosis
- Williams' syndrome
- Idiopathic hypercalcemia
- Hyperparathyroidism
- Bartter's syndrome
- Familial hypocalciuric hypercalcemia

Hypocalcemia. Neonatal hypocalcemia is defined as an ionized serum calcium concentration below 4.4 mg/dL (1.1 mmol/L) in full-term infants. For preterm infants, insufficient normative data at different gestational ages exists; hence, a total serum calcium concentration below 7 mg/dL (1.75 mmol/L) remains a practical definition. Hypocalcemia conventionally is divided into early hypocalcemia, which occurs in the first 2 to 4 days of life, and late hypocalcemia, which occurs after the first 4 days, usually at about 1 week of age.

There is a physiologic fall in the calcium concentration during the first 48 hours of life. This is due to the abrupt interruption of maternal calcium supply and low dietary intake. In preterm infants, this fall in calcium is more rapid and inversely proportional to gestational age. Factors that contribute to early hypocalcemia in preterm neonates include inadequate PTH release, decreased responsiveness of renal tubules to PTH, and relative resistance to 1,25-dihydroxyvitamin D.

Infants of diabetic mothers are at increased risk of hypocalcemia due to hypomagnesemia. Mothers with diabetes have increased losses of magnesium in the urine, which in turn causes fetal hypomagnesemia and secondary hypoparathyroidism. Improvement in diabetes control during pregnancy has been associated with lower occurrence of hypocalcemia (Banerjee et al., 2003).

Hypocalcemia in the first few days of life is also seen following birth asphyxia. These infants have increased serum calcitonin and a relative increase in phosphorus load due to reduced glomerular filtration. Treatment of associated acidosis with bicarbonate may further aggravate hypocalcemia in these infants, due to increased calcium binding to albumin as mentioned earlier.

Late hypocalcemia typically occurs by the end of the first week of life. It is seen more often in term than in preterm infants and is caused by the relative resistance of renal tubules to PTH. This leads to increased phosphate retention and hypocalcemia. Low serum magnesium levels lead to hypocalcemia due to their inhibitory effect on PTH secretion (see the section on Magnesium later in the chapter). Infants fed cow's milk are also more prone to late hypocalcemia due to its high phosphorus content. Maternal vitamin D deficiency may be a predisposing factor; hence, vitamin D supplementation (400 IU) for all infants and 600 IU for breastfeeding and pregnant mothers is currently recommended. **Quality and Safety: Furosemide therapy can cause hypocalcemia and nephrolithiasis secondary to calciuresis.** Phototherapy also appears to be a cofactor associated with neonatal hypocalcemia, particularly in preterm infants. The mechanism is incompletely understood.

Neonatal hypoparathyroidism is characterized by low PTH, hypocalcemia, and hyperphosphatemia. It can be caused by structural abnormalities of the parathyroid glands, defects in the PTH molecule, or dysregulation of PTH secretion. In rare cases, late hypocalcemia can occur as a consequence of subclinical maternal hyperparathyroidism: maternal hypercalcemia leads to fetal hypercalcemia, which suppresses the fetal parathyroid glands. After birth, when the maternal source of calcium is no longer available, the suppressed parathyroid glands are unable to maintain a normal serum calcium concentration. Because maternal

hyperparathyroidism is often asymptomatic, neonatal hypocalcemia may provide the initial clue to maternal disease.

Neonatal hypocalcemia may be asymptomatic or can cause symptoms such as irritability, tremors, poor feeding, muscle twitching, and seizures. Diagnosis of hypocalcemia is based on definitions outlined earlier. Serum magnesium level should also be measured due to its effects on calcium homeostasis.

Several factors complicate the choice of treatment for neonatal hypocalcemia: (a) In most cases, the condition is asymptomatic and self-limited; (b) It may be associated with seizures without being the cause of seizures; (c) It may coexist with other perinatal complications, such as asphyxia and hypoglycemia, which can cause similar clinical signs. If the hypocalcemia is asymptomatic, 10% calcium gluconate (9.4 mg of elemental calcium per mL) may be given orally at a rate of 75 mg/kg/day divided into six equal doses. If hypocalcemia is symptomatic (e.g., seizures), 10% calcium gluconate must be given intravenously at a rate of 2 mL/kg over 10 minutes while the heart rate is being continuously monitored and the infusion stopped at the first sign of bradycardia. For late hypocalcemia caused by increased phosphorus load, human milk or formulas low in phosphorus and supplementation with calcium are recommended. If associated with hypomagnesemia, serum magnesium should be corrected prior to treating hypocalcemia.

Hypercalcemia. Hypercalcemia is defined as a serum calcium level over 11 mg/dL (2.75 mmol/L) or an ionized calcium level greater than 1.45 mmol/L. Hypercalcemic disorders, such as subcutaneous fat necrosis, Williams's syndrome, congenital hyperparathyroidism, neonatal Bartter's syndrome, osteopetrosis, and familial hypocalciuric hypercalcemia, are all exceedingly rare among newborns. Hypercalcemia is usually iatrogenic and results from excessive administration of calcium or vitamin D, or by insufficient phosphorus intake (human milk). Hence, before embarking on an elaborate differential diagnosis and expensive tests, one should carefully review the actual calcium, phosphorus, and vitamin D intakes.

Secondary hyperparathyroidism may be caused by maternal hypoparathyroidism or hypocalcemia, which leads to high PTH levels in the fetus. This condition is usually transient and resolves completely by 6 months of age. Primary hyperparathyroidism is caused by mutations in the *CASR* gene (Houillier & Paillard, 2003). The type presenting in neonates is familial hypocalciuric hypercalcemia characterized by abnormally low urine calcium and high PTH levels in the presence of an elevated serum calcium.

Clinical signs are nonspecific and include constipation, polyuria, and bradycardia. Infants with long-standing hypercalcemia may present with failure to thrive. Nephrocalcinosis (calcium deposition in the renal parenchyma) and nephrolithiasis (renal stones) accompanied with hematuria are often the earliest presentation of hypercalcemia. Nephrocalcinosis is a common finding in VLBW infants due to the calciuric effects of commonly used drugs such as furosemide. Long-term outcomes for infants with nephrocalcinosis are unknown.

Treatment of hypercalcemia is as follows:

- Calcium and vitamin D supplementation is suspended, and dietary intake of calcium and vitamin D is restricted (human milk or vitamin D–free formula is given).
- Urinary excretion of calcium is promoted by fluid administration (about twice the maintenance requirement).
- In the case of vitamin D excess, glucocorticoids are given to reduce intestinal absorption and bone resorption of calcium.
- As a last resort, pamidronate can be tried, although experience with bisphosphonates in newborns is limited. Pamidronate is generally given at a dose of 1 mg/kg, as a single 4-hour IV infusion. Additional doses are given weekly if necessary as serum calcium nadir occurs by day 6 to 7.
- Dialysis may be needed in case of severe and refractory hypercalcemia.

Phosphorus. Phosphorus is absorbed mainly in the duodenum and jejunum by both active and passive diffusion. Absorption depends on the amount of phosphorus in the diet, the relative concentrations of phosphorus and calcium (excessive calcium can diminish phosphorus absorption and vice versa), and the presence of phosphorus-binding substances (e.g., phytates in soy-based formulas).

The kidneys excrete phosphorus and it is under the control of PTH and fibroblast growth factor (FGF 23) activity. High levels of PTH and FGF 23 lead to hypophosphatemia due to their phosphaturic effects. Normally, about 95% to 99% of the filtered phosphorus is reabsorbed in term infants. Preterm infants have a greater fractional excretion of phosphorus in urine.

Disorders of phosphorus balance are listed in Box 19.5.

Hypophosphatemia. Hypophosphatemia is defined as a serum phosphorus level below 4 mg/dL (1.29 mmol/L) and is a common feature in preterm infants with metabolic bone disease, which is caused by insufficient intake of calcium and phosphorus. Adequate levels of phosphorus are needed to cause apoptosis (programmed cell death) of hypertrophic cells in the bony growth plate. **Quality and Safety: Therefore, hypophosphatemia leads to formation of abnormal bone tissue and metabolic bone disease** (Tiosano & Hochberg, 2009). Phosphorus deficiency can also result in muscle weakness and impaired white cell function.

In very rare cases, hypophosphatemia may be caused by neonatal hyperparathyroidism. In infancy, hypophosphatemia can occur due to disorders of vitamin D metabolism (vitamin D–dependent rickets) or defects in renal phosphorus transport (hypophosphatemic rickets).

Severe hypophosphatemia, a serum phosphorus level below 1 mg/dL (.32 mmol/L), is uncommon and usually occurs only in newborns receiving parenteral alimentation with an inadequate amount of phosphorus. Respiratory failure and decreased myocardial performance have been described as possible consequences of severe hypophosphatemia.

Hyperphosphatemia. Hyperphosphatemia is defined as a serum phosphorus level over 7 mg/dL (2.26 mmol/L) and can be caused by ingestion of milk formulas containing high amounts of phosphorus,

Box 19.5

DISORDERS OF PHOSPHORUS BALANCE

Hypophosphatemia

- Metabolic bone disease
- Inadequate parenteral phosphorus administration
- Malabsorption
- Hyperparathyroidism
- Familial hypophosphatemia: vitamin D–resistant rickets, X-linked hypophosphatemia

Hyperphosphatemia

- Impaired excretion of phosphorus: renal failure
- Hypoparathyroidism
- Excessive parenteral or enteral administration of phosphorus

excessive parenteral administration of phosphorus, impaired phosphorus excretion (renal failure), or by defects in hormonal regulation (hypoparathyroidism). Severe hyperphosphatemia may cause metastatic calcifications and hypocalcemia. Management includes alimentation with human milk or with a low-phosphorus formula, and calcium supplementation to increase binding of phosphorus to promote its fecal excretion. Reducing the parenteral phosphorus intake usually resolves parenteral hyperphosphatemia. In renal failure, 1,25-dihydroxyvitamin D, which exerts its effects independent of functioning renal tissue, can be given to counteract hypocalcemia secondary to hyperphosphatemia.

Supplementation with 1,25-dihydroxyvitamin D and calcium may be used to treat hypoparathyroidism in newborns arising from maternal hyperparathyroidism (transient secondary hypoparathyroidism) or from permanent primary hypoparathyroidism (sporadic or hereditary).

Metabolic Bone Disease. This condition occurs primarily in VLBW infants and is associated with a number of prenatal and postnatal risk factors (Box 19.6). Early initiation of enteral nutrition, use of specialized preterm formulas, and parenteral supplementation of calcium and phosphorus has led to a decrease in the incidence of this disease. The relative calcium, phosphorus, and vitamin D content of commonly used enteral feeds for VLBW infants are given in Table 19.4. Management of metabolic bone disease is centered on maximizing calcium and phosphorus intake. Infants that are unable to tolerate preterm formulas or appropriately fortified human milk require supplementation with elemental calcium at 20 mg/kg/day (up to a maximum of 80 mg/kg/day) and elemental phosphorus at 10 to 20 mg/kg/day (up to a maximum of 50 mg/kg/day). Serum 25-hydroxyvitamin D levels should be maintained above 20 ng/mL and medications like furosemide, dexamethasone, and caffeine should be judiciously used.

Magnesium. Magnesium is distributed primarily in the skeleton and the intracellular space. It is involved in energy production, cell membrane function, mitochondrial function, nerve conduction, and protein synthesis. In the serum, about a third of the magnesium is bound to albumin.

Magnesium is absorbed in the small intestine by both a passive and an active saturable mechanism. Absorption is related to intake, and approximately half of the dietary magnesium is absorbed. The kidneys, under the influence of many hormones, regulate the serum magnesium concentration and normally less than 5% of the filtered magnesium is excreted. PTH, calcitonin, ADH, and insulin increase magnesium reabsorption. The majority of magnesium reabsorption occurs in the ascending limb of the loop of Henle. PTH also mobilizes magnesium from the bone to increase the serum magnesium concentration. An acute decline in the serum magnesium concentration increases secretion of PTH, but chronic magnesium deficiency reduces PTH secretion and may cause hypocalcemia.

The recommended intake for preterm infants is based on placental accretion rates: 8 to 15 mg/kg/day (Agostoni et al., 2010). Magnesium content of mature human milk is about 26 mg/L. In parenteral solutions, its concentration should be maintained between 36 and 48 mg/L to avoid precipitation.

Disorders of magnesium balance are listed in Box 19.7.

TABLE 19.4

CALCIUM, PHOSPHORUS, AND VITAMIN D CONTENT OF ENTERAL FEEDS

	Unfortified Human Milk (20 kcal/oz)	Fortified Human Milk (24 kcal/oz)	Preterm Formula (24 kcal/oz)
Calcium (mg/kg)	37	184–218	210–234
Phosphorus (mg/kg)	21	102–125	107–130
Vitamin D (IU/day)	2.4	283–379	290–468

Note: For 160 mL/kg/day of feeds for an infant weighing 1,500 g.

Box 19.6

RISK FACTORS FOR METABOLIC BONE DISEASE

Prenatal

- Premature birth: abrupt cessation of placental calcium and phosphorus accretion
- Intrauterine growth restriction
- Preeclampsia
- Maternal vitamin D deficiency

Postnatal

- Inadequate intake of calcium and phosphorus
- Medications: diuretics, methylxanthines, steroids
- Vitamin D deficiency
- Sedation or paralysis

Box 19.7

DISORDERS OF MAGNESIUM BALANCE

Hypomagnesemia

- Infant of diabetic mother
- Intrauterine growth restriction
- Malabsorption syndromes
- Loop diuretics and aminoglycosides
- Isolated renal magnesium wasting

Hypermagnesemia

- Maternal treatment with $MgSO_4$ (e.g., for tocolysis, preeclampsia)
- Excessive magnesium administration with parenteral nutrition
- Magnesium-containing antacids
- Magnesium therapy for neonatal pulmonary hypertension

$MgSO_4$, magnesium sulfate.

Hypomagnesemia. Hypomagnesemia is defined as a serum magnesium level below 1.6 mg/dL (0.66 mmol/L). Hypomagnesemia may be a cause or the effect of neonatal hypoparathyroidism. Magnesium transfer from the mother to the fetus is impaired in maternal disorders with placental insufficiency and predisposes neonates to hypomagnesemia. Infants of diabetic mothers have an increased incidence of hypomagnesemia as a consequence of maternal magnesium depletion (Banerjee et al., 2003). **Emergency Alert: Loop diuretics and aminoglycosides have been associated with renal magnesium wasting.** Isolated defects of intestinal malabsorption and renal wasting of magnesium have also been described.

Symptoms of hypomagnesemia are usually not apparent until the levels fall below 1.2 mg/dL (0.49 mmol/L). The symptoms of hypomagnesemia are similar to hypocalcemia and frequently coexist in clinical practice. Neonatal hypomagnesemia is usually benign and transient (except in cases of malabsorption and renal wasting). It can cause hyperexcitability, tremors, and, occasionally, severe hypocalcemic seizures that are unresponsive to anticonvulsant medications and calcium replacement. They respond to slow infusion of 0.1 mL/kg of 50% magnesium sulfate ($MgSO_4$). **Emergency Alert: Complications include systemic hypotension and arrhythmias.** Treatment can be repeated with close monitoring of the serum magnesium concentration every 12 hours, until normal magnesium levels are achieved. In cases of malabsorption syndromes, daily oral supplementation of 1 mL/kg of 50% $MgSO_4$ may be required.

Hypermagnesemia. Hypermagnesemia is defined as a serum magnesium level over 2.8 mg/dL (1.15 mmol/L). Hypermagnesemia is usually secondary to excessive administration through parenteral nutrition or following maternal treatment with $MgSO_4$ for tocolysis, neuroprotection, or seizure prevention in preeclampsia. Serum levels following maternal treatment seldom reach dangerous levels and gradually return to normal after several days. Rarely, magnesium-containing antacids and treatment of persistent pulmonary hypertension of the newborn with $MgSO_4$ can cause hypermagnesemia.

The most common presentation of hypermagnesemia is perinatal depression of the infant following maternal magnesium therapy. Clinical signs include hyporeflexia, lethargy, and respiratory depression. Hypermagnesemia can lead to a decrease in PTH and 1,25-dihydroxyvitamin D production resulting in a fall in serum calcium concentration. Treatment of hypermagnesemia is usually supportive. It is important to maintain adequate hydration to promote urinary excretion. Loop diuretics may also be used to aid renal elimination. Rarely, mechanical ventilation may be required to overcome respiratory depression.

ACID–BASE BALANCE

A number of complex physiologic processes are at work in a normal infant to maintain the pH within a tight range of 7.35 to 7.45. This pH range is essential for normal metabolic functioning, growth, and development. These processes are disrupted in critically ill neonates and preterm infants, leading to either acidosis or alkalosis. Preterm infants are especially at risk for acidosis due to their impaired renal ability to acidify urine and lower renal threshold for bicarbonate absorption compared to term infants.

The following are the two main processes that help maintain acid–base balance.

Acute Compensation

Whenever acute changes in the acid–base status occur, there are two major buffering mechanisms that come into play to restore pH to normal levels. First, the H^+/K^+ exchanger can alter the relative concentrations of H^+ and K^+ in the intracellular and extracellular spaces. For example, when there is acidosis (decrease in serum pH), this exchanger causes the H^+ ions to move intracellularly and K^+ to move extracellularly. Hence, acute acidosis is often complicated and accompanied by hyperkalemia. The second buffering mechanism is via carbonic anhydrase, an enzyme that catalyzes the conversion of water (H_2O) and carbon dioxide (CO_2) to carbonic acid (H_2CO_3) and vice versa. The H_2CO_3 can dissociate to form H^+ and HCO_3^- ions.

CO_2 crosses the blood–brain barrier and decreases the pH, resulting in activation of central chemoreceptors that increase the respiratory drive and lead to CO_2 excretion. Similarly, alkalosis results in hypoventilation, leading to retention of CO_2 in an attempt to normalize the pH. It is important to note that respiratory compensatory mechanisms can only partially normalize serum pH. Hence, if the serum pH is normal, a mixed acid–base disorder should be suspected rather than a compensated condition.

Long-Term Compensation

The lungs and kidneys are responsible for maintenance of long-term acid–base homeostasis. The lungs primarily excrete CO_2, a by-product of energy metabolism. The kidneys excrete a daily acid load of about 1 to 2 mEq/kg and more in pathologic processes such as sepsis or lactic acidosis. The kidneys also maintain acid–base balance by reabsorption and excretion of bicarbonate, which may be disrupted in conditions such as RTA.

Metabolic Acidosis

Metabolic acidosis is defined as a serum pH of less than 7.30 with a normal P_{CO_2} level and decreased HCO_3^- level. It is a common finding in preterm and critically ill neonates. It is divided into two categories based on anion gap: (a) increased anion gap metabolic acidosis and (b) normal anion gap metabolic acidosis (Box 19.8). Anion gap is defined as the difference between the measured cations (positively charged ions) and anions (negatively charged ions) in the serum. It can be calculated by the formula:

$$\text{Anion gap} = (Na^+ + K^+) - (Cl^- + HCO3^-).$$

Normal anion gap is 8 to 16 mEq/L

The most common cause of increased anion gap metabolic acidosis is lactic acidosis. Endogenous lactic acid, a by-product of

Box 19.8

CAUSES OF METABOLIC ACIDOSIS

Increased Anion Gap

- Sepsis, necrotizing enterocolitis
- Hypoxia
- Hypovolemic shock
- Inborn errors of metabolism (organic acidemia, glycogen storage disease, galactosemia, mitochondrial defects)
- Maternal salicylate use

Normal Anion Gap

- Renal tubular acidosis
- Secretory diarrhea
- Carbonic anhydrase inhibitors (e.g., acetazolamide, dorzolamide)

anaerobic metabolism, is produced in conditions with poor tissue perfusion as seen in sepsis, hypoxia, or NEC. Acidosis with increased anion gap can also be seen in the case of inborn errors of metabolism like organic acidemias, glycogen storage disease, galactosemia, or mitochondrial defects. A condition unique to neonates is the *late metabolic acidosis* of prematurity. It is usually seen in the third week of life and is caused by the excess acid load following the use of high protein (casein/whey) formulas. This is mostly a self-limited condition and resolves as the kidneys mature.

Normal anion gap metabolic acidosis is commonly seen in RTA, diarrhea, and with certain medications. In proximal RTA (type II), there is a defect in the bicarbonate reabsorption, while in distal RTA (type I), there is an inability to excrete H^+ ion. In diarrhea, there is an excessive loss of HCO_3^- ion in the stool. Medications like carbonic anhydrase inhibitors cause decreased uptake of HCO_3^- in the kidneys. In order to maintain electrical neutrality, the serum chloride level is usually elevated in normal anion gap metabolic acidosis.

Treatment is aimed at correcting the underlying cause. Bicarbonate should be used with extreme caution as it can inadvertently increase P_{CO_2}, with a consequential shift in the oxyhemoglobin dissociation curve to the left, leading to decreased oxygen delivery to the tissues and intracellular acidosis.

Metabolic Alkalosis

Metabolic alkalosis is defined as a serum pH greater than 7.45 with a normal P_{CO_2} level and elevated HCO_3^- level. The most common cause of metabolic alkalosis in preterm infants is chronic diuretic therapy for BPD. Depletion of the extracellular fluid volume leads to metabolic alkalosis by activation of the renin–angiotensin–aldosterone system leading to Na^+ absorption and H^+ and K^+ excretion in the renal tubules. Volume depletion also reduces the GFR and thus the amount of bicarbonate filtered. This is termed as contraction alkalosis. Metabolic alkalosis is divided into two categories (Box 19.9): (a) chloride responsive and (b) chloride resistant. A urinary chloride level can help delineate the type.

Chloride-responsive metabolic alkalosis is associated with a low urinary chloride level and is seen after chronic diuretic therapy (furosemide acts by inhibiting the Na^+-K^+-Cl^- cotransporter), excessive loss of gastric hydrochloric acid due to vomiting or prolonged nasogastric aspiration, and congenital chloride-wasting diarrhea (rare).

Chloride-resistant metabolic alkalosis is associated with a high urinary chloride level and is seen in early diuretic therapy; excessive administration of bicarbonate, acetate, or citrate; and Bartter's syndrome (rare).

Mild to moderate metabolic alkalosis does not warrant therapy. Treatment is aimed at correcting the underlying cause. Metabolic alkalosis secondary to chronic diuretic therapy is treated by supplementing chloride in the form of KCl either enterally or parenterally. Discontinuation or alteration of the diuretic dose may also be required. Alkalosis due to loss of gastric acid is corrected by appropriate fluid replacement (normal saline or Ringer's lactate). Acetazolamide has been occasionally used for treatment in critically ill neonates but the evidence is limited (Andrews, Johnson, Lammers, Harrison, & Miller, 2013).

Box 19.9

CAUSES OF METABOLIC ALKALOSIS

Chloride Responsive

- Chronic diuretic therapy
- Loss of gastric acid (nasogastric suction or vomiting)
- Congenital chloride diarrhea

Chloride Resistant

- Early diuretic therapy
- Excessive administration of base (bicarbonate, acetate, or citrate)
- Bartter's syndrome

Respiratory Acidosis

Respiratory acidosis is an increase in P_{CO_2} associated with a decrease in serum pH. It is caused by conditions that decrease the respiratory drive (ventilation) leading to CO_2 retention. The most common causes are RDS, transient tachypnea of newborn (TTN), pneumonia, meconium aspiration, and chronic lung disease. It can also be seen acutely in an obstructed or improperly positioned endotracheal tube. A strategy of permissive hypercapnia (respiratory acidosis) is often used in infants with chronic lung disease to minimize ventilator-associated lung injury and facilitate weaning of respiratory support.

Respiratory Alkalosis

Respiratory alkalosis is a decrease in P_{CO_2} associated with an increase in serum pH. The most common cause of respiratory alkalosis in neonates is mechanical overventilation. A factitious decrease in P_{CO_2} is also observed whenever an air bubble is trapped in the blood gas specimen. True central hyperventilation (increased respiratory rate) requires further diagnostic workup as it is associated with intracranial pathologies and hyperammonemia.

Identifying Acid–Base Disturbances

When one of the four conditions mentioned earlier is present in isolation, it is called a simple acid–base disorder. In these conditions, an appropriate respiratory or renal compensation occurs to counteract the primary abnormality to mitigate large changes in the serum pH. For example, a primary metabolic acidosis is associated with a respiratory compensation wherein P_{CO_2} levels decrease and respiratory alkalosis ensues. Similarly, a primary respiratory acidosis is associated with compensatory renal changes (increase in secretion of H^+ ion) that lead to metabolic alkalosis. The respiratory compensation of primary metabolic abnormalities occurs rapidly, while metabolic compensation for a primary respiratory acid–base disorder occurs more slowly. There is an initial acute but modest response followed by a chronic renal response that usually takes 3 to 5 days. If the compensation in pH from a respiratory or renal process is greater or lesser than expected, a mixed acid–base disorder is suspected. For example, in a septic patient with metabolic acidosis due to poor perfusion, there may be associated respiratory failure leading to respiratory acidosis and a higher than expected P_{CO_2} level. Appropriate diagnosis of acid–base disturbances requires (a) identification of the primary abnormality (history, clinical examination, and laboratory data) and (b) assessment of the degree of secondary compensation. The expected values for appropriate secondary compensation for the various disorders are given in Table 19.5 (Adrogue & Madias, 2010).

Nursing Management

Nurses have a vital role to play in the fluid and electrolyte management of infants admitted to the NICU. In addition to obtaining

TABLE 19.5

COMPENSATORY RESPONSE TO PRIMARY ACID–BASE DISTURBANCES

Acid–Base Disturbance	Primary Finding	Secondary Compensation
Metabolic acidosis	Every 1 mEq/L decrease in HCO_3^-	Decrease in Pco_2 by 1.2 mmHg
Metabolic alkalosis	Every 1 mEq/L increase in HCO_3^-	Increase in Pco_2 by 0.7 mmHg
Respiratory acidosis	Every 10 mmHg increase in Pco_2	Acute: increase in HCO_3^- by 1 mEq/L Chronic: increase in HCO_3^- by 4 mEq/L
Respiratory alkalosis	Every 10 mmHg decrease in Pco_2	Acute: decrease in HCO_3^- by 2 mEq/L Chronic: decrease in HCO_3^- by 4 mEq/L

vital signs and monitoring intake–output and daily weights, they are responsible for securing peripheral and central vascular access to ensure the safe delivery of IV fluids and medications. **Quality and Safety: It is crucial for a bedside nurse to promptly recognize and report the signs and symptoms of fluid and electrolyte imbalance to avoid complications associated with inappropriate fluid administration.**

Assessment and Evaluation in Fluid and Electrolyte Therapy. The estimation of an infant's fluid and electrolyte needs depends on the gestational age, day of life, weight, and the underlying disease process. The needs of a 4-kg infant with perinatal asphyxia and seizures are vastly different from those of a 32-week, 1,750 g infant with RDS or a 24-week, 500 g infant with multiple complex problems. Each represents a different disease process along with varying degrees of organ maturation necessitating careful management of fluid and electrolytes to maintain homeostasis.

Fluid Requirement. Fluid needs of an infant can be calculated using body weight, body surface area, or caloric expenditure (Behrman, Kleigman, & Jenson, 2011). In clinical practice, the total daily fluid requirement is approximated based on the gestational age, weight, and the day of life of an infant. It is then further adjusted by accounting for past and projected losses. Factors that impact water loss in neonates are given in Table 19.1. An example of this is the term newborn infant with a large gastroschisis. This midline abdominal wall defect predisposes the infant to large IWLs because of the exposed abdominal organs. Similarly, a 24-week, 500 g infant with the typical "translucent" skin that has not yet formed a competent epidermal barrier is predisposed to dehydration due to large IWL through the skin. The fluid requirements for such an infant may be as high as 150 to 200 mL/kg/day. In contrast, a birth-asphyxiated full-term infant may need fluids restricted to no more than 40 to 50 mL/kg/day for the first 48 to 72 hours of life.

Environmental factors such as temperature and humidity also affect IWL. The use of radiant warmers increases IWL, while the use of a double-walled, well-humidified incubator significantly reduces the IWL. Finally, it is critical for a nurse to double-check fluid orders to ensure that the correct fluids and rate are delivered. The approximate maintenance requirements of newborns in the first week of life (based on birthweight) are given in Table 19.2.

Fluid Output. The underlying disease process dictates the frequency of fluid (intake–output) calculations, which are usually performed once a day. In neonates recovering from acute renal failure (polyuric phase), calculations may need to be done every 4 hours, whereas in conditions with decreased urine output (renal failure, nephrotoxic drugs) it may suffice to calculate every 12 to 24 hours. Urine output is measured and expressed in mL/kg/hour and, if less than 1 mL/kg/hour, the infant is diagnosed to have oliguria.

For example, if a 32-week gestation 2-kg infant has 240 mL of urine in a 24-hour period,

$$\text{UOP} = 240 \text{ mL}/24 \text{ hour} = 10 \text{ mL/hour}$$

$$10 \text{ mL/hour} / 2 \text{ kg} = 5 \text{ mL/kg/hour}$$

This is an adequate UOP for an infant of this weight and gestational age.

Neonates can also have significant fluid losses through vomiting, diarrhea, ostomy, nasogastric tube, chest tube, and surgical wound drainage. In general, if the fluid loss from these sources exceeds 20 mL/kg in 24 hours, replacement fluids should be initiated to prevent fluid and electrolyte imbalance. Table 19.3 gives the electrolyte concentrations of different body fluids and can be used to guide the choice of replacement fluids.

Infant Weight. Weight is a sensitive indicator of overall fluid status. Infants are usually weighed daily; however, extremely low birth weight (ELBW) infants are weighed more often (i.e., every 12 hours) as fluid requirements are recalculated on the basis of weight changes. It is important to weigh infants accurately, as inaccuracies can lead to wrong calculations and detrimental outcomes. Neonates should be weighed nude, with minimal extraneous equipment (e.g., EKG leads, probes), at the same time each day, and on the same scale. In-bed scales that give constant weight readouts simplify the weighing process and reduce infant stress. Birth weight is used to calculate daily fluid requirements during the first week of life as physiologic fluid shifts occur and impact daily weights. Once the infant regains birth weight, the daily weights are used to calculate fluid needs.

Physical Examination. The physical examination can reveal changes in the infant's fluid status and should be used in conjunction with laboratory data to plan interventions in fluid and electrolyte therapy. A general assessment of hydration status includes the infant's color, skin turgor, activity, mucous membranes, fontanelles, and capillary refill:

- *Color:* Pink and well perfused, rather than pale and mottled (indicates dehydration)
- *Skin turgor:* Good turgor, rather than "tenting" (indicates dehydration) or edematous and shiny (indicates fluid overload)
- *Activity:* Active with good tone, rather than lethargic and hypotonic (indicates dehydration or overhydration)
- *Mucous membranes:* Pink and moist, rather than dry and gray (indicates dehydration)
- *Fontanelles:* Soft and flat, rather than depressed (indicates dehydration) or tense and full (may indicate overhydration)
- *Capillary refill:* It is an important indicator of peripheral perfusion and hydration status. Normal capillary refill time in neonates is less than or equal to 2 seconds. Capillary refill greater than 3 seconds is concerning for dehydration.

Vital Signs

Heart Rate: Tachycardia is a relatively early sign of dehydration. As a variety of other factors can also cause tachycardia in neonates (pain, anemia, or caffeine therapy), the heart rate trend is more useful in diagnosing fluid imbalance rather than absolute values.

Blood Pressure: Hypotension and shock occur late in dehydration. Acute changes in the mean arterial blood pressure are a significant risk factor for IVH in extremely preterm neonates (Bada et al., 1990).

Laboratory Data. The frequency of laboratory assessment depends on the clinical status of the infant. In most preterm and critically ill infants that require intravenous fluids, a daily basic metabolic panel (BMP) is obtained for the first 3 days of life. These assessments are made more frequently in infants with high fluid losses or with significant derangements in electrolytes. On the other hand, infants with relatively stable electrolytes despite being on chronic diuretic therapy may only require weekly checks.

Point-of-care assessment of urine specific gravity (normal 1.005–1.012) and acute changes in central hematocrit are also helpful in assessing hydration status at the bedside.

SUMMARY

The care of infants with alterations in fluid and electrolyte balance presents a management challenge for both physicians and nurses. A thorough understanding of the underlying pathophysiology and the rationale for therapy enables the healthcare team to provide more informed care for these infants and to anticipate and prevent problems.

CASE STUDY

A 24-week female infant with a birth weight of 500 g was born to a 30-year-old gravida 1 para 1 mother following preterm labor. Pregnancy was complicated by limited prenatal care, and maternal group B streptococcus status is unknown. The delivery occurred via a caesarian section under general anesthesia. Upon delivery, the infant was limp, blue, and apneic and required intubation and mechanical ventilation. Apgar scores were 2, 6, and 8 at 1, 5, and 10 minutes, respectively. Upon arrival to the NICU, the nurse obtains peripheral IV access and screening septic workup is drawn. Umbilical venous and arterial lines are placed and the infant is given a dose of ampicillin and gentamicin. Infant is started on a $D_{7.5}W$ with amino acids at 80 mL/kg/day. Vital signs remain stable and a BMP obtained at 24 hours of life is normal. Venous blood gas is pH 7.26, P_{CO_2} 49 mmHg, and base deficit of –5. Bilirubin level is noted to be 8 mg/dL and the infant is started on phototherapy. On day of life (DOL) 2, the infant's fluid goal is increased to 100 mL/kg/day and 1/4 sodium acetate is added to fluids, but she loses peripheral access. The nurse also reports concerns with the umbilical venous line fluids repeatedly backing up and notices that the bed is soaked with clear fluid. Following this, a peripherally inserted central catheter (PICC) is placed by the nurse and IV fluids are restarted at the previous rate. A BMP obtained on DOL 3 shows Na^+ 161 mEq/L, K^+ 6.5 mEq/L, Cl^- 129 mEq/L, $HCO3^-$ 16 mEq/L, BUN 53 mg/dL, creatinine 1.26 mg/dL, glucose 73 mg/dL, and serum osmolality 345 mOsm/L.

■ Differential Diagnoses for Hypernatremia

- Dehydration due to peripheral/central line malfunction (umbilical venous line repeatedly backing up with clear fluid soaking the bed, lack of intravenous fluids while PICC was being attempted)
- Excessive IWL due to immature skin and phototherapy (24-week infant with high bilirubin)
- Excessive administration of sodium (addition of 1/4 sodium acetate to fluids on DOL 2)

■ Assessment

Weight: Birth weight 500 g, weight on DOL 2, 450 g. 10% weight loss.

Vital signs: Heart rate 180 beats/minute; respiratory rate 60 breaths/minute; blood pressures: systolic 40 mmHg, diastolic 18 mmHg; mean arterial pressure 25 mmHg.

■ Physical Examination

- GENERAL: decreased spontaneous activity
- HEENT: normocephalic, anterior fontanelle slightly sunken
- RESPIRATORY: bilateral breath sounds equal and clear
- CARDIOVASCULAR: tachycardia with continuous murmur; pulses = +1; capillary refill ~3 seconds
- ABDOMEN: soft, round, and not tender to palpation, no hepatosplenomegaly noted
- GENITOURINARY: immature female genitalia
- SKIN: immature skin with developing areas of breakdown

■ Diagnostic Tests

- BMP
- Serum osmolality
- Urine specific gravity
- Blood gas
- Complete blood count

■ Development of Management Plan

The management plan involves evaluating the fluid status based on clinical examination and laboratory data. This extremely premature infant has lost 10% of birth weight on DOL 2, and on physical examination has signs concerning for dehydration. BMP on DOL 3 shows increased serum osmolality, hypernatremia, hyperkalemia, hyperchloremia, and metabolic acidosis. The most likely cause of hypernatremia is dehydration due to cessation of intravenous fluid delivery secondary to loss of peripheral and central venous access. Furthermore, a fluid goal of 80 to 100 mL/kg/day in the first 48 hours of life is inadequate for this ELBW infant weighing only 500 g due to high IWL through the immature skin. Phototherapy is an additional risk factor that augments the IWLs. Early sodium supplementation in the absence of adequate diuresis can increase the risk for hypernatremia.

The total fluid goal for this infant should be increased by about 40 to 60 mL/kg/day to correct dehydration. **Quality and Safety: Normal saline boluses should be avoided as ELBW infants at this age have poor cerebral blood flow autoregulation and are at significant risk for IVH. The incubator temperature and humidity should be set to maintain a thermoneutral environment.**

■ Evaluation of Intervention

Periodic assessment of the infant's weight, vital signs, and physical examination are critical. A BMP is repeated to evaluate the electrolytes 12 to 24 hours later. The correction of sodium levels should not be greater than 10 to 12 mEq/L/day (or 0.5 mEq/L/hour), due to the risk for cerebral edema. The infant is also monitored for signs of hyperkalemia and metabolic acidosis.

■ Outcome

After the fluid goal was readjusted and measures were taken to reduce IWL, the electrolyte abnormalities slowly corrected over a 48-hour period.

EVIDENCE-BASED PRACTICE BOX

Virtually all preterm infants need intravenous fluid infusions for a variable length of time, depending on the degree of prematurity and severity of complications. The optimal daily fluid requirements are tailored to the infant's needs. In 2014, Bell and Acarregui published a meta-analysis to determine the effect of varying levels of fluid intake on postnatal weight loss, morbidity, and mortality in preterm infants. Five randomized controlled trials evaluating different intravenous fluid intakes were included in the analysis.

The water intake in the "Restricted Fluids" group ranged from 50 to 122 mL/kg/day, while in the "Liberal Fluids" group it ranged from 80 to 169 mL/kg/day. The postnatal weight loss was significantly higher, along with a trend toward increased risk of dehydration in the fluid-restricted group. The risk of PDA (relative risk, RR, 0.52 and number needed to treat, NNT, was 7) and NEC (RR 0.43 and NNT was 20) was significantly lower in the fluid-restricted group. In addition, there was a trend toward reduced risk of chronic lung disease and IVH in the fluid-restricted group but it did not reach statistical significance. There was no difference in mortality between the two groups.

The authors concluded that appropriately restricted fluid intake (without causing dehydration) in preterm neonates could potentially reduce the risk of PDA and NEC.

CHAPTER 20

Nutrition Management of Premature Infants

Diane M. Anderson

INTRODUCTION

Meeting the nutritional needs of premature and sick infants is essential to their survival (Heird, Driscoll, Schullinger, Grebin, & Winters, 1972). Under conditions of total starvation, these infants have reserves for only 4.5 days, and daily provision of intravenous glucose will prolong survival for only about 7 days. Therefore, the mandate is to meet the basic nutrient requirements of these infants and to understand their metabolic limitations to avoid physiologic stress and morbidity related to the delivery of enteral and parenteral nutrition (PN). Nutrition management of the premature infant continues shortly after birth with intravenous fluids, PN, and/or enteral feedings depending on the infant's gestational age and clinical condition. The goal is for the premature infant to grow at the same rate and composition as a fetus of the same gestational age without imposing undue metabolic stress (American Academy of Pediatrics [AAP] Committee on Nutrition, 2014c). The goal for the premature infant differs from that of the healthy term infant who is breastfeeding. The premature infant has increased nutrient demands and will require fortification of human milk to meet nutrient needs. Due to illness and immaturity, PN and gavage feedings will be needed. Premature infants are at nutrition risks for many reasons, including early birth, which limits nutrient stores such as calcium, iron, and fat; rapid growth, which increases nutrient demand; illness, which may alter nutrient need, nutrient tolerance, and feeding modality; immature gastrointestinal tract, which presents as decreased gut motility, decreased digestive abilities, and decreased tolerance of feedings; and cold stress increasing energy demand.

After birth, infants lose weight due to fluid losses and low nutrient intakes. Once birth weight is regained, the premature infant will gain weight at the intrauterine rate of 15 g/kg/day and parallel their birth weight curve. By discharge, many infants will have a weight less than the 10th percentile for their postmenstrual age and be classified as extrauterine growth restriction (EUGR; Ehrenkranz, 2010). Improved nutrition during week 1 of life has been associated with better weights at discharge and improved developmental outcomes at 18 months corrected age (Stephens et al., 2009; Valentine et al., 2009). Nutrition and a neonate's nutritional status impact the growth patterns—both immediate and long term. Evidence is mounting to support the need for good nutrition for the premature or sick neonate if short- and long-term complications are to be minimized.

This chapter starts with a brief review of the metabolism of nutrients, minerals, and vitamins in the neonate. It then discusses the developmental and physiologic issues that are unique to the premature and sick infant. A discussion of neonatal nutrition with special emphasis on the premature infant describes the challenges of providing appropriate nutrients. The various nutrition routes are included.

NUTRIENTS

Protein

Protein must be broken down into amino acids to be absorbed. Protein digestion and absorption take place in the stomach, small intestinal lumen, and the intestinal cell, the enterocyte (Neu, 2017). Protein digestion begins in the stomach by gastric acid, hydrochloric acid, and the enzyme pepsin. Protein digestion continues in the intestinal lumen by the presence of pancreatic enzymes. Protein is now in the form of peptides (group of amino acids). In the enterocyte, the peptides are further broken down to amino acids. The amino acids and some small peptides are then absorbed into the blood. The intestine of the infant is immature, and intact proteins can cross into the bloodstream and perhaps induce an allergic reaction to milk protein. The openness of the intestine wall to intact protein is greater with infants born at less than 33 weeks' gestation, but closure does occur a few days after birth (Neu, 2017). In the fetus, gastric acid production has been found at 13 weeks' gestation, and gastric levels are lower in premature infants than levels seen in term infants. Gastric enzymes appear at 16 weeks' gestation and pancreatic enzymes by 24 weeks' gestation. Protein digestion and absorption does not appear impaired with premature infants (Neu, 2017).

Fat

Food fat is mainly present as triglycerides that are three fatty acids attached to the carbohydrate, glycerol. Fat is digested in a two-step process in the intestine. The first step is to make the triglyceride water soluble with the mixing of bile salts from the liver. The second step breaks the triglyceride into two fatty acids and a monoglyceride by the pancreatic lipases, lingual lipase, gastric lipase, intestinal lipase, or milk bile acid stimulated lipase present in human milk. The monoglyceride and free fatty acids can be directly absorbed

into the enterocyte or enter by transporter protein for fatty acids (Neu, 2017). Once in the enterocyte, triglycerides are made and are grouped with cholesterol, lipoproteins, and other lipids to form chylomicrons. The chylomicrons circulate by the lymphatic system into the blood system and then into cells throughout the body. Fat digestion and absorption are limited in infants due to decreased levels of bile salts and lipase levels. Bile acid levels are low due to decreased syntheses and decreased intestinal reabsorption. Fetal lipase levels are detected at 21 weeks' gestation, but do not reach adult concentrations until 6 months of age in the term infant. Premature infants have lower lipase levels at birth than term infants. Fat is 40% to 50% of the dietary calories from human milk or infant formula, so it is a major component of intake by infants for their growth.

Medium chain triglyceride (MCT) oil has been added to premature infant formulas. MCT oils do not require bile salts or pancreatic lipases to be digested and are absorbed directly into the bloodstream by the infant. The addition of MCT does not help the premature infant absorb more fat, but may be helpful for infants with major absorption problems such as infants with short gut syndrome.

Carbohydrate

Carbohydrate must be in its simple form or as monosaccharides to be absorbed. Lactose is the major carbohydrate in human milk and is composed of the monosaccharides glucose and galactose. Starch consists of glucose polymers, and sucrose contains glucose and fructose. Digestion of carbohydrate begins in the mouth with salivary amylase to break it down to smaller-size carbohydrates or oligosaccharides. The digestion continues with human milk alpha-amylase when consumed and pancreatic amylase enzymes in the intestine. The final digestion occurs on the brush border of the enterocyte with the enzymes lactase, maltase, and sucrase used to break down lactose, starch, and sucrose. The monosaccharides are carried into the enterocyte by a transport protein and into the blood by a different transport protein. Premature infants have decreased levels of the enzymes lactase, maltase, and sucrase, but after birth with lactose-containing human milk, the lactase enzymes are increased by 2 weeks of age (Neu, 2017). Formulas for premature infants contain a blend of lactose and glucose polymers that are well tolerated. Infants who have intestinal damage following necrotizing enterocolitis (NEC) or have developed short gut syndrome may not tolerate lactose and will need a formula containing glucose polymers (corn syrup solids).

Summary

The absorption of the three major nutrients is relatively inefficient in the preterm as well as the term infant. Diets such as human milk or premature infant formulas are well tolerated. For nurses, a basic understanding of these mechanisms of absorption is essential so that the rationale for various dietary adjustments can be understood.

VITAMINS, MACROMINERALS, AND TRACE MINERALS

Infants received most of their fat-soluble vitamin stores during the last trimester of pregnancy. Premature infants will have lower vitamin A, D, E, and K stores than the term infant. Premature infants do not absorb fat-soluble vitamins well because of their poor ability to digest and absorb fat (Leaf & Lansdowne, 2014). Premature infants have decreased bile salts and pancreatic lipase concentrations, both of which are needed for fat and fat-soluble vitamins to be absorbed. Premature infants have increased vitamin needs due to limited vitamin stores, increased demand for growth, and limited absorptive capabilities.

Water-soluble vitamins—B complex and vitamin C—are less likely to create deficiency states owing to their relative availability and method of absorption in infants. Information on water-soluble vitamin needs are limited for the premature infant, and there is much to be learned (Leaf & Lansdowne, 2014).

The absorption of sodium, potassium, chloride, and bicarbonate across the intestinal mucosa in the infant appears to differ from that in the adult. Under normal circumstances, this difference appears to be of no consequence. In unusual circumstances, such as diarrhea, the increased intestinal permeability may lead to large intestinal losses of these electrolytes as well as water. This causes the infant to develop dehydration and electrolyte imbalance more rapidly than later in life. Basic requirements also vary in the infant because renal absorption and excretion of these minerals are not well regulated owing to organ immaturity, which is accentuated in the premature infant.

Calcium absorption occurs by active transport and passive diffusion (Namgung & Tsang, 2017). Active transport depends on vitamin D. Passive diffusion of calcium may be enhanced by the presence of bile salts and lactose. Bile salts and lactose increase intestinal cell permeability.

Zinc that is ingested, as well as that which is resecreted from pancreatic and biliary secretions, is absorbed in the small bowel (AAP Committee on Nutrition, 2014d). Absorption varies based on the bioavailability of the source and the presence of other minerals in the diet such as iron and copper, which are known to interfere with absorption (Domellof, 2014).

GASTROINTESTINAL FUNCTION OF THE PREMATURE INFANT

Research on the developing fetus has determined that much of the gastrointestinal tract begins to function early in fetal life. Anatomically, the foregut and hindgut are present as early as 4 weeks' gestation, with the intestinal villi appearing at 8 weeks (Mahe, Helmrath, & Shroyer, 2017; Parry, 2017). It is clear, however, that even in the full-term infant, the gastrointestinal tract is inefficient in its ability to propel, absorb, and utilize nutrients and maintain homeostasis during stress.

Developmentally, the issues of the premature infant begin with the inability to suck, swallow, and breathe in a coordinated fashion. This problem places a heavy burden on the caregiver to provide adequate nutrient intake via all artificial methods. Suck, swallow, and breath coordination matures around 32 to 34 weeks' gestation. There are many additional reasons why this coordination can be delayed. For example, it is common to observe late coordination in infants who have cardiorespiratory disease and who are physiologically unstable. Another large group of infants who cannot regulate their own intake is those that remain on assisted ventilation. The sequence of the infant suck, swallow, and breathe pattern has been described as mature when the suck/swallow/respiration has a 1:1:1 to 2:2:2 pattern (Amaizu, Shulman, Schanler, & Lau, 2008). This sequence not only presumes maturity of the infant but also depends on physiologic stability. Nonnutritive sucking has obvious differences from nutritive sucking that make it only one of several indicators of feeding readiness.

The second physiologic issue of the premature is the absence or weakness of the gag and cough reflexes. This challenge increases the risks to premature infants when gastric enteral feedings are used. The risk of aspiration must be considered when the stomach is used for feeding. The assessment for presence of the gag reflex

is easy to do by direct observation while passing a feeding tube. It is nearly impossible to assess the adequacy of the gag reflex in the prevention of aspiration if vomiting or reflux occurs. **Quality and Safety: The risk of aspiration should be considered in all premature infants when started on enteral feeding.** In addition, if the infant actually vomits owing to this challenge, chronic loss of nutrients becomes problematic. Reflux has frequently been linked as a cause of apnea. New research suggests that often they occur together, but it is the apnea that leads to the gastric reflux (Martin, 2017). During an apnea episode, the respiratory neural output is decreased, accompanied by relaxation of the lower esophageal tone, and results in gastroesophageal reflux. On rare occasions, reflux can result in apnea.

The third challenge is the relative relaxation of the lower esophageal sphincter. The purpose of this sphincter is to allow food to pass into the stomach. Inappropriate relaxation may lead to reflux of food back into the esophagus (Margolis & Picoraro, 2017). Inadequate sphincter function is an additional risk factor for all premature infants when orally fed.

Delayed gastric emptying is the fourth physiologic challenge in premature infants. Gastric emptying is relatively delayed in infants. This process is delayed in disease states, and nurses find that milk feedings do not predictably empty in preterm infants or sick term infants. This challenge may be the single limiting factor when the preterm infant is placed on enteral feeds in that little can be done toward feeding progression until stomach emptying occurs. If the stomach emptying remains a limiting factor, it can be bypassed with transpyloric feedings.

Intestinal dysmotility is the fifth major challenge in the premature infant. Clinicians can observe improvement around 30 to 33 weeks' gestation and maturity of motility by 36 weeks' gestation (Margolis & Picoraro, 2017). If there are central nervous system abnormalities, then motility can be adversely affected. If intestinal motility is the limiting factor in the progression of enteral feedings, it should be identified as such before multiple formula changes are made. It is always essential to identify the specific challenge as the causative factor when addressing a plan for the delivery of enteral nutrients.

Incompetence of the ileocecal valve, the sixth challenge, is not plainly assessed by the clinician. This valve acts as a barrier between small and large bowel contents, thus separating bacterial flora as well as regulating the time for the small bowel to absorb nutrients before its contents are delivered to the colon for water absorption. When reflux through this valve occurs, the small bowel is colonized with bacteria. With the presence of undigested nutrients in the small bowel and bacteria proliferation, hydrogen gas is produced. This mechanism is part of one sequence of events hypothesized to lead to NEC (Wilson-Costello, Kliegman, & Fanaroff, 2013).

The seventh and last challenge is the passage of the first meconium stool. Term infants should pass a stool within 48 hours of life (Clark, 1977). Many premature infants will pass their first stool within 48 hours of life, but some premature infants can take up to greater than 1 week of age without problems (Verma & Dhanireddy, 1993). Term infants who have not stooled by 48 hours will need to be monitored and may need to be assessed for gastrointestinal obstruction.

Summary

The premature infant has many developmental and mechanical challenges that make the use of the gastrointestinal tract difficult or impossible. The tract matures with postnatal age and physiologic stability and needs to be reassessed regularly. Feeding assessment needs to be monitored to make changes in feedings as indicated.

PARENTERAL NUTRITION

Indications

PN describes a form of providing nutrients—food and fluid—by an intravenous route other than orally. PN is indicated for very low birth weight (VLBW) infants to supplement the advancement of enteral feedings; infants with congenital abdominal or cardiac anomalies that preclude enteral nutrition; and infants that develop the gastrointestinal illnesses, NEC, short bowel syndrome, or intractable diarrhea requiring bowel rest or limitation of feedings. PN may begin the first day of life to provide hydration, glucose homeostasis, positive nitrogen balance, and normal blood calcium levels. Nutrient concentrations will be advanced as tolerated.

Infants are started on PN on the first day of life when slow feeding advancement is anticipated. Starter PN may be used that contains a set concentration of glucose, protein, and perhaps calcium. The starter PN is available 24/7 and can be infused shortly after birth to infants to promote hydration, glucose homeostasis, and nitrogen balance. Early initiation of PN for the VLBW infant improves nitrogen balance, glucose tolerance, and growth (Poindexter, Langer, Dusick, & Ehrenkranz, 2006; Thureen, Melara, Fennessey, & Hay, 2003; Valentine et al., 2009). Intravenous lipids may be provided on day 1 to provide essential fatty acids and promote nitrogen balance (Vlaardingerbroek et al., 2013). **Quality and Safety: Electrolytes are not indicated on day 1 of age.** Vitamins may not be added to the standard starter PN solutions, as they decrease the shelf life. PN can then be advanced as described in the following sections. Tables 20.1 and 20.2 provide the guidelines for PN. Table 20.3 provides parenteral calculations.

Energy

Energy intakes of 30 to 50 kcal/kg are adequate for nitrogen balance during the first days of life (Denne & Poindexter, 2007). Energy intakes of 90 to 100 kcal/kg are the goal for growth with PN. For enteral feedings, 105 to 130 kcal/kg/day will meet the needs of most premature infants (AAP Committee on Nutrition, 2014c).

Glucose

Glucose homeostasis is an issue for premature infants, and blood levels should be monitored as parenteral glucose loads are advanced to ensure tolerance. Premature infants are at risk for hyperglycemia for many reasons including an excessive glucose load is provided, gluconeogenesis continues in the presence of elevated blood glucose levels, insulin production is decreased, insulin resistance exists, stress, or the development of sepsis (Schanler & Anderson, 2008).

Neonates usually produce glucose at the rate of 3 to 5 mg/kg/minute for the term infant and up to 8 to 9 mg/kg/minute in the ELBW infant (Poindexter & Ehrenkranz, 2015). Glucose tolerance is impaired in the VLBW infant, and starting glucose at less than 6 mg/kg/minute is recommended (AAP Committee on Nutrition, 2014c). Often 4.5 to 6 mg/kg/minute is provided to the premature infant and advanced slowly to a goal of 11 to 12 mg/kg/minute to meet energy needs for growth (AAP Committee on Nutrition, 2014c). Glucose can be advanced by 1 to 2 mg/kg/minute (Carlson & Kavars, 2016). The addition of parenteral protein enhances insulin release and the tolerance of the glucose load (Thureen et al., 2003). By monitoring blood glucose loads, slowly advancing glucose loads, and providing parenteral protein, the need for additional insulin may be avoided. Insulin will decrease hyperglycemia,

TABLE 20.1

GROWING PREMATURE INFANTS—PARENTERAL GUIDELINES: ENERGY, PROTEIN, MINERALS

Nutrient	Unit (kg/day, Except As Noted)
Energy, kcal	90–100
Glucose, mg/kg/minute	11–12
Carbohydrate, g	16–17
Protein, g	2.7–4
Fat, g	3
Calcium, mg	60–80

but it does increase the incidence of hypoglycemia (Alsweiler, Harding, & Bloomfield, 2012). Increased weight gain and increased head circumference growth with decreased linear growth has been reported, which may reflect greater adipose deposition (Alsweiler et al., 2012). Serum glucose levels above 150 mg/dL are defined as hyperglycemia for premature infants (Poindexter & Ehrenkranz, 2015). Decreasing the glucose load is the first step in preventing increases in blood glucose levels. Insulin use is reserved

TABLE 20.2

PEDIATRIC MULTIVITAMIN BY DOSAGE FOR INFANTS

Vitamin	2 mL/kg Infants <2.5 kg	5 mL/day Infants ≥2.5 kg

TABLE 20.3

CALCULATIONS FOR PARENTERAL NUTRITION

Nutrient	Calculations
Dextrose	3.4 kcal/g
Protein	4 kcal/g
20% Lipid	10 kcal/g (which is 9 fat kcal and 1 glycerol kcal) or 2 kcal/mL (1 fat g/5 mL)
GIR mg/kg/min	([mL/kg/day] × [grams glucose/100 mL] × [1,000 mg/g])/1,440 minute/day For example, infant receiving 130 mL/kg/day of 12.5% dextrose ([130 mL/kg/day] × [12.5 g dextrose/100 mL] × [1,000 mg/g])/1,440 GIR = 11.3 mg/kg/minute

GIR, glucose infusion rate.

for infants with persistent blood glucose levels over 200 mg/dL (Poindexter & Ehrenkranz, 2015). The precise blood glucose level used to indicate insulin therapy has not been defined. Tight blood glucose control is not recommended for premature infants because of the increased incidence of hypoglycemia and mortality (Alsweiler et al., 2012; Beardsall et al., 2008).

Premature infants are at risk for hypoglycemia due to poor glycogen stores, impaired gluconeogenesis, increased glucose need with acute illness (sepsis, respiratory distress), maternal therapy with beta-blockers, and hyperinsulinemia commonly seen with infants of diabetic mothers (Burris, 2017). **Emergency Alert: Hypoglycemia will occur when inadequate glucose is provided, glucose is not delivered due to intravenous line infiltration, PN has been rapidly discontinued, or insulin has been administered.**

Protein

Protein may be started at 2 to 3 g/kg/day and results in normal plasma amino acid levels, increased nitrogen balance, and increased protein anabolism (AAP Committee on Nutrition, 2014c; Denne & Poindexter, 2007; Thureen et al., 2003). Early protein intake of 3 g/kg/day is associated with better gain in weight, length, and head circumference at 36 weeks' postmenstrual age, and decreased incidence of head circumference less than the 10th percentile at 22 months corrected age (Poindexter et al., 2006).

Protein is advanced to 3.5 to 4 g/kg/day (AAP Committee on Nutrition, 2014c; van Goudoever, Vlaardingerbroek, van den Akker, de Groof, & van der Schoor, 2014). During the first week of life, blood urea nitrogen (BUN) does not consistently correlate to parenteral protein intake and should not be used to limit protein intake unless renal dysfunction is demonstrated by decreased urine output and elevated serum creatinine (Blanco, Falck, Green, Cornell, & Gong, 2008; Radmacher, Lewis, & Adamkin, 2009; Ridout, Melara, Rottinghaus, & Thureen, 2005). BUN level can reflect hydration status, excessive protein intake, inadequate protein or energy intake, illness, renal function, and hepatic synthesis (Radmacher et al., 2009).

Parenteral protein is provided as amino acids, and the use of the pediatric solutions is recommended. Three pediatric solutions are available in the United States: Aminosyn-PF (ICU-Medical), Premasol (Baxter), and TrophAmine (B. Braun; Poindexter & Ehrenkranz, 2015). These solutions provide a blend of amino acids to produce blood amino acid levels similar to those found with breastfed, term infants, or cord blood levels found with premature infants (Poindexter & Ehrenkranz, 2015). The premature infant's ability to synthesize cysteine, tyrosine, and arginine is limited, so these should be provided in the early diet. Cysteine is not stable in solutions, so it is added as cysteine hydrochloride. The addition of cysteine improves nitrogen balance and increases the acidity of the solution, which allows greater amounts of calcium and phosphorous to be added (Soghier & Brion, 2010).

Lipids

Intravenous lipids are given to provide essential fatty acids and kilocalories. One-half to 1 g of lipids will meet the essential fatty acid requirement of linoleic acid (Poindexter & Ehrenkranz, 2015). Not providing lipids in the first week of life can result in biochemical fatty acid deficiency for premature infants with limited fat stores. Intravenous lipids may be started at 1 to 2 g/kg on day 1 of life and advanced to 3 g/kg/day (AAP Committee on Nutrition, 2014c). Infants who have decreased serum levels of lipoprotein lipase or suffer from metabolic stress may not clear lipids well. Infants most at risk include those who are small for gestational age, suffer from intrauterine growth restriction, are early gestational age, extremely low birth weight, have sepsis, or have received steroids (AAP Committee on Nutrition, 2014c; Choi et al., 2015; Shulman & Phillips, 2003). To promote clearance of the triglycerides in lipids, the lipids should be provided over 24 hours, and 20% emulsions should be given (Poindexter & Ehrenkranz, 2015). The phospholipid emulsifier decreases the clearance of fatty acids, and the concentration of emulsifier is the same in the 10% and 20% emulsions. By using 20% emulsion, less volume and less phospholipid will be given per gram of lipid (5 vs. 10 mL) (AAP Committee on Nutrition, 2014c; Lapillonne, 2014). Serum triglycerides may be monitored, but acceptable levels have not been determined (Neu, 2009). A level less than 200 mg/dL has been suggested (AAP Committee on Nutrition, 2014c).

In the United States, soybean oil emulsions (Intralipid) are available. The soy oil provides the essential fatty acids of linoleic acid (omega-6 fatty acid) and linolenic acid (omega-3 fatty acid). A fish oil emulsion (Omegaven) from Europe has been only available when approval for compassionate use was obtained from the United States Food and Drug Administration (FDA) to treat parenteral nutrition associated liver disease (PNALD; Premkumar, Carter, Hawthorne, King, & Abrams, 2014). As of July 27, 2018, the FDA (n.d.) has approved Omegaven as a new drug to treat pediatric patients with Parenteral Nutrition Associated Cholestasis. Fish oil contains the omega-3 fatty acids, docosahexaenoic acid (DHA), and eicosapentaenoic acid and vitamin E that have anti-inflammatory and antioxidant properties, which may aid in the treatment of PNALD (Hojsak et al., 2016). Fish oil does not contain the phytosterols that are contained in soy oil and have been linked to the development of PNALD (Hojsak et al., 2016). Smoflipid (soy oil, MCTs, olive oil, and fish oil) blend is approved in the United States for adults, and it is used off label for the neonate (Premkumar & Calkins, 2018). Results of studies with the use of Smoflipid for neonates have been mixed with regard to the prevention and treatment of PNALD (Hojsak et al., 2016). Investigations are needed with Smoflipid to demonstrate growth and development for the premature infant (Premkumar & Calkins, 2018).

Carnitine

Carnitine facilitates the transport of long-chain fatty acids into the mitochondria for oxidation. Premature infants have limited carnitine stores and a decreased ability to synthesize carnitine (Clark, Chace, & Spitzer, 2017; Hay, 2008). Human milk and infant formula provide sources of carnitine, while parenteral solutions do not contain carnitine unless added. A dosage of 10 mg/kg/day may be provided for infants receiving only PN for greater than 2 to 3 weeks (AAP Committee on Nutrition, 2014c; Hay et al., 2014).

Fluid and Electrolytes

Premature infants have high and variable fluid needs based on birth weight, gestational age, clinical condition, and the environment in which the infant is nursed (Dell, 2015). **Quality and Safety: Constant monitoring and assessment are indicated to promote normal hydration status.** Monitoring includes body weight, fluid intake, urine output, stool output and other fluid losses, and serum electrolytes (Dell, 2015). A weight loss up to 15% is common in the first week of life (Dell, 2015).

Quality and Safety: Sodium is not added in the first few days of life to allow for the diuresis of the extracellular fluid, but intravenous saline infusions or flushes may be indicated. These sources of sodium must be accounted for when prescribing PN sodium. The usual sodium requirement is 2 to 4 mEq/kg/day. Potassium is not needed on the first day of life, but is added as renal function is established and serum potassium levels become normal. A potassium intake of 2 to 3 mEq/kg/day will usually

meet the needs of the infants (Poindexter & Ehrenkranz, 2015). Chloride may be provided with sodium and potassium. Acetate is indicated when acidosis occurs (Poindexter & Ehrenkranz, 2015). All serum electrolytes require monitoring to ensure normal serum levels.

Calcium, Phosphorus, and Magnesium

Calcium, phosphorus, and magnesium are needed for metabolic management and bone mineralization. Calcium and phosphorus should be provided at a 1 to 1.3/1 molar ratio of calcium to phosphorus to promote normal blood levels and bone mineralization (Carlson & Kavars, 2016). Calcium and phosphorus need to be provided together instead of in alternate-day administrations to avoid urinary mineral wasting or abnormal blood calcium and phosphorus levels (Carlson & Kavars, 2016). Phosphorus is often not included in starter PN solutions. Phosphorus needs to be added to the next order of PN to avoid hypercalcemia and hypophosphatemia (Hair, Chetta, Bruno, Hawthorne, & Abrams, 2016).

Vitamins

Pediatric multivitamin injections are available but are not designed for the premature infant (AAP Committee on Nutrition, 2014c). The dosage schedule is based on the infant's weight and is shown in Table 20.2. At these intakes, adequate amounts of vitamins E and K are provided, low amounts of vitamins A and D are given, and many B vitamins are greater than recommendations (AAP Committee on Nutrition, 2014c). Parenteral vitamins are not available as single vitamins.

Trace Minerals

Trace mineral guidelines are shown in Table 20.1. Trace minerals are available as multimineral packets or as separate minerals. Extra zinc is indicated for infants with intestinal losses and monitoring blood zinc levels may be helpful (Domellof, 2014; Schanler & Anderson, 2008; Shulman, 1989). When cholestasis is present, copper and manganese intakes are decreased due to elimination of these trace minerals in the bile. With restricted copper intake, blood copper levels may need to be monitored to detect copper deficiency (Marquardt, Done, Sandrock, Berdon, & Feldman, 2012). Selenium and chromium intakes are limited with impaired renal function (AAP Committee on Nutrition, 2014c).

ENTERAL NUTRITION

Premature infants have increased nutrient needs to support fetal growth. Table 20.4 provides enteral nutrient guidelines. Enteral feedings are always the goal for the nourishment of premature infants. The infant should be evaluated daily for starting feeds, feed advancement, milk fortification, or vitamin and mineral supplements.

Oral Care With Colostrum

Colostrum from the infant's own mother can be provided on the first day of life to support the infant's oral microbiota development (Gephart & Weller, 2014; Sohn, Kalanetra, Mills, & Underwood, 2016). Colostrum can be provided by syringe or swab into the buccal pouch of the oral cavity. Research is needed to establish dose frequency and duration of oral care (Gephart & Weller, 2014).

Human Milk

The milk of choice for all infants is human milk, and pasteurized donor human milk is recommended as a supplement to the infant's own mother's milk for all premature infants (Eidelman et al., 2012). The human milk diet for the premature infant results in a decreased incidence of mortality, sepsis, NEC, retinopathy of prematurity, and bronchopulmonary dysplasia, improved neurodevelopment, and a quicker time to full enteral feedings with less days of PN needed (Abrams, Schanler, Lee, Rechtman, & the Prolacta Study Group, 2014; Hair, Peluso, et al., 2016; Meinzen-Derr et al., 2009; Schanler, Shulman, & Lau, 1999; Sisk, Lovelady, Dillard, Gruber, & O'Shea, 2007; Sullivan et al., 2010; Vohr et al., 2007).

Pasteurized donor milk needs to be obtained from one of the donor human milk banks or commercial banks to ensure safety

TABLE 20.4

ENTERAL NUTRIENT GUIDELINES FOR GROWING PREMATURE INFANTS (U/KG/DAY)

Nutrient	Amount	Nutrient	Amount
Energy, kcal	105–130	Selenium, mcg	5–10
Protein, g	3.5–4.5	Iodine, mcg	10–55
Carbohydrate, g	10–14	Vitamin A, IU	1,332–3,663
Fat, g	5–7	Vitamin D, IU	200–400[a]
Calcium, mg	150–220	Vitamin E, IU	2.2–11
Phosphorus, mg	75–140	Vitamin K, mcg	4.4–28
Magnesium, mg	7.9–15	Vitamin C, mg	20–55
Sodium, mEq	3–5	Thiamin, mcg	140–300
Potassium, mEq	2–5	Riboflavin, mcg	200–400
Chloride, mEq	3–5	Niacin, mg	1.5–5
Iron, mg	2–4	Vitamin B_6, mcg	50–300
Zinc, mcg	1,000–3,000	Folate, mcg	35–100
Copper, mcg	120–150	Vitamin B_{12}, mcg	0.1–0.8
Chromium, mcg	0.03–2.25	Biotin, mcg	1.7–16.5
Manganese, mcg	1–15	Pantothenic acid, mg	0.5–2.1

[a] Vitamin D intake is per day.

Greer (Eds.), *Pediatric nutrition handbook* (7th ed., pp. 83–121). Elk Grove Village, IL: Author; Koletzko, B., Poindexter, B., & Uauy, R. (2014). Recommended nutrient intake levels for stable, fully enterally fed very low birth weight infants. In B. Koletzko, B. Poindexter, & R. Uauy (Eds.), *Nutritional care of preterm infants scientific basis and practical guidelines* (pp. 297–299). Basel, Switzerland: Karger.

of the product. Donors are screened for infections, medications, drugs, or high-risk activities by history and blood tests. Mothers who would like to donate milk should be referred to one of the banks for proper screening. The Human Milk Banking Association of North America (www.hmbana.org) is a volunteer association that nonprofit Human Milk Banks may be a member of and whose members are required to meet the standards for human milk banking guidelines, set by the association guidelines (AAP Committee on Nutrition, 2014c).

Fortification by a multinutrient fortifier is indicated for VLBW infants to meet their increased nutrient demands. Bovine milk fortifiers are available as powder packets or liquid vials. These fortifiers contain carbohydrate, fat, protein, vitamins, and minerals. Iron supplements will be needed if a low-iron fortifier is used. The bovine fortifiers have been added at 100 mL/kg of human milk intake (Kim et al., 2015; Moya, Sisk, Walsh, & Berseth, 2012). Donor human milk fortifiers contain human milk with concentrated protein and additives of calcium, phosphorus, and zinc. Multivitamins and iron supplements are needed with this fortifier. Donor human milk fortifiers have been added at 40, 60, 100, or 120 mL/kg of human milk intake (Hair, Peluso, et al., 2016; Sullivan et al., 2010). Table 20.5 compares human milks with the fortifiers fed at a standard volume of 150 mL/kg and at the usual milk kilocalorie concentrations.

TABLE 20.5

SELECTIVE NUTRIENT COMPARISON OF HUMAN MILK WITH FORTIFICATION—150 ML/KG

Nutrient	AAP (2014c) and Koletzko, Poindexter, & Uauy (2014) (/kg)	Human Milk (20 kcal/oz)	Human Milk + Liquid Bovine Milk Fortifier (24 kcal/oz)	Human Milk + Donor Milk Fortifier (24 kcal/oz)

The donor milk fortifier is available as 24, 26, 28, and 30 kcal/oz supplements. The 26 kcal/oz fortification is often used to provide more protein and energy to support growth. The 28 and 30 kcal/oz supplements are helpful with infants who are fluid restricted. A pasteurized human milk cream is available to increase the mother's or donor human milk to 20 kcal/oz. This supplement has led to improved weight gain and growth in length (Hair et al., 2014).

Infant Formulas

Premature infant formulas are more nutrient dense than standard infant formulas and contain nutrients in a more easily digested form. Table 20.5 shows a selected nutrient comparison. Premature infant formulas come as 20, 24, and 30 kcal/oz milks. The 20 and 24 kcal/oz milks will meet the needs of most premature infants. The 30 kcal/oz milk is indicated for infants who are fluid restricted. The 30 kcal/oz milk can be mixed with 24 kcal/oz milk at different proportions to make milks greater than 24 kcal/oz. The 24 kcal/oz premature formulas are available as regular and high protein. See Table 20.6 for comparison of formulas fed at a standard volume of 150 mL/kg.

Postdischarge milks are designed for the premature infant at discharge. The nutrient composition is in between the composition of standard and premature infant formulas. Studies on these formulas have been on infants less than 1,800 g birth weight (Carver et al., 2001; Koo & Hockman, 2006; Lucas et al., 2001). Studies have shown both improved growth and poorer growth for premature infants fed postdischarge formula as compared

TABLE 20.6

SELECTIVE NUTRIENT COMPARISON OF INFANT FORMULAS—150 ML/KG

Nutrient	AAP (2014c) and Koletzko et al. (2014) (/kg)	Standard (Term) (20 kcal/oz)	Premature High Protein (24 kcal/oz)	Postdischarge (22 kcal/oz)
Energy, kcal	105–130	101	120	110
Protein, g	3.5–4.5	2.0–2.2	4.0–4.4	3.1–3.2
Calcium, mg	150–220	67–80	201–219	117–134
Iron, mg	2–4	1.5–1.8	2.2	2.0
Zinc, mg	1–3	0.8–1.0	1.8	1.1–1.3

to the term formulas. There have been reports of better growth for infants fed these formulas for 6 to 9 months (Carver et al., 2001; Lucas et al., 2001). Premature infants who are formula fed should be evaluated for these formulas at discharge (AAP Committee on Nutrition, 2014c). A recommendation has been made that the infant's weight for length be consistent at the 25th percentile to discontinue the discharge milks (AAP Committee on Nutrition, 2014b). Premature infants receiving this formula will not require additional vitamins (AAP Committee on Nutrition, 2014c). Infants will receive 2 mg/kg/day of iron on these formulas at normal volume intake. The iron guideline is 2 to 4 mg/kg/day (AAP Committee on Nutrition, 2014c). Additional iron may be provided if needed.

Soy infant formulas are not recommended for premature infants, because they have low mineral and vitamin content (Abrams et al., 2013). The absorption and utilization of nutrients by premature infants is not documented with the currently available soy formulas (AAP Committee on Nutrition, 2014c).

Specialized infant formulas including the protein hydrolysates and free amino acid formulas are used for infants with malabsorption problems such as short gut who do not tolerate human milk. Vitamin or mineral supplementation may be needed with these formulas, as they are not designed to meet the needs of the premature infant.

Feeding Management

Enteral feedings should be considered for all infants. Trophic feedings that are small feedings to feed the gut and do not serve as a major nutrition source are frequently used for infants who are VLBW or clinically stressed. Studies have ranged from 1 to 25 mL/kg/day, and human milk is the milk of choice (AAP Committee on Nutrition, 2014c). Reported benefits of early small feedings include decreased incidence of indirect hyperbilirubinemia, cholestatic jaundice, and metabolic bone disease, increased concentrations of gastric hormones, full feedings achieved more quickly, faster maturation of intestinal motility patterns, increased lactase activity, and reduced intestinal permeability (Berseth, 1992; Dunn, Hulman, Weiner, & Kliegman, 1988; Meetze et al., 1992; Shulman et al., 1998a, 1998b). By meta-analysis, the incidence of NEC was not increased with trophic feedings (Morgan, Bombell, & McGuire, 2013). There is no standard time for the length of trophic feedings as the studies have used different lengths of time for trophic feeding, different days of life to initiate feedings, and different milks. Trophic feedings can be initiated with umbilical catheters in place (Davey, Wagner, Cox, & Kendig, 1994).

Nutritive feedings are often advanced by 10 to 35 mL/kg/day for VLBW infants (Senterre, 2014). One review compared studies that used 15 to 20 mL/kg/day versus 30 to 40 mL/kg/day feeding rate advancement (Oddie, Young, & McGuire, 2017). No difference was reported in the incidence of mortality and NEC between the slow or more rapidly fed feeding groups. The smaller volume rates resulted in longer times to achieve full enteral feeding volumes and a borderline increased incidence of sepsis was noted.

Several investigations report that the implementation of a standardized feeding guideline including the use of human milk in the neonatal intensive care unit (NICU) is associated with a decrease in the incidence of NEC (Nathan et al., 2018; Patole & de Klerk, 2005).

Feeding Method

The feeding method for the infant will depend on the infant's gestational age, weight, clinical condition, and the experience of the nursery nursing staff (AAP Committee on Nutrition, 2014c). The premature infant does not coordinate sucking, swallowing, and breathing until 32 to 34 weeks' gestation. Nasogastric and orogastric feedings are used for infants too young or ill to breastfeed or bottlefeed (AAP Committee on Nutrition, 2014c). Transpyloric feedings are used for infants with persistent gastric residuals or emesis without intestinal pathology present, but research is lacking to support this method for routine feeding of premature infants (AAP Committee on Nutrition, 2014c; Watson & McGuire, 2013). Continuous milk infusion is needed for infants fed via transpyloric feedings, as the intestine has limited compliance (Schanler & Anderson, 2008). Gastrostomy feedings are indicated for infants with congenital anomalies or neurologic impairment (Sapsford & Smith, 2016).

Continuous and bolus feedings are used with gastric feedings, and there have been numerous studies suggesting that each method is best (Premji & Chessell, 2011). One concern with continuous infusion is the reported loss of fat and calcium (Rogers, Hicks, Hamzo, Veit, & Abrams, 2010).

Feeding Assessment

Feeding assessment is indicated for premature infants because they do not tolerate feedings well and are at risk for illness. Consensus is lacking on the criteria to evaluate feeding tolerance (Schanler & Anderson, 2008). Clinical assessment may include physical examination of the abdomen, the presence or absence of bowel sounds and their quality, gastric residuals, emesis, and changes in stool (Schanler & Anderson, 2008). Gastric residuals may be due to immature intestinal motor activity, feeding intolerance, NEC, or intestinal obstruction (Anderson, 2012). Residuals are frequently noted before feedings are initiated and during trophic feedings. These residuals may be ignored if no other signs of feeding tolerance or illness are present. Residuals at 50% or greater of a bolus feeding or 1.5 times an hourly rate for continuous feedings had been suggested to evaluate the infant for intolerance/illness (Schanler et al., 1999). A residual volume of 2 to 3 mL/kg per feed has also been used (Schanler et al., 1999). Shulman, Ou, and Smith (2011) reported that the premature infant's gastric residuals do not correlate with the obtaining of full gavage feedings. A recent study suggests that the use of selective gastric residual check instead of routine checking is linked to the achievement of full enteral feedings sooner without an increased incidence of NEC (Riskin et al., 2017). The bilious residual may be due to the feeding tube moving into the intestine, bile reflux into the stomach, or intestinal obstruction (Schanler & Anderson, 2008).

The tonicity of the abdomen should be evaluated. An increase in tonicity will occur with air swallowing, feeding intolerance, infrequent stooling, or NEC. Visual loop of bowel may indicate illness. A workup for obstruction, NEC, and sepsis may be indicated, especially if other signs of illness are present, such as an increased number of apneas and bradycardias, an increased number of desaturation events, or the presence of lethargy (Schanler & Anderson, 2008).

Blood in the residual or stool is a worry and needs to be evaluated. Etiologies include a sign of illness, feeding-tube irritation of the intestine, anal fissure, or blood swallowed during delivery (Anderson, 2012).

GROWTH AND GROWTH CHARTS

Daily weights, weekly lengths, and weekly head circumferences should be obtained, and weekly measures should be plotted on intrauterine growth curves. The intrauterine charts are developed from the birth weight, birth length, and birth head

circumferences from a large group of infants (Fenton & Kim, 2013; Olsen, Groveman, Lawson, Clark, & Zemel, 2010). Premature infants can be plotted against these charts to assess how their growth compares to the goal of fetal growth (AAP Committee on Nutrition, 2014c). The Fenton chart is a fetal infant chart that goes from 22 weeks' gestation to 50 weeks' postmenstrual age (Fenton & Kim, 2013). The fetal portion is based on infants from Germany, the United States, Italy, Australia, Scotland, and Canada and the 40 to 50 weeks is taken from the World Health Organization (WHO) growth charts. The Fenton chart is electronically available from the website (http://ucalgary.ca/fenton; Figure 20.1A and 20.1B).

(B)

FIGURE 20.1 (*continued*)

The Olsen chart is based on a large, racially diverse sample from the United States and goes from 23 to 41 weeks' gestation (Olsen et al., 2010). The gender-based charts include weight, length, and head circumference. These charts may be downloaded for individual patient use at the following: www.aap.org/en-us/Documents/GrowthCurves.pdf

Once the premature infant reaches 40 weeks' postmenstrual age, the WHO growth charts can be used to assess catch-up growth (Grummer-Strawn, Reinold, & Krebs, 2010). These charts are based on the growth of infants who were predominantly breastfed for the first year of life and represent ideal growth. The WHO growth charts can be downloaded from https://www.cdc.gov/growthcharts/who_charts.htm.

The INTERGROWTH-21st Project produced birth classification charts for the very preterm infants of 24 to 33 weeks' gestation and another chart from 24 to 42 weeks' gestation

TABLE 20.7

GROWTH GOALS

Weight gain	15–20 g/kg/day for infants <2 kg 20–30 g/kg/day for infants >2 kg 15–20 g/kg/day for infants 23–36 weeks' gestation
Length gain	0.7–1 cm/week
Head circumference	0.7–1 cm/week

Sources: Data from Anderson, D. M. (2012). Nutrition for premature infants. In P. Q. Samour & K. King (Eds.), *Pediatric nutrition* (4th ed., pp. 53–69). Sudbury, MA: Jones & Bartlett; Fenton, T. R., Anderson, D., Groh-Wargo, S., Hoyos, A., Ehrenkranz, R. A., & Senterre, T. (2018). An attempt to standardize the calculation of growth velocity of preterm infants—evaluation of practical bedside methods. *Journal of Pediatrics, 196*, 77–83. doi:10.1016/j.jpeds.2017.10.005

(Villar et al., 2016). Postnatal growth charts for premature infants were developed based on the growth of 201 infants born between 26 and before 37 weeks' gestation who were followed to 64 weeks' gestation (Villar et al., 2015). Infants were born in eight countries (Brazil, China, India, Italy, Kenya, Oman, United Kingdom, and the United States). Growth charts can be downloaded from https://intergrowth21.tghn.org

During the first week of life, premature infants can lose up to 15% of their birth weight, which is the loss of extracellular fluid (Dell, 2015). Goals for weekly rate of gain are given in Table 20.7. Since weights are obtained daily, a weekly rate can be calculated daily. Closely monitoring growth is important to ensure the best growth for these high-risk infants and their future development. Extremely low birth weight (ELBW) infants have demonstrated improved neurologic outcomes and growth at 18 to 22 months of corrected age when their growth rates in the nursery were greater than 18 g/kg/day for weight or 0.9 cm/week for head circumference (Ehrenkranz et al., 2006). When poor growth occurs, assessment of the etiology should be explored. Poor growth may be related to medical conditions or nutrition management. Medical issues that may contribute to poor growth include acidosis, hyponatremia, increased work of breathing, cold stress, anemia, infections, and the use of steroids (Anderson, 2012). These conditions require treatment before nutrition can be fully utilized. Issues related to nutrition are given in Box 20.1.

Biochemical Indices

Serum electrolytes, glucose, BUN, and creatinine will be monitored daily or more frequently if abnormal during the first week of life. Once stable, these serum values will be obtained once to twice a week for the infant receiving PN or diuretics, or for the infant who has an abnormal value (Anderson, 2012). While on PN, serum conjugated bilirubin and serum alanine aminotransferase (ALT, serum glutamic-pyruvic transaminase) will be drawn weekly starting at 2 weeks of PN therapy to detect PNALD. Serum phosphorus and alkaline phosphatase activity levels are drawn on infants at risk for osteopenia, which includes VLBW infants and infants with a prolonged course of PN or milk intake of formula not designed for premature infants. If alkaline phosphatase activity levels reach 800 IL/L, a radiograph of the wrist/knees (rickets survey) can be used to document metabolic bone disease of prematurity (Mitchell et al., 2009). Hematocrit and hemoglobin levels are obtained as needed (Schanler & Anderson, 2008).

Box 20.1

CONSIDERATIONS FOR POOR GROWTH—NUTRITION FACTORS

Feeding intolerance—abnormal stools, excessive residuals, or emesis

Full nutrition just achieved that meets nutrient guidelines

Nutrition Not Optimized

Parenteral nutrient concentrations not adequate

Incorrect amount of fortifier added to human milk

Incorrect calculations

Human Milk

Continuous infusions will lead to fat losses

Use of foremilk that is low in fat and kilocalories

Ordered Diet Not Received

Infant not able to consume adequate milk and is not supplemented with gavage feedings

Feedings held for tests

Volume of feedings ordered per kg has not kept up with weight gain

Nutrition Solution Not Prepared Correctly, or Incorrect Milk Feeding Provided

Intravenous fluid administration has been held to provide medication or blood

Ostomy output is excessive, so parenteral fluids will need to be increased and enteral feedings decreased to meet infant's nutrition needs

Source: Data from Anderson, D. M. (2012). Nutrition for premature infants. In P. Q. Samour & K. King (Eds.), *Pediatric nutrition* (4th ed., pp. 53–69). Sudbury, MA: Jones & Bartlett.

POSTDISCHARGE NUTRITION

Prior to discharge, the infant's nutritional status should be assessed for present growth status, feeding volume allowed and infant's actual volume intake, presence of any abnormal serum levels that require treatment, and the mother's desire to breastfeed. Depending on the infant's history regarding osteopenia, ability to nurse, and fluid allowance, the infant's feeding recommendation will be individualized. The infant should be placed on the discharge diet prior to discharge to assess growth and feeding tolerance to the plan. Parents need to demonstrate their ability to feed their infant, administer supplements, and prepare special milks if indicated.

The breastfed infant will need multivitamins and iron to provide vitamin D at 400 IU/day and iron at 2 to 4 mg/kg/day (Abrams et al., 2013; AAP Committee on Nutrition, 2014c). Infants may require formula supplementation to meet needs for growth, and two to three feeds per day may be provided to increase nutrient intake. By using bottle feedings of formula instead of formula powder added to expressed human milk, the mother can actually breastfeed her infant and possibly avoid bacterial contamination of powder infant formulas. Nutrient intake can be greater with the use of two to three bottles of discharge formula than making all the human milk 22 kcal/oz with discharge formula powder.

Mothers should be referred to lactation consultation for postdischarge support.

In a recent study, discharged premature infants were for 12 weeks fed their mothers' milk, which was fortified with bovine human milk fortifier for half of their feedings, and the other half of feedings were breastfed or expressed milk (O'Connor et al., 2008). This group of infants was compared to a group of premature infants fed their mothers' milk supplemented with iron and vitamins. At 12 weeks postdischarge, the bovine human milk fortified group was longer and had greater head circumferences. At 1 year corrected age, the infants who received the bovine fortified milk were longer, had greater head circumferences, and had greater weights (Aimone et al., 2009). No differences were noted in development at 18 months corrected age (Aimone et al., 2009).

The postdischarge formula may be used for infants who are not breastfed. Vitamin and iron supplements are generally not indicated (AAP Committee on Nutrition, 2014c).

Infants should be referred to the Special Supplemental Nutrition Program for Women, Infants and Children (WIC) and to the early children intervention programs. A medical home should provide the necessary assessment and management of the infant's nutrition needs related to growth and normal development.

SUMMARY

This chapter has reviewed the basic physiology of digestion and the importance of adequate neonatal nutrition for positive growth and development. Different routes of feeding as well as different formulas and breast milk feeding have been discussed. Neonatal nutrition is a challenge but sets the course for a lifetime of health.

CASE STUDY

■ **Identification of the Problem.** Premature infant not gaining weight

■ **Assessment: History and Physical Examination.** The premature female infant was delivered by spontaneous vaginal delivery following one course of antenatal steroids to a 30-year-old G2 P1 woman. The infant required oxygen at birth and was weaned to room air by 12 hours of age. Sepsis workup was completed for preterm delivery, and results were negative. Her Apgar scores were 6^{1}, 8^{5}. She was placed in a humidified incubator. She developed hyperbilirubinemia and was treated with phototherapy from day 2 to 5 of age.

She was born at 28 weeks' gestation with a birth weight of 900 g, length of 37 cm, and head circumference of 26.5 cm. She is classified as appropriate for gestational age, for her birth weight is between the 10th and 50th percentile. Her length and head circumference are between the 10th and 50th percentile. She is now 21 days of age and 31 weeks' postmenstrual age. She regained birth weight by 2 weeks of age and now weighs 950 g, which is below the 10th percentile. Her rate of weight gain this past week was 8 g/kg/day. Her length is 38 cm, and her head circumference is 27 cm.

She was started on PN day 1 of age at 80 mL/kg/day providing 45 kcal/kg, GIR of 5.2 mg/kg/minute of glucose, 2.4 g protein/kg, and 1 g/kg of lipid. Mom's milk was started day 2 of age at 20 mL/kg/day and provided for 3 days as trophic feedings before advancing milk by 20 mL/kg/day to a volume of 150 mL/kg/day. PN was advanced to meet guidelines and was discontinued when 120 mL/kg of human milk feedings were achieved on day 9 of age. Today's diet order is human milk fortified with bovine human milk fortifier to 24 kcal/oz at 150 mL/kg/d by a continuous infusion of 5.5 mL/hour by a nasogastric tube. Diet should provide 120 kcal/kg and 3.9 g protein/kg/day.

Physical examination is normal.

■ **Differential Diagnoses**

- Infant needs formula supplement
- Infant not receiving diet as ordered
- Infant has increased requirements
- Diet order incorrect
- Infant just achieved appropriate diet
- Infant has abnormal labs
- Infant has a low temperature
- Infant is not tolerating feedings
- Documented weight incorrect
- Inadequate intake

■ **Diagnostic Tests**

- Check incubator temperature management: baby was on manual control mode at 35°C
- Recheck diet orders: at 5.5 mL/hour the infant is only receiving 140 mL/kg/day; order placed in the computer was for 22 kcal/oz milk instead of 24 kcal/oz; infant actually receiving 102 kcal/kg and 2.5 g protein/kg/day
- Review infant's flow sheet for output: no emesis, no stool for 2 days, abdomen soft
- Review vitals: yesterday the baby's skin temperature was 35°C
- Review labs: labs from 3 days ago: serum sodium 140 mEq/dL, potassium 5 mEq/dL, chloride 108 mEq/dL, BUN 12 mg/dL, hemoglobin 11 g/dL, and hematocrit 33%
- Review daily weight: slow, steady increase of 10 g/day; no large increases or decreases; weight is probably accurate

■ **Working Diagnosis**

- Infant cold stressed
- Inadequate nutrition intake

■ **Development of Management Plan**

- Change incubator temperature management to servo control mode at 37°C
- Change feeding order to 6 mL/hour to provide 150 mL/kg
- Order 24 kcal/oz human milk with bovine human milk fortifier

Implementation and Evaluation of Effectiveness

- Feeding order changed today
- Daily weights followed closely for the next 3 to 5 days to ensure good weight gain; weight gain since change in diet is 13 g/kg/day
- Change to bolus feedings to increase nutrient delivery; weight gain is now 15 g/kg/day; length and head circumference have increased 1 cm each this past week
- Once infant demonstrated good weight gain, incubator temperature management changed back to manual control mode

■ **Outcome.** Growth can occur when infant's temperature is maintained. Human milk fortified with bovine human milk fortifier to 24 kcal/oz at 150 mL/kg given as a bolus meets infant's nutritional needs. Infant's growth is appropriate on human milk fortified to 24 kcal/oz diet at 150 mL/kg.

EVIDENCE-BASED PRACTICE BOX

Cysteine is an amino acid that is a precursor for taurine and glutathione, or cysteine may go directly into protein formation (Soghier & Brion, 2010). Cysteine may be semi-essential for the premature infant due to the infant's limited ability to synthesize cysteine from methionine (Poindexter & Ehrenkranz, 2015). Cystathionase, the enzyme responsible for cysteine synthesis, has been reported at low concentrations in the livers of premature infants, yet the extrahepatic tissue may contain adequate amounts of this enzyme. Not all studies with premature infants report limited ability to synthesize cysteine (Poindexter & Ehrenkranz, 2015). Early studies did not show a positive nitrogen balance with the addition of cysteine, which may have been related to the low level of energy provided and the lack of tyrosine in some amino acid solutions (Soghier & Brion, 2010).

A recent meta-analysis compared six studies that were randomized control trials or quasi-randomized trials (Soghier & Brion, 2010). Five studies added cysteine to cysteine-free PN and compared nitrogen balance to those infants not receiving cysteine. The sixth study added *N*-acetylcysteine (cysteine precursor) to a parenteral solution containing a little cysteine. Four of the five studies with the addition of cysteine reported a positive nitrogen balance, which was significant by meta-analysis. The *N*-acetylcysteine additive did not improve nitrogen balance. Growth was only examined by two studies that reported no gains in growth. No studies reported mortality or morbidity information. Four trials examined serum cysteine levels that were significantly elevated as compared to infants not receiving cysteine. More research is needed to explore the effects of parenteral cysteine on infant growth to include changes in weight, length, head circumference, body composition, and bone mineralization (Soghier & Brion, 2010). The addition of cysteine hydrochloride increases the acidity of the parenteral solutions and permits more calcium and phosphorus to be added without precipitation of the minerals occurring (Poindexter & Ehrenkranz, 2015; Schanler & Anderson, 2008; Soghier & Brion, 2010). The addition of the cysteine hydrochloride may result in metabolic acidosis in the infant, and acetate may be added to the parenteral solution to correct or prevent the acidosis.

QUALITY AND SAFETY

- Safe tube administration of parenteral nutrition, enteral nutrition, and medications is the goal. Traditionally, one connector has been available for use with all types of tubing and has allowed the accidental connection of an enteral system to an intravenous system (Litman, Smith, & Mainland, 2018). Sentinel events of severe patient injury or death have been reported (The Joint Commission, 2014).
- Globally, new standards for small bore connectors, ISO 80369, have been developed for different clinical applications that are physically incompatible with each other and should prevent the infusion of the fluid to an incorrect site. The standards were developed with The International Organization for Standardization, the Association for Advancement of Medical Instrumentation, clinicians, manufacturers, and regulators, including the U.S. Food and Drug Administration (The Joint Commission, 2014; Litman et al., 2018).
- New connectors have new problems. The ENFit® tube has a male end and the syringe has a female end, which is reverse of the previously used feeding-tube connectors. The female end syringe has more dead space, which can lead to medication overdose if not cleared properly (Guenter & Lyman, 2016). The male end or port of the feeding tube needs to be cleaned appropriately. Residual milk or medications can be a source of bacterial growth and infection (Guenter & Lyman, 2016).
- To plan transition, Global Enteral Device Supplier Association (GEDSA) is a resource. GEDSA is a nonprofit trade association (www.StayConnected.org).
- To change to new connectors, the following is needed (Guenter & Lyman, 2016; The Joint Commission, 2014):
  - Available supplies of approved connectors
  - Commitment of the facility's chief of operations
  - Education of staff on how to use connectors
  - Quality indicators in place for assessment
  - Communication established with individual device manufacturer

PARENT VOICES

Heather Tanner

Nutrition Story in the NICU: Born at 30 weeks, our son lacked the breathe, suck, swallow reflex. He needed a central line and an NG/OG tube to deliver his nutrition. Feeding very preterm babies involves the risk of NEC. It was something I had never heard of. During the course of his 10-week stay, our son had pneumatosis twice. His feeding schedule was changed, but I wasn't told why—pneumatosis. Informing parents about common conditions like ROP, NEC, PDA . . . helps us as parents understand why his treatment was changed. Later, at 6.5 months our son developed pneumatosis again. Only this time, he was at a specialty children's hospital and they recognized it right away and told us first thing. He received evidence-based treatment, including being made NPO for 7 days and the use of parenteral nutrition during gut rest. It gave us clearer answers as to how we could advocate for his nutrition while in the hospital. Parents want to be informed decision makers. Educate them and allow their participation in the course of care. Without education, they cannot advocate.

The baby had feeding issues that required rehospitalization: Our son was born at 30 weeks diagnosed with an in utero midgut volvulus. He had abdominal surgery and lost two-thirds of his small intestine. He was on parenteral nutrition for such a short time while tube feeds were steadily increased. At 4 weeks, he was reconnected and weaned slowly off tube feeding to bottle feeding. At discharge, he drank all his feeds and was sent home without any enteral feeding necessary. At that time, he had no diagnosis other than being premature. He struggled to feed at home orally until he was 6.5 months. He had lost so much intestine in the NICU, his remaining gut was not functioning properly. He was admitted to a children's specialty hospital and finally diagnosed with intestinal failure, short bowel syndrome, and failure to thrive (FTT). What he needed from the very beginning was intestinal rehabilitation. Losing intestine requires careful nutritional monitoring long term. We had no idea that he suffered with malabsorption until 6.5 months. He was so depleted, even though he was finishing full feeds. Fed does not equal nourished.

Ali Dunn

My twins were born at 28 weeks. Much too small and fragile to eat by mouth, let alone to latch and suck. So, like many preemie mommas, I started pumping. The NICU staff that were caring for my twins stressed the importance of every drop of breast milk. The lactation consultant and the sweet NICU nurses cheered over any amount of milk I was able to express. Pumping made me feel like a mother. When I had very little to give my preemies in the NICU, pumping for them gave me a sense of purpose. When I had very little control over their care and their health, I felt empowered by my ability to provide something they needed. When I felt like my body had failed in growing my babies to term, I felt it redeemed itself by producing the perfect food for them. So, even though it was hard and time-consuming, I never gave up. And 43 days after they were born, I was able to feed my babies a bottle for the first time. The encouragement of the NICU nurses was very important in being able to establish and maintain a pumping routine that continued long after my twins left the NICU.

Deborah A. Discenza

I woke up in my postpartum room, foggy from the birth the night before. As I stared at the breast pump at the foot of my bed, I told my husband that I needed to start pumping breast milk. I figured it was one way I could help my daughter in the NICU. So not knowing what we were doing, we used the pump. It was almost comical, doing a lot of things wrong. But I pumped a little bit of yellowish liquid and told my husband to go ask the nurse if this was useful or if it should be thrown out. A few minutes later, he came back with a big grin on his face. "They are rushing it down to the NICU right now," he said. "She called it 'liquid gold.'" I was excited to have done this for my daughter and worked hard over the next couple of weeks to increase my supply. At one point, I attempted breastfeeding and did not succeed assuming that Becky would not be able to do it. I kept pumping. No one talked to me, no one educated me, I did this all on my own with a few visits to the lactation consultant for advice on pumping. At one point, I noticed the team added preemie formula to my daughter's intake. I was surprised, wondering why. My husband told me that they said it was to give our daughter the extra calories. I assumed they knew best. But then, a short time later as we started down the path toward discharge, I had a nurse bully me, saying that she breastfed her kids so I should do the same with my daughter. I was stunned and felt totally attacked. I did not know what to say, or how to defend myself. I was mad. I later called the medical director and filed a complaint and said I wanted that nurse to never care for my child again. To me, upon reflection, that nurse had no idea what I had done to care for my daughter. That should have counted. That moment of bullying should have been a moment of praise for what I had done on my own and to gently educate me, without bullying, on keeping breastfeeding ongoing as I got home with my daughter. What she did was wrong and I know that now. I did an incredible job for my daughter, who, as it turned out, had a major feeding issue that lasted until she was 12 years old when we got her into feeding therapy. Never ever assume that you know what a preemie parent is going through with pumping, breastfeeding, and more if you have been in the NICU yourself.

CHAPTER 21

Neonatal and Infant Pharmacology

Beth Shields

INTRODUCTION

Neonatal and infant pharmacology requires an understanding of the impact of immature organ systems on pharmacologic drug response. Research in pharmacology has lagged behind the enhanced survival rates for sick newborn infants of all birth weight subgroups. Optimal understanding of infant pharmacology is of vital importance, as the average number of drugs administered to premature infants weighing less than 1,000 g ranges from 15 to 20. Rapidly changing physiologic characteristics contribute to unpredictable dose response relationships. It is not always appropriate to determine neonatal dosing through extrapolation from childhood or adult studies. Few well-controlled trials or road maps outline the use of medications in this high-risk patient population (Ku & Smith, 2015). This chapter reviews the basic principles of neonatal and infant drug therapy. Discussion of the nursing implications is included.

DRUG THERAPY: EVIDENCE-BASED MEDICINE

The individualization of drug therapy in premature and term infants is essential because of rapid and variable maturation of all physiologic and pharmacologic processes. The phrase *therapeutic orphans*, coined many years ago, stresses the relative lack of drug safety and efficacy information in the pediatric population (Shirkey, 1968). Fifty years later, published literature on the use of medications in the neonatal population remains sparse. Conducting well-controlled trials is difficult, and therapeutic regimens are often supported by case reports, small studies, or past experiences of a particular clinician (Laforgia et al., 2014; Neville et al., 2014; O'Hara, Wright, & Schneider, 2015). Advances in clinical medicine, study design, and sampling and analytical techniques are assisting in moving the concept of therapeutic orphans to a more historical perspective (Ku & Smith, 2015; Reed, 2011).

PEDIATRIC LABELING

The Food and Drug Administration (FDA) approves the initial labeling of medication. Since the early 1970s, over 75% of medications approved have no pediatric indications. However, once a drug is FDA approved, it may be prescribed by a licensed provider for any indication deemed appropriate. Most infants in the neonatal intensive care unit (NICU) are prescribed at least one medication that is used off-label, that is, the use of a medication in any age group for a condition that is not included in the medical labeling (Krzyaniak, 2016; Laforgia et al., 2014; Rumore, 2016). Over the past 10 years, increased federal legislation has been passed to encourage the collection of safety, pharmacogenomic, pharmacokinetic, and pharmacodynamic data to aid in pediatric-specific labeling for medications. The Best Pharmaceuticals for Children Act (BPCA) and the Pediatric Research Equity Act (PREA) are important pieces of legislation with an emphasis on therapeutic areas and specific pediatric subpopulations. The passage of BPCA and PREA has resulted in more than 500 pediatric labeling changes. BPCA provides financial incentive to drug companies that test medications with a remaining patent in pediatric patients. PREA requires pediatric testing for new drug applications (Neville et al., 2014; Wharton, 2014). A list of drugs with a current exclusivity provision is outlined in the Pediatric Exclusivity Provision Best Pharmaceuticals for Children Act List of Pediatric Therapeutic Needs, June 2017, www.bpca.nichd.nih.gov.

PEDIATRIC DOSING METHODS

Infants are not small adults, and, as such, cannot simply be given a portion of an adult dose. Drug dosages must be prescribed for each infant on an individual basis. Their unique pharmacotherapeutic requirements predispose this population to errors in individual dosage calculations. Guidelines have been developed in an attempt to prevent dosing errors in this diverse patient population (Riley & Meyers, 2016; The Joint Commission, 2008). Several dosing methods have been used to calculate the optimal drug dose for both preterm and full-term infants. Pediatric dosage handbooks employ dosing methods based on age, body weight, and body surface area (BSA) as well as pharmacokinetic dosing (Reed, 2011; Taketomo, 2017; www.neofax.micromedexsolutions.com). Each method provides only an estimate, and dosages must constantly be reevaluated and adjusted according to clinical efficacy and toxicity. To calculate a drug dosage based on age or body weight, it is important to understand the meaning of terms commonly used in the pediatric population (Table 21.1). Because of the ease of calculation, dosing based on weight (mg/kg/dose or mg/kg/d) is the most common method. Weight-based dosing is expressed as a dosage range versus an absolute dose. In recent years, there has been an increased emphasis on the use of metric units only for weight-based dosing

TABLE 21.1

PEDIATRIC DRUG DOSING: AGE/WEIGHT TERMINOLOGY

Term	Definition
Gestational Age	By dates: number of weeks from the onset of mother's last menstrual period until birth
	By examination: assessment of gestation (time from conception until birth) by a physical and neuromuscular examination
Low birth weight	Birth weight of <2,500 g
Very low birth weight	Birth weight of <1,500 g
Small for gestational age	Birth weight <10th percentile for GA
Appropriate for gestational age	Birth weight between 10th and 90th percentile for GA
Large for gestational age	Birth weight >90th percentile for GA
PNA	Chronologic age (in days) after birth
Postconceptional age	GA at birth plus PNA
Preterm infant	<37 completed weeks' GA at birth
Full-term infant	38–42 weeks' GA at birth
Neonate	0–28 days PNA
Infant	1 month to 1 year of age
Child	1–12 years of age

GA, gestational age; PNA, postnatal age.

Source: Adapted from Engle, W. A., Blackmon, L. R., Batton, D. G., Bell, E. F., Denson, S. E., Kanto, W. P., Jr., . . . Stark, A. (2004). Age terminology during the perinatal period. *Pediatrics, 114*(5), 1326–1364 (reaffirmed July 2014). doi:10.1542/peds.2004-1915.

(American Academy of Pediatrics [APA], 2017, Institute for Safe Medication Practices [ISMP], 2017). Dosing based on BSA (mg/m^2/dose) requires both a weight and height to accurately assess an infant's BSA. Lack of appropriate pediatric dosing information makes this method impractical, and it has not been shown to increase accuracy or safety (O'Hara et al., 2015).

ADVERSE DRUG EFFECTS

Like the elderly, infants are prone to adverse drug effects (ADEs). An ADE is an injury (both preventable and not preventable) that results from the use of a drug (Allegaert & van den Anker, 2014). Unique drug delivery factors, including individual dosage calculations, preparation of small doses from concentrated commercial solutions, multiple commercial concentrations, and slow intravenous (IV) rates, make neonates more prone to ADEs. Neonates are particularly predisposed to ADEs because of immature metabolic and excretion pathways as well as potential drug exposures during pregnancy, delivery, and lactation. In some instances, medications used for years have come into question. For example, acetaminophen with codeine products, commonly prescribed for pain in the postpartum period, have recently been shown to have the potential for central nervous system (CNS) depression and apnea in a cohort of breastfed infants. In addition, a strengthened warning against the use of tramadol in breastfed women had been added by the FDA. Such adverse effects may be related to unique metabolic pathways in some mothers (FDA, 2017).

Several classic neonatal ADEs have occurred because of lack of knowledge or forethought regarding developmental differences between neonates and older infants and children. Examples of such ADEs include chloramphenicol-associated gray baby syndrome, neonatal gasping syndrome, and numerous case reports of ADEs caused by absorption of drugs through the skin of newborn infants (Robertson, 2003a, 2003b). The enhanced survival of extremely premature infants must raise awareness concerning the increased risk of serious short- and long-term adverse effects of neonatal drug therapy. Data support an increased incidence of neurodevelopmental delay and cerebral palsy in infants treated with high-dose systemic dexamethasone in an attempt to decrease the incidence of bronchopulmonary dysplasia (Watterberg et al., 2010).

MEDICATION ERRORS

Medication errors in the neonatal population are an iatrogenic cause of ADEs. Such errors have been noted at a rate three to eight times that published in the adult patient population. It is estimated that one fifth to one half of all medication errors in a pediatric hospital occur in the NICU (Poole & Carleton, 2008). Medication errors can occur at any stage of the medication use process. Errors are particularly high risk in the neonatal population due to the need for multiple dosing calculations; wide weight ranges; immature renal, hepatic, and immune pathways; and extended lengths of stay. Prevention strategies include collaborative efforts of a multidisciplinary healthcare team, use of computerized physician order entry systems, barcode medication administration, standardization of doses and medication concentrations, and provision of measuring tools that more closely match prescribed volumes for oral medications (APA, 2017; The Joint Commission, 2008; Krzyaniak, 2016, Krzyaniak & Bajorek, 2016; Paul et al., 2015; Rinke et al., 2014; Rostas, 2017; Sauberan, Dean, Fiedelak, & Abraham, 2010; Yin et al., 2017). Each year, the ISMP lists best practices, many of which are pertinent to the NICU (Box 21.1).

The use of standard IV and oral compound concentrations is suggested by both ISMP and The Vermont Oxford Network (VON) for the neonatal patient population (Phillips, 2011). In addition, Standardize for Safety is an initiative to reduce IV and oral liquid medication errors and to standardize concentrations through transitions of care (American Society of Health System Pharmacists, 2016).

Inadvertent overdoses of heparin gained a great deal of press in neonatal literature. Heparin is on the ISMP high-alert list and can cause considerable patient harm. In addition to the issues outlined earlier, stocking of look-alike products with 100- or 1,000-fold strength differences has contributed to these errors (Monagle, Studdert, & Newall, 2011; Riley & Meyers, 2016). Changes in packaging have resulted from the medication errors with heparin.

Box 21.1

2018–2019 TARGETED MEDICATION SAFETY BEST PRACTICES FOR HOSPITALS

Measure and document patient weights in metric units, kilograms, only.

- Modify scales to lock out the ability to weigh in pounds (lb)
- Have conversion charts that convert from kilograms (or grams for pediatrics) to lb near all scales so parents can be told the weight in lb
- Ensure computer information system screens (i.e., infusion pumps) prompt for weights in metric units only

Purchase oral liquid devices (oral syringes) that display only the metric scale (mL).

- For discharge, provide parents with oral syringes that measure liquid volumes in mL
- Ensure that oral liquid medications not commercially available in unit dose packaging are dispensed by the pharmacy in an oral or ENFit syringe

Segregate and differentiate neuromuscular blocking agents from other medications.

- Standardize storage and clearly label with auxiliary stickers

Administer high-alert intravenous (IV) medication infusions via a programmable infusion pump utilizing dose error-reduction software.

- Smart pumps with drug libraries

When compounding sterile preparations, perform independent verifications to ensure appropriate volumes of medications and diluents (volume) prior to addition to the final container.

- At a minimum, perform this verification for all high-alert medications, as well as pediatric and neonatal preparations

Note: Focus on those recommendations pertinent to the neonatal patient population.

Source: Institute for Safe Medication Practices. (2017). Targeted medication safety best practices for hospitals. Retrieved from https://www.ismp.org/guidelines/best-practices-hospitals

Many institutions now use checklists for medications, requiring two people to review the orders and what is to be administered before the medication is actually given. Medication Administration Records and physician order entry systems now have built-in checks and balances for drug incompatibilities and wrong dosages. A required system override is necessary in order to dispense a drug that is not considered within a safe range. That being said, many institutions have not used these electronic systems, and systems are only as good as the information that is included in the database.

DEVELOPMENTAL PHARMACOKINETICS

Pharmacokinetics is the study of a drug concentration versus time, and encompasses the four major processes of absorption, distribution, metabolism, and elimination (ADME) of a drug and its metabolites in the body. Developmental pharmacokinetics—or the change in the ADME of drugs with organ maturation—is a well-known phenomenon (Figure 21.1). To fully comprehend the ADME of drugs, pharmacokinetic terminology must be applied. Standard pharmacokinetic terminology is used when describing the ADME of medications (Table 21.2). In addition to the pharmacokinetics of a drug, the pharmacodynamics of a particular medication is also important. Pharmacodynamics is the relationship between the pharmacokinetics of a drug and its therapeutic or toxic effects in a specific patient. Pediatric drug-dosing regimens are influenced by both the effect of the body on a drug (pharmacokinetics) and the effect of a drug on the body (pharmacodynamics). Data support age-dependent differences in the interaction of a drug and its receptors, ultimately resulting in an altered pharmacodynamic response (Kearns et al., 2003).

Absorption

Absorption refers to the translocation of a drug from the site of administration into the systemic circulation. With the exception of the IV route, all other routes of administration require a drug to cross membranes in order to reach the systemic circulation and exert its pharmacologic effects. Bioavailability is the pharmacokinetic term that has been used to describe the extent to which a drug enters the systemic circulation (Soldin & Soldin, 2002). Drugs administered via the IV route are 100% bioavailable and delivered directly to the bloodstream. Drug absorption depends on the physiochemical properties of the drug—including molecular weight, degree of ionization, lipid solubility, and drug formulation characteristics. In addition, patient-dependent factors, many of which are age related, affect drug absorption (Johnson, 2011; Kearns et al., 2003).

Medications are administered to infants via many routes including oral (PO), IV, intramuscular (IM), intraosseous (IO), percutaneous, intranasal, rectal, intratracheal, and inhalation. There has been an increased use of intranasal administration in older infants for procedural sedation and refractory seizures, as well as cases where IV access is difficult. Parenteral administration (IV) of drugs is important when a rapid response is desired or clinical status precludes oral absorption. Muscle tone, muscle mass, and regional blood flow to the area influence absorption of medications from an IM injection. Neonates, particularly premature neonates, may have significantly decreased muscle mass, as muscle mass is directly proportional to an infant's gestational age (GA; Kearns et al., 2003). The IM injection of a medication may result in a delay in peak serum concentrations due to poor or erratic absorption. Medications commonly administered to neonates via the IM route include vitamin K, ampicillin, and gentamicin.

Absorption from the gastrointestinal tract depends on factors including gastric acidity, gastric emptying time, bacterial colonization of the gastrointestinal tract, intestinal transit time, biliary and pancreatic function, and the type of infant milk diet (Johnson, 2011; Kearns et al., 2003; O'Hara et al., 2015). The maturation of gastric pH differs in preterm versus term infants and seems to correlate with postnatal age rather than postconceptional age. The gastric pH at birth approaches 6 to 8 because of the presence of residual amniotic fluid, falls to approximately 1.5 to 3 several hours after birth, and then slowly increases over the next 10 days in term infants. The lack of gastric acid output early in postnatal life is called relative achlorhydria. Gastric pH will reach adult values by 2 years of age (Woo, 2004). Gastric pH affects drug ionization and drug absorption. A more basic environment (higher gastric pH) will decrease the absorption of acidic drugs (i.e., phenytoin, phenobarbital) and favor the oral absorption of more basic or acid-labile drugs (i.e., ampicillin, penicillin, and erythromycin).

Most drugs are absorbed in the small intestine. Therefore, gastric emptying time will play an important role in both the rate and

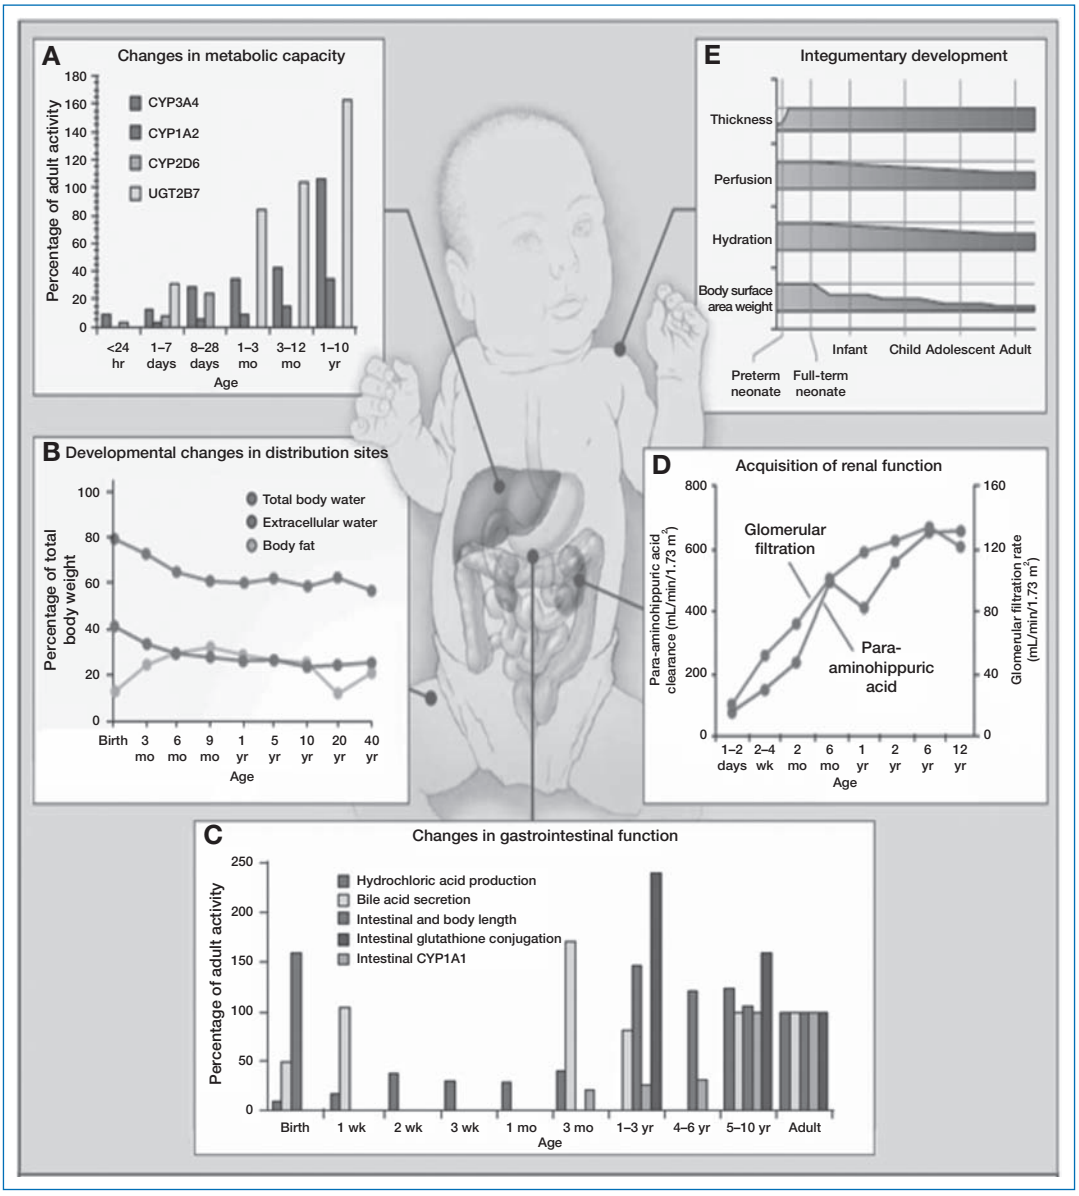

FIGURE 21.1 Age-dependent changes in both the structure and function of the gastrointestinal tract.

Source: Adapted from Kearns, G. L., Abdel-Rahman, S. M., Alander, S. W., Blowey, D. L., Leeder, J. S., & Kauffman, R. E. (2003). Developmental pharmacology—Drug disposition, action, and therapy in infants and children. *New England Journal of Medicine, 349*(12), 1157–1167. doi:10.1056/NEJMra035092.

extent of oral drug absorption. Gastric emptying time is delayed in the neonatal patient, especially in the premature infant. Gastric emptying may be prolonged up to 6 to 8 hours and may not attain adult values until 6 to 8 months of age. Oral absorption may also be delayed in the neonate because of decreased intestinal transit time and activity of pancreatic enzymes as well as low concentrations of intraluminal bile acids (Kearns et al., 2003; Woo, 2004).

Percutaneous absorption or absorption through the skin depends on skin integrity, blood flow to the skin, thickness of the epidermal layer (i.e., stratum corneum), skin hydration, and the ratio of surface area per kilogram of body weight (BSA-to-weight ratio). Percutaneous absorption may be increased substantially in newborn infants because of an underdeveloped stratum corneum, smaller amounts of subcutaneous fat, and increased skin hydration. Maturation of premature skin is related to postnatal age, and the attainment of an epidermal layer similar to that of a full-term neonate occurs within 3 weeks of postnatal life.

The greater the BSA to weight ratio, the greater the absorption of a drug is on a per-kilogram basis with topical medications. The ratio of a newborn's skin to BSA is approximately three times that of an adult. Systemic toxicity has been described in neonates after the administration of topical iodine, hexachlorophene, salicylic acid, epinephrine, and corticosteroids (O'Hara et al., 2015; Woo, 2004). The rectal mucosa may serve as a site of drug absorption in neonates who are unable to take medications by mouth, and in whom rapid IV access cannot be achieved. Rectal absorption depends on regional blood flow, retention of the drug in the rectum, and chemical properties of the drug. The rectal route of administration results in less efficient absorption when compared to the oral route, and in many instances higher mg/kg doses may be required. Medications commonly administered via the rectal route in infants include acetaminophen, diazepam, and sodium polystyrene sulfonate.

Distribution

Once a medication has reached the bloodstream, it will distribute among various organs, fluids, and tissues. The distribution of drugs within the body is influenced by many factors, including

TABLE 21.2

PHARMACOKINETIC TERMINOLOGY

Pharmacokinetic Term	Abbreviation	Definition
Bioavailability	F	The extent to which a drug enters the systemic circulation
Volume of distribution	Vd	The relation between the distribution amount of drug in the body and the measured plasma concentration
Clearance	Cl	The ability of eliminating organs to remove a drug from the blood or plasma
Elimination half-life	$t_{1/2s}$	The time required for half the amount of drug present in the blood to disappear
Steady-state concentration	Cpss	A concentration at which the rate of drug administration is equal to the rate of drug elimination

Source: Adapted from Soldin, O. P., & Soldin, S. J. (2002). Review: Therapeutic drug monitoring in pediatrics. *Therapeutic Drug Monitoring, 24*(1), 1–8. doi:10.1097/00007691-200202000-00001

total body water, total body fat, plasma and tissue binding, membrane permeability, and the infant's hemodynamic status. Drugs that are hydrophilic mainly distribute into body water, while lipophilic drugs preferentially distribute into fat. The pharmacokinetic term used to describe the relation between the amount of drug in the body and the measured plasma concentration is the apparent volume of distribution (Vd) (Johnson, 2011).

Total body water can be divided into intracellular and extracellular spaces. At birth, a full-term neonate is approximately 80% water, with 45% as extracellular and 35% as intracellular fluid. By 1 year of age, a child is approximately 60% water, with 20% extracellular and 40% intracellular fluid (Kearns et al., 2003) (Figure 21.1). Body fat is approximately 1% of the total body composition of a premature infant at 29 weeks' GA, increases to approximately 15% at term, and is 25% of total body composition between 1 and 2 years of age. Water-soluble medications have a much higher volume of distribution in neonates than in adults; therefore, neonatal dosing is higher on a per-kilogram basis (i.e., gentamicin, vancomycin). Fat-soluble medications have a much smaller distribution volume in a neonate than in an adult. Neonatal dosing of medications that are fat soluble is lower on a per-kilogram basis (Kearns et al., 2003; Woo, 2004).

Several physiologic variables can produce both quantitative and qualitative differences in plasma and tissue binding of drugs. In general, neonatal plasma protein binding of drugs is decreased in comparison to adults. The decrease in plasma protein binding in neonates is a result of several factors, including the decreased formation of plasma proteins by the immature neonatal liver. Albumin is the major drug-binding protein in plasma and binds primarily to acidic drugs (i.e., phenobarbital, phenytoin). A lower plasma pH may decrease protein binding of acidic drugs, and the presence of endogenous substances may compete for protein-binding sites. Endogenous substances in the neonate include free fatty acids and bilirubin, as well as transplacentally acquired interfering substances such as hormones and pharmacologic agents. Reduction in protein binding of drugs leads to an increase in the unbound or active component of the drug (Kearns et al., 2003; O'Hara et al., 2015).

Metabolism

Metabolism of drugs is necessary for both drug activity and clearance. Drug metabolism is influenced by genetic factors (pharmacogenomics), age, and the activity of drug-metabolizing enzymes. Most drugs are fat soluble and require biotransformation into more water-soluble substances before elimination from the body. This process of biotransformation occurs mainly in the liver, and produces active as well as inactive metabolites.

The two main types of drug metabolism are phase I (nonsynthetic) and phase II (synthetic) reactions. Phase I reactions include oxidation, reduction, methylation, hydrolysis, and hydroxylation. The cytochrome P450 mixed-function oxidase system is responsible for most phase I reactions. Phase II reactions include conjugation with glycine, glucuronic acid, and sulfate. Phase I reactions appear to mature more rapidly, meeting or exceeding adult capacity by 6 months of age.

Phase II reactions reach adult levels in children by 3 to 4 years of age. Maturation of these enzymatic pathways will affect neonatal metabolism of medications and thereby affect the clinical response to medications (Figure 21.1). **Emergency Alert: Examples of drug toxicity in neonates with immature metabolic pathways include the gray baby syndrome, caused by decreased capacity to glucuronidate chloramphenicol, as well as neonatal gasping syndrome, which results from the decreased capacity of infants to glycinate benzyl alcohol.** Benzyl alcohol is a preservative found in multidose medications and flush solutions (O'Hara et al., 2015; Robertson, 2003a).

Neonates may use different pathways to metabolize drugs than older infants and children use. These pathways may result in a modified pharmacologic response to medications. For example, neonates are not able to metabolize morphine adequately to its 6-glucuronide metabolite, a metabolite that is 20 times more active than morphine as an analgesic. Theophylline, a drug used for the treatment of apnea of prematurity, presents another example of altered metabolic pathways. Theophylline is oxidized to inactive components in adults but is *N*-methylated to caffeine, a pharmacologically active agent in the neonate.

Maturation of hepatic enzymes may also be influenced by prenatal or postnatal exposure to enzyme-inducing (i.e., phenobarbital, phenytoin, rifampin) or enzyme-inhibiting (i.e., erythromycin) agents. One drug may alter the metabolism of another medication, thereby increasing or decreasing effectiveness, creating toxicity, or producing subtherapeutic levels. Drug activity may also be interfered with by concurrent disease states. Interferences such as these are referred to as drug–disease state interactions (Kearns et al., 2003).

Elimination

Systemic clearance (Cl) is the ability of the eliminating organs (kidney, liver, lung, skin) to remove a drug from the blood or plasma. Drugs and their metabolites are primarily eliminated by the kidneys. The principal renal mechanisms responsible for drug excretion include glomerular filtration, tubular secretion, and

tubular reabsorption, all of which are immature at birth. Overall renal function increases with age, although as with hepatic metabolism, the maturation rate of individual physiologic functions varies (Figure 21.1). Glomerular filtration matures several months before tubular secretion; tubular reabsorption is the last to mature. The glomerular filtration is directly proportional to GA after 34 weeks' gestation. The increase in glomerular filtration after birth depends on postconceptional age and is influenced by increased cardiac output, decreased peripheral vascular resistance, increased mean arterial pressure, and increased surface area for filtration. The clinical importance of increases in glomerular filtration becomes apparent when one examines drugs excreted primarily by filtration such as gentamicin and vancomycin. Tubular reabsorption and secretion are also decreased in the neonate. Ampicillin, a drug commonly used in the neonatal population, undergoes tubular secretion (Woo, 2004).

The elimination half-life ($t_{1/2}$) of a drug refers to the time it takes for half the amount of drug in the blood to be eliminated. The volume of distribution and clearance of a medication are determinants of a drug's half-life. Half-life is an important factor in determining the appropriate interval between drug doses. Drugs with a long half-life are given at less frequent dosing intervals, whereas those with shorter half-lives may need to be given via a continuous infusion (Johnson, 2011).

With constant drug dosing, the elimination half-life will determine the time to reach the so-called steady-state serum concentration. Steady state refers to the time at which the rate of drug administration equals the rate of drug elimination. When drug concentrations are monitored in clinical practice, steady-state concentrations should be obtained. Steady-state concentrations are reached in approximately five half-lives. This factor explains the rationale for administering a loading dose for medications with long half-lives. A loading dose is a single dose of a medication that is used to rapidly attain a serum concentration and therefore the desired clinical effect. A loading dose produces a higher circulating concentration earlier in the therapeutic course as opposed to waiting five half-lives. In neonates, loading doses are commonly administered for caffeine, phenobarbital, phenytoin, digoxin, and levetiracetam (Johnson, 2011).

THERAPEUTIC DRUG MONITORING

Therapeutic drug monitoring (TDM) is the use of serum drug concentrations and pharmacokinetic and pharmacodynamic principles to regulate drug dosages. TDM is of particular importance in the neonatal population, which may under- or overrespond to the usual dosing regimens. Additional unique considerations in the neonate include the precise delivery of very small doses and volumes of medications, the availability of blood for measurement of drug concentrations, interference of endogenous substances with drug assays, frequent changes in neonatal pharmacokinetic parameters, and the extrapolation of therapeutic serum concentrations from adult data to the neonatal population (Fullas, Padomek, Thieman, & Van Gorp, 2011; Johnson, 2011; Touw, Westerman, & Sprij, 2009).

TDM is used for drugs in which a correlation between the measured plasma concentration and drug efficacy or toxicity exists. Drugs with narrow therapeutic indexes are ideal candidates for TDM. A drug exhibits a narrow therapeutic index if the plasma concentration required for therapeutic effects is relatively close to the concentration known to produce toxicity. Drugs for which TDM is used in the neonatal population include caffeine, phenobarbital, phenytoin, levetiracetam, gentamicin, tobramycin, amikacin, vancomycin, and digoxin. TDM allows the clinician to aim for a therapeutic range, which is usually safe and effective, with minimal drug toxicity.

With the exception of drugs administered via a continuous infusion, drug concentrations in the plasma are not static. The time of blood sampling relative to the time of drug administration is of utmost importance. For some medications, both trough and peak concentrations are monitored, whereas with other medications it is routine to monitor trough concentrations. Obtaining levels once a patient achieves steady-state concentrations provides the most accurate information with regard to drug efficacy or toxicity. Patients with altered organ function or rapidly changing clinical status may require closer monitoring of serum concentrations than do other patients.

Certain medications such as phenytoin are highly plasma protein–bound. For these medications, two types of assays are available: total and free serum concentrations. Free levels indicate the amount of free, unbound drug that is available to exert its effects on target tissues. When free phenytoin serum assays are not available, caution must be used in the interpretation of total serum concentrations. Levels may be falsely interpreted as low when the actual amount of active drug is adequate or toxic (Soldin & Soldin, 2002).

FETAL AND INFANT EXPOSURE TO MATERNAL MEDICATIONS

Fetal Exposure

Approximately 90% of women take one medication during pregnancy, with 70% taking at least one prescription medication. Over the last 30 years, the use of prescription medications during the first trimester has increased over 60%. Virtually any medication or substance given to the mother, either intentionally or inadvertently, can cross the placental membrane (Pernia & DeMaagd, 2016).

The amount of drug that passes into the fetal circulation depends on several factors, including the molecular weight, protein binding, lipid solubility, ionization of the drug, maternal drug serum concentrations, and integrity of the placental barrier. Physiologic changes during pregnancy can affect absorption, distribution, metabolism, and excretion of medications in the mother. Pregnancy results in many pharmacokinetic changes in the mother, including a greater volume of distribution, additional fat stores, and lower protein binding. Fetal exposure to a medication may lead to deleterious effects on the exposed fetus or may result in minimal or no adverse outcomes.

In recent years, the FDA has worked to collect and include more comprehensive information on drug labels regarding the drug's effects during pregnancy, including revisions to the product labeling (Food and Drug Administration, 2014). The Pregnancy and Lactation Labeling Rule (PLLR) or Final Rule, introduced by the FDA in 2014, addresses shortcomings in the current pregnancy category labeling, and strives to better convey the risks versus benefits during pregnancy and lactation. Over-the-counter (OTC) medications are not affected by the PLLR. The Females and Males of Reproductive Potential, new to the labeling, includes information about the need for pregnancy testing, contraception, and information about infertility as it relates to the drug. This information can assist healthcare providers in counseling pregnant women and nursing mothers who need to take medications (Pernia & DeMaagd, 2016; Ramoz & Patel-Shori, 2014). The PLLR removes pregnancy letter categories—A, B, C, D, and X—and requires the label to be updated when information becomes outdated (Table 21.3).

PLLR labeling changes came into effect on June 30, 2015. Prescription drugs and biologic products submitted after June 30,

TABLE 21.3

COMPARISON OF PREGNANCY AND LACTATION RULES 1979 VERSUS 2015

Rule in Phase Out	New Pregnancy and Lactation Label Ruling
Pregnancy risk categories (A, B, D, X) assigned	Pregnancy risk letter categories eliminated
Pregnancy Labor and delivery	Combined to form one section: Pregnancy • Pregnancy exposure registry • Risk summary • Clinical considerations and data
Nursing mothers	Lactation • Risk summary • Clinical considerations and data
	Females and males of reproductive potential • Pregnancy testing • Contraception and infertility

Source: Adapted from Pernia, S., & DeMaagd, G. (2016). The new pregnancy and lactation labeling rule. *Pharmacy and Therapeutics, 41*(11), 713–715. Retrieved from https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5083079

2015, will use the new format immediately, while labeling for prescription drugs approved on or after June 30, 2001, will be phased in gradually (Table 21.4).

Lactation Exposure

An often-overlooked source of exposure to medications is transfer from the maternal circulation into breast milk. The lactation subsection provides information about using a drug while breastfeeding, such as the amount of drug in breast milk and potential effects on the breastfed infant. The safety and potential risks to the nursing infant must be considered during maternal drug use. Maternal drug use includes OTC drugs, prescription drugs, illicit drugs, and herbal products. The pH and size of a drug molecule, protein-binding properties, lipid and water solubility, and diffusion rate will all influence the quantity of drug that passes from maternal serum into breast milk. Additional considerations include the time the medication is taken in relation to the period of nursing, the dose and frequency of a medication, the pharmacokinetics of the drug, the length of nursing, and the amount of milk ingested. Published literature outlines guidelines regarding the transfer of drugs and chemicals into human milk. Only a small number of medications, including radiopharmaceuticals and chemotherapeutic medications, are considered contraindicated in the breastfeeding infant (Eidelman et al., 2012).

MEDICATION ADMINISTRATION

Once an appropriate drug dosage is established, the optimal route and method of drug administration are also of utmost importance. Many commercially available dosage forms are not suitable for use in the pediatric patient population. Developmental considerations with regard to medication administration must also be considered.

TABLE 21.4

IMPLEMENTATION SCHEDULE OF THE NEW PLLR

Applications for Drug or Biological Product	Compliance Requirements
Approved prior to June 30, 2001	Remove pregnancy category within 3 years of the effective date of PLLR. No other compliance requirements.
Approved June 30, 2001–June 29, 2002	3 years after the effective date of PLLR
Approved June 30, 2002–June 29, 2005	5 years after the effective date of PLLR
Approved June 30, 2005–June 29, 2007	3 years after the effective date of PLLR
Approved June 30, 2007–June 30, 2015	4 years after the effective date of PLLR
Pending approval on June 30, 2015	4 years after the effective date of PLLR or at time of approval, whichever is later
Submitted on or after June 30, 2015	Time of submission

PLLR, Pregnancy and Lactation Labeling Rule.

Oral Administration

Many drugs prescribed for infants and children are not available in oral dosage forms that can be easily administered to small infants and children. Oral medications are administered to an infant via a nipple, dropper, syringe, or feeding tube. The preferred dosage form for infants is an alcohol-free, sugar-free, dye-free, and low-osmolality liquid preparation. However, orally administered medications may only be commercially available as tablets or capsules or as concentrated oral solutions or suspensions. **Quality and Safety: High-osmolality substances administered to the neonate have been associated with many adverse effects, including the development of necrotizing enterocolitis and decreased intestinal transit time.**

Preparation and delivery of small therapeutic doses from concentrated commercial oral solutions may be difficult. Alteration (dilution or compounding) of an adult dosage form raises issues regarding compatibility, stability, and the risk for medication errors. Commonly prescribed oral medications that are not commercially available in an appropriate liquid formulation include hydrocortisone, captopril, ursodiol, and spironolactone. Oral medications may also contain silent or inactive ingredients that supply the "delivery system" of the drug or serve to flavor, sweeten, and preserve the drug. Such inert ingredients may be harmless in adults but may, when administered frequently to neonates, result in toxicity (Mennella & Beauchamp, 2008; Robertson, 2003b). **Emergency Alert: An additional safety concern in the sick neonate is the inadvertent connection between an enteral feeding system and a nonenteral system such as an IV catheter (Box 21.2).**

Box 21.2

GLOBAL STANDARD (80369) TO REDUCE RISK OF TUBING MISCONNECTIONS: ENFIT

Approximately 10 years ago, an international group of manufacturers, clinicians, and regulators began collaborating with the International Organization of Standardization (ISO) and the Association for the Advancement of Medical Instrumentation (AAMI) to develop a new connector (ISO 80369 enteral and gastric design standards) to limit the ability to insert male connectors into female feeding ports; this initiative reverses the orientation of these oral connections.

The new standards will reduce the risk of connectors for two unrelated patient delivery systems being physically misconnected (Institute for Safe Medication Practices 2015; Skog, 2016). Enteral (feeding) Luer connections have been noted to have the highest rate of misconnections. California is the only state that required compliance by 2017, but other states are expected to follow behind. The Global Enteral Device Supplier Association (GEDSA) has launched a "Stay Connected" campaign to encourage participation in this medication safety initiative. Healthcare organizations must plan for a transition in the supply chain and train healthcare providers.

The federally registered trademark name for these new oral connections is ENFit. These new standards address dose accuracy with specific considerations for small doses in the neonatal population. Syringe sizes of 5 mL or less require ENFit Low Dose Tip Syringe design.

Source: Institute for Safe Medication Practices. (2015). *ENFit enteral devices are on their way...Important safety considerations for hospitals*. Retrieved from http://www.ismp.org/newsletters/acutecare/showarticle.aspx?id=105

Intravenous Administration

The most effective means of rapid drug delivery in a critically ill neonate is IV administration. As with oral medications, small doses and delivery volumes complicate the delivery of IV medications. Furthermore, IV medication delivery is often delayed, prolonged, or incomplete in the neonatal patient. A distal drug delivery site and slow infusion rates delay IV drug delivery. A major impact of delayed drug delivery is the potential for subtherapeutic plasma concentrations or even clinical failure with some medications. This is particularly important for medications that may require TDM. In addition, touch contamination, or the wrong delivery route or method, in the extremely vulnerable premature infants makes the use of closed IV systems of utmost importance. Central-line bundle initiatives have been instituted in many institutions in an effort to reduce central line–associated bloodstream infections (CLABSI; Taylor, McDonald, & Tan, 2015).

Several techniques are currently used to administer parenteral medications in the neonatal population and include IV push, IM, and use of smart infusion pumps. The infusion device, IV tubing, a container holding the medication (i.e., syringe, IV bag), dead space at injection ports, and IV in-line filters will affect drug delivery. Patient-specific factors such as body position and vascular occlusion may also affect IV drug delivery (Harding, 2011).

Administration of medications using the IV push method allows rapid drug delivery, but is not appropriate for many medications. Drug delivery with a smart IV infusion pump and microbore tubing is the preferred method of IV drug administration in the neonatal population. A syringe pump allows absolute control over the rate of drug delivery with minimal IV fluid volume, at a rate that is independent of the primary IV rate. Microbore tubing allows the use of minimal volumes of flush solution. In addition to intermittent medications, continuous infusion medications such as pressors and inotropes may be administered via a syringe pump. Smart pumps incorporate computer technology, allowing the use of drug libraries, standard drug concentrations, and sophisticated checks, including soft- and hard-dosing limits. A potential disadvantage of syringe pumps, in particular the smart pumps, is the capital expense required to purchase the pump (Harding, 2011).

Many of the problems that plague commercially available oral medications can also be found in commercial IV medications. IV medications may be available in concentrations that prohibit accurate measurement and administration of small neonatal doses. Use of standard parenteral concentrations in the neonatal population is highly recommended to decrease medication errors as well as continuity of medication therapy through transitions of care (http://ismp.org/newsletters/acutecare/showarticle.aspx?id=105). Continued work in standardizing concentration among all pediatric patients is ongoing, with final recommendations coming for all pediatric patients in the coming years. In selection of parenteral medications, not only drug concentration but also preservatives and other ingredients in the parenteral preparation are factors. Benzyl alcohol is a common preservative added to parenteral drug products. Severe toxicity has been reported in neonates after the use of flush solutions that contain benzyl alcohol. Whenever possible, preservative-free parenteral products should be used in the neonatal population for the first 2 months of life.

The osmolality of a drug solution is an important delivery factor. Tissue irritation or pain at the injection site can occur when a drug solution with an osmolality significantly different from that of the serum (275–295 mOsm/kg) is administered intravenously. As a point of reference, the osmolality of dextrose 10% in water, an IV solution used commonly in the newborn infant, is 505 mOsm/kg. Infiltration of a hypotonic or hypertonic solution can cause trauma and necrosis of the injection site (Beall, Mulholland, & Gephart, 2013; Murphy, Gilmour, & Coombs, 2017; Ramasethu, 2004).

Premature infants typically have fluid restrictions as well as limited IV access, and the question of IV drug compatibilities often comes into play. Drug compatibility involves the question of both physical (visual) and chemical (nonvisual) compatibilities. IV drug compatibility is not clear-cut. This is true because of the influence of alterations in drug concentration, order of drug infusion, pH, and temperature. For these reasons, reference books and articles may provide conflicting information with regard to drug compatibilities. Two drugs are physically incompatible when turbidity, cloudiness, or a precipitate is formed after two or more drugs are mixed together. A physical incompatibility results when calcium gluconate and sodium bicarbonate–containing or phosphorus-containing solutions are mixed in the same IV solution or IV tubing. Chemical incompatibility implies a loss of potency or formation of a toxic byproduct when two or more substances are mixed. Epinephrine and sodium bicarbonate are chemically incompatible when co-infused (Taketomo, 2017; Trissel, 2016).

Extravasation and infiltration are used interchangeably in the literature; both terms reflect a leakage of IV fluid or medication out of a vein and into surrounding tissues (Gil, Shah, Suarez, & Weiss, 2017; Ramasethu, 2004). Extravasation in neonates with circulatory compromise can lead to significant morbidity, functional impairment, or cosmetic defects. Many medications (i.e., potassium, calcium, parenteral nutrition, and dopamine) that are incorporated into the drug regimens of patients in the NICU are

capable of causing tissue damage if extravasation occurs. The use of small or superficial venous access sites in areas that are difficult to immobilize should be avoided for administration of these agents unless absolutely necessary. Particularly tenuous sites include areas surrounding tendons, nerves, or arteries or near the face and forehead. The degree of cellular injury is often directly related to the physiochemical characteristics of the infusant—including osmolarity, pH, molecular weight, volume and location, and mechanical compression due to trapped fluid in tissues (Gil et al., 2017).

The treatment of extravasation injuries that result from infiltration of medications and IV solutions is controversial. Many infiltrates resolve spontaneously following the removal of the IV catheter. Treatment involves the use of specific antidotes and may be based on the staging of the infiltrate. Three possible antidotes—hyaluronidase, phentolamine, and topical nitroglycerin paste—have been studied most extensively in the neonatal population. The mechanism by which IV fluids and medications cause tissue necrosis varies, and optimal treatment choices vary with each extravasated agent (Gil et al., 2017; Ramasethu, 2004; Thigpen, 2007; Table 21.5).

Intraosseous Administration

Intraosseous placement, medication administration directly into the marrow of a bone, may be a viable alternative for parenteral drug delivery in neonates. This route of administration may be considered when IV access cannot be readily obtained. Use of intraosseous access is widely accepted in the pediatric population during resuscitation efforts. A recent study examined the use of intraosseous medication administration as opposed to umbilical venous cannulation (UVC) in a simulated neonatal resuscitation in the delivery room. Intraosseous access was faster and was not perceived as more technically difficult in this simulated trial. Intraosseous medication administration may be a viable alternative to UVC placement in certain neonatal resuscitations (Rajani, Chitkara, Oehlert, & Halamek, 2011).

Intranasal Administration

Intranasal delivery allows use of the highly vascularized nasal mucosa and olfactory tissue to facilitate the rapid transport of specific medications into the bloodstream and brain. The onset of intranasal administration approaches that of parenteral medication delivery. In addition to the ease of administration, the fact that no needle stick is involved makes this an attractive medication delivery modality. Key factors to the intranasal administration of medications include the use of both nares to increase available surface area for drug absorption and the use of concentrated medications (Milesi et al., 2017; Wolfe & Braude, 2010).

TABLE 21.5

EXTRAVASATION TREATMENT

Extravasated Drug/Fluid	Treatment
Parenteral nutrition	Topical nitroglycerin, hyaluronidase
Calcium	Topical nitroglycerin, hyaluronidase
Dopamine	Phentolamine, topical nitroglycerin
Dobutamine	Phentolamine
Epinephrine	Phentolamine

Source: Adapted from Ramasethu, J. (2004). Pharmacology review: Prevention and management of extravasation injuries in neonates. *NeoReviews, 5,* 491–497. doi:10.1542/neo.5-11-e491

Aerosol Administration

The use of aerosolized medications in the neonatal setting has increased with the resurgence of bronchopulmonary dysplasia, the increased prevalence of pulmonary hypertension, and to assist in pharmacologic medication management in infants with no IV access. The rationale for aerosol medication delivery includes direct delivery to the target organ (lungs) with decreased systemic ADEs (Sahni & Phelps, 2011). An example of an aerosolized medication is prostacyclin for pulmonary hypertension treatment in neonates.

Overall, the therapeutic efficacy of aerosolized medications depends on the delivery of an adequate dose of medication to the target sites within the lung. The primary factors that influence lung deposition include particle size, mode of assisted ventilation, inhaler device and placement, and age of the infant. The available methods to aerosolize medications in the neonate include nebulization either intermittently or continuously or a metered-dose inhaler (MDI) with a spacing device. Studies have revealed conflicting results with regard to the optimal method and efficacy of aerosol drug delivery in the neonate, including systems for mechanically ventilated infants. Those infants on oscillatory ventilation present further unique medication delivery challenges (Mazela & Polin, 2011).

Medication Administration in Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is a highly technical and invasive technique used to treat cardiorespiratory failure when conventional means and technologies fail. ECMO is used for a variety of indications in the neonatal population, including those with persistent pulmonary hypertension, meconium aspiration, sepsis, respiratory distress syndrome, pneumonia, congenital diaphragmatic hernia, and in postoperative congenital heart disease patients. Patients who undergo ECMO receive on average more than 10 different medications, including antibiotics, sedatives, analgesics, inotropes, diuretics, antiepileptics, and medications that are used to maintain the ECMO circuit. Varying pharmacokinetics may be observed, depending on the actual site of injection. There is substantial variability between individual circuits. In general, larger volumes of distribution and decreased drug clearance are observed.

Medications may be administered to ECMO patients either into the ECMO circuit before or after the filter or directly into the patient. Distribution and delivery of medication are more consistent when drugs are injected after the filter. Administration into this site places the patient at risk for development of air emboli, and administration of medications should be done with great caution. Medications injected directly into the reservoir or before the filter usually result in a prolonged time of actual drug delivery to the patient and incomplete drug administration. A large part of the ECMO circuit consists of disposable polyvinyl chloride or silicone tubing of varying length, oxygenators, and centrifugal pumps. The amounts of tubing and other components contribute to a large surface area with the potential for drug binding, particularly for highly lipophilic medications. Therefore, increased doses may be required initially when these medications are used or when the circuit is changed or primed with blood or crystalloid during ECMO therapy (Lonabaugh, Lunsford, Fang, & Kaufman, 2017; Wildschut, Allegaert, Ahsman, Mathot, & Tibboel, 2010).

Interpretation of pharmacokinetic parameters in this type of patient is often difficult because of the influences of the site of injection, flow rate of the ECMO circuit, and clinical status and organ function of the patient. Gentamicin and vancomycin are two antibiotics that are commonly administered to infants on ECMO. Pharmacokinetics for these agents vary, not only with the ECMO circuit but also with the clinical status of the infant—including altered renal function in a sick infant. In addition, pharmacokinetics was found to vary with the infant's GA, postnatal age, and weight. Peak effect for these patients is often delayed, thus resulting in false interpretation of serum peak levels for aminoglycoside antibiotics (Wildschut et al., 2010).

MEDICATION SHORTAGES

In 2011, the White House focused legislation to curb drug shortages of life-sustaining or supporting medications. Such medications are those whose discontinuation could have life-threatening consequences, including medications used to treat specific neonatal conditions. The focus of drug shortages also targets those drug companies that voluntarily choose to discontinue a medication, which then may lead to a national drug shortage. Companies are to notify the FDA 6 months in advance of their intent to discontinue production of such a medication.

Despite this legislation, the United States has experienced both an increased number and duration of medication shortages over the past decade. ISMP has noted that 6% of adverse outcomes with drug shortages occur when a pharmacy attempts to compound a strength of a medication that is no longer available (Lau, Khazanie, Rowe, & Fauman, 2016). This can be extremely problematic in the neonatal population.

The neonatal population has seen the impact of such national shortages over the past several years. Parenteral electrolytes including sodium, potassium, and calcium salts have led to restricted use of such agents based on availability. In addition, restrictions in parenteral nutrition solutions of essential trace macronutrients including pediatric amino acid formulations and multivitamins may have long-term consequences for the growth and development of infants. Some institutions find themselves with a shortage of parenteral vitamin K, an agent used routinely to prevent hemorrhagic disease of the newborn (Traynor, 2011; Ventola, 2011).

SUMMARY

The individualization of drug therapy is critical in the neonatal population. The neonatal population presents a unique challenge with regard to both medication dosing and administration. Drug dosing on a mg/kg basis is the most common method because of the ease of calculation. A lack of large, well-controlled trials in this unique patient population results in drug dosing based on extrapolation from the adult literature or anecdotal experience. Furthermore, developmental pharmacokinetics—or the change in ADME of drugs—creates a population whose drug dosing is constantly changing. Once an appropriate dosing regimen is determined, the optimal drug administration technique including smart infusion pumps as well as oral syringe devices with metric markings is equally important to avoid iatrogenic adverse medication events.

EVIDENCE-BASED PRACTICE BOX

Quality Improvement: Oral Glucose Gel for Neonatal Hypoglycemia

Neonatal hypoglycemia is a leading cause for admission to the neonatal intensive care unit (NICU) with current therapeutic options resulting in interruption of breastfeeding and mother–infant bonding. Low blood glucose levels are common among newborn infants with an estimated prevalence of 15% of newborns. As little as one low glucose level may contribute to problems with academic achievement and development during childhood. Infants on the first or second day of life may be asymptomatic or have symptoms including hypotonia, lethargy, jitteriness, seizures, hypothermia, congestive heart failure, or poor feeding.

Neonatal hypoglycemia should be treated as soon as possible to prevent complications of neurologic damage. Neonatal hypoglycemia is defined as a plasma glucose level of less than 30 mg/dL in the first 24 hours of life and less than 45 mg/dL thereafter.

New treatment algorithms use a more novel therapy, oral glucose 40% gel, extrapolated from adult experience. This allows treatment without the use of intravenous dextrose or interruption of breastfeeding. Dosing of 200 mg/kg/dose (or 0.5 mL/kg/dose) orally for one dose STAT is recommended at most centers (Bennett, Fagan, Chaharbakhsi, Zamifiirova, & Flicker, 2016). Some centers utilize this more novel therapeutic option only in neonates 35 weeks of gestation or greater (Harris, Weston, Signal, Chase, & Harding, 2013).

Storage of 40% dextrose gel tubes in automated dispensing cabinets in Labor and Delivery, Mother Baby Units, and NICUs provides options for rapid therapy. The opportunity for suppliers to manufacture a glucose gel product that is dye and preservative free in smaller unit of use packaging would be more appropriate for neonates. A significant decrease in admission rates to the NICU for hypoglycemia and supporting mother–infant bonding are two factors favoring this new therapeutic option.

PARENT VOICES

Tracy Pella

We gave birth to our twins at 23 + 4 weeks. One of our sons passed away the same day and our other son spent 134 days in the NICU. While in the NICU, our son was on several medications. As a parent, this was very overwhelming. Doctors and nurses would explain the medication and the need for our son to have them. They would do their best to explain them in layman terms. On most days, we were told more information than we could process. Not only were we first-time parents, but neither of us came from a medical background. For the most part, providers were willing to explain. As a nurse, please remember many of us parents are highly educated and deeply care about our child's health, yet medical terms and medications may need to be explained in a way we are able to understand. Often, our questions may be taken as challenging, but they are truly to be able to fully understand what you need us to know.

CHAPTER 22

Emerging Technologies in Neonatal Care: Healthcare Simulation for Neonatal Care

Carole Kenner

WHAT IS HEALTHCARE SIMULATION?

Over the past few years, the number of medical institutions opening healthcare simulation programs has increased exponentially (D. Arnold, LeMaster, Todd, & Wallin, 2012). The advent of advanced, high-fidelity simulation technology over the past 10 to 15 years has made this possible. Healthcare simulation is defined by David Gaba (2004) as, "a technique—not a technology—to replace or amplify real patient experiences with guided experiences, artificially contrived, that evoke or replicate substantial aspects of the real world in a fully interactive manner." Healthcare simulation involves four important components: (a) the scenario: the story where a participant is immersed in a realistic clinical situation; (b) the simulator: a tool used to create a realistic physical space, equipment, and/or patient such as a mannequin; (c) the experience: suspension of disbelief and "near-life" experience during the scenario by the participants; and (d) the debrief: reflective discussion where the learning occurs (see Figure 22.1).

Simulation in healthcare is an ever-evolving educational methodology that began over 20 years ago in the field of anesthesiology (Gaba, 1992; Rosen, 2008). It has taken a long time for the medical field to embrace simulation, likely due to the limitations of realistic simulators, but also due to the resistance in traditional medical education to try new methods of education, when tried and true methods such as lectures and bedside teaching have seemingly worked. However, simulation offers benefits that cannot be achieved in traditional lecture or bedside teaching with the mantra of *see one, do one, teach one* educational activities. It is based on adult learning principles, making it a very effective tool for educating healthcare providers (see Table 22.1; J. Arnold, 2011). Adult learners, including providers in neonatal care, are independent, self-directed, and motivated to learn when what they are learning applies to their professional roles (Murphy & Halamek, 2005). Adult learners also respond well to receiving immediate feedback on their performance and being able to apply their newly acquired knowledge right away. Additionally, simulation can provide education on demand with the opportunity to repeat high-risk situations until all participants manage a situation properly. Simulation bridges the gap between education and the acquisition of high-stakes, low-frequency skills in clinical practice that are essential for acquisition and maintenance of skills in high-risk patient care fields, such as neonatal intensive care (Galloway, 2009). It is being used for inpatient care as well as the transition home.

Most importantly, simulation is an educational opportunity where it is safe to make mistakes—there is no risk to patients. In fact, the goal of high-fidelity simulation encounters is often for participants to make mistakes. Every mistake made in a simulation is a mistake that could then be prevented in the real world. Previously, other high-risk industries such as aviation and nuclear power have utilized simulation to improve safety and minimize risk.

Simulation-based research in healthcare continues to show that use of simulation-based learning methodologies enhances performance in both real-life clinical situations and simulated resuscitations (Andreatta, Saxton, Thompson, & Annich, 2011). In addition, use of debriefings after real or simulated resuscitations have been found to result in improved learning, knowledge, and skills (Rudolph, Taylor, & Foldy, 2001). Some units are filming resuscitations for the purposes of improving teamwork, neonatal outcomes, and to debrief after the event. These films are destroyed after team reviews. Although these scenarios are not simulations, they are another example of the use of technology in neonatal training and quality improvement. This chapter outlines various technologies that are impacting neonatal care.

History of Healthcare Simulation

Simulation, although growing in use in healthcare education, has been used for many years in other high-risk industries. Military, aviation, and nuclear power have been using simulation to practice and prepare for rare and/or dangerous situations and highly strategic missions. Simulation in healthcare has learned many lessons from all these industries, especially the aviation industry. In the early years of aviation, simulation pilots practiced the technical skills of taking off, flying, and landing a plane as early as the time of the first planes and gliders. From the early days of gliding, it was usual for "pilots" to sit in the glider, which was exposed to a strong facing wind, and "feel" how to keep the wings horizontal with their controls (Moore, 2008). Flight simulation has now moved forward to highly advanced and realistic technology cockpit simulators that allow pilots to practice flight crises they hope they will never encounter in their careers. However, despite very realistic and advanced flight simulation training in which all pilots participated, up until the 1980s, the aviation industry was concerned about the frequency of major flight crises. So big was the problem that NASA launched an all-out study of jet transport accidents and incidents between 1968 and 1976 and found that the leading causes of these accidents were not deficiencies in the

TABLE 22.1

HOW ADULT LEARNING PRINCIPLES CORRELATE WITH HEALTHCARE SIMULATION

Adult Learning Principle	Simulation Curriculum Correlate
Adults prefer to apply what they learn soon after learning it	Simulation provides immediate, hands-on practice
Adults prefer learning concepts and principles	Preparation and presentation of key concepts prior to simulation allows for conceptual learning
Adults learn better at their own pace	Simulation provides repetitive and deliberate practice educational opportunities
Adults like to help set their own learning objectives	Learner-focused debriefings after simulation allow for reflection on personal objectives
Adults like to receive immediate feedback	Debriefing, enhanced with video review of simulation scenarios, is real time, immediate, and learner focused

pilot's knowledge or skill, but, more likely, failures in teamwork, communication, and leadership (Cooper, White, & Lauber, 1980). With this information, aviation developed a new form of training, coined Crew Resource Management, which focused on training the whole aircraft team on human factors such as effective communication, flat hierarchy, teamwork, workload distribution, and situational awareness (Helmreich & Sexton, 2003; Helmreich, Wilhelm, Klinect, & Merritt, 2001). As a result of the initiation of Crew Resource Management in aviation in the 1980s, it is much safer to fly our blue skies.

Healthcare simulation has evolved from the lessons learned in aviation simulation. Although healthcare simulation began as early as the 1960s with the development of the first low-fidelity mannequin-based simulator, Resusci Anne® by Laerdal, as a field, simulation in healthcare has had a rapid surge in activity, technological advances, and research over the past 10 years. Resusci Anne, a low-fidelity or low-tech mannequin, was developed and introduced in 1960 by Norwegian toymaker Asmund S. Laerdal (Laerdal Medical Company, 2012). He teamed up with two physicians, anesthesiologist Peter Safar, MD, and emergency medicine physician James Elam, MD, who developed mouth-to-mouth breathing (the airway component of CPR), as a life-saving procedure. Together, they developed a life-sized doll to train medical and nonmedical personnel in CPR. Resusci Anne was modeled after a young girl whose body was pulled from the River Seine in Paris at the turn of the 19th century. Her death was a popular story in Europe at the time. It was assumed she had committed suicide over unrequited love, by jumping in the river, as there were no other visible causes of death. Because her identity could not be established, a death mask was made as was customary at the time. Moved by her story, Asmund S. Laerdal adopted her mask for the face of his new resuscitation-training mannequin.

Healthcare simulation has come a long way since Resusci Anne. We now have everything from virtual reality and haptic simulators to whole-body mannequins that are so realistic and interactive that healthcare providers forget a mannequin-based patient is not real. Whole-body, highly technical mannequins are often referred to as high-fidelity mannequin-based simulators. These mannequins are so sophisticated that they have pulses and breathe, have heart and lung sounds, turn blue when cyanotic, talk or cry, sweat or bleed, and sometimes move (Figures 22.2 and 22.3). In neonatal simulation, there are four high-fidelity, whole-body mannequins now available (Table 22.2). Each has slightly different features; therefore, the choice of the best simulator is based on the needs of the specific simulation scenario one is trying to create. Some of the Laerdal mannequins today are being used to teach Helping Babies Breathe,® a low technology resuscitation program for low-resource countries as well as the breastfeeding mannequin to teach breastfeeding techniques. Both these mannequins are of low technology but serve the same purpose as the high-fidelity simulations—to gain skills without patient risk.

The high-fidelity mannequins take this training to another level. They interact with the providers. When a healthcare team administers a drug or an intervention, the mannequin's vital signs

FIGURE 22.2 High-fidelity mannequin-based simulators.

can change appropriately. Now, a healthcare team is able to take care of a patient in a realistic environment in real time without the interruptions of a teacher telling them the vitals or asking what they might do in that situation. Now, the team must actively do all the things needed to appropriately care for their patient in a safe environment.

Simulation and Patient Safety

Simulation is an increasingly recognized tool to improve patient safety in healthcare. It provides an effective method to meet the needs of adult learners, while improving patient safety and outcomes through a safe environment, to improve and maintain skill proficiency.

Medical error accounts for approximately $24 billion in healthcare costs annually in the United States and 98,000 lives lost annually. It is the fifth leading cause of death in the United States. Both the Institute of Medicine (IOM) and The Joint Commission (TJC) have reported that medical errors result from deficiencies in teamwork, leadership, and communication rather than technical or cognitive deficiencies, similar to that of the aviation industry (TJC, 1998; Kohn, Corrigan, & Molla, 2000). In 1999, the IOM's *To Err Is Human: Building a Safer Healthcare System* found that the leading causes of medicine errors (70%) were due to lack of communication and leadership, not a lack of medical knowledge or skill of the practitioner (Laerdal Medical Company, 2012). Similarly in 2004 and 2007, the TJC during extensive review of sentinel events found lack of teamwork, communication, and safety culture as the leading cause of error in these events. The TJC has recommended that all healthcare institutions implement simulation-based training to improve teamwork and communication. Just as the aviation industry developed Crew Resource Management to address deficiencies in teamwork, leadership, and communication, healthcare has developed Crisis Resource Management (CRM) training. CRM in healthcare simulation was first described by David Gaba, MD, an anesthesiologist and the father of modern healthcare simulation (Rall & Gaba, 2005). He reported 15 important CRM skills, such as role clarity, effective communication, personnel support, adequate use of all resources, and situational awareness, that all effective healthcare teams should embody to deliver safe care during high-risk clinical situations. Because simulation-based training focuses more on behavioral and teamwork skills than on individual technical skills, it provides the perfect opportunity for multidisciplinary teams to train together and practice these skills. Up until now, healthcare professionals have trained in silos: nurses in nursing school, physicians in medical school, and so on. However, when a patient crashes, healthcare providers are expected to work as a well-oiled team to successfully resuscitate a patient, even though they may have never had an opportunity to practice working together. In today's complex healthcare system, healthcare needs pit crews, not cowboys. No longer are autonomy, knowledge and experience, and self-sufficiency enough to provide safe and effective healthcare. Now, more than ever, healthcare providers need to work as a team within a system to provide safe and effective care. High-fidelity simulation provides opportunity for healthcare teams to only practice these important skills in a time-pressured, realistic, and safe environment.

There is a growing body of evidence that not only technical skills but also behavioral skills are improved with simulation-based training, ultimately improving patient care outcomes and decreasing medical errors (Andreatta et al., 2006, 2011; Barsuk, Cohen, Feinglass, McGaghie, & Wayne, 2009). In obstetrics and gynecology, researchers have shown that team-based simulation training can result in decreased need for massive transfusion protocols in postpartum hemorrhage situations (Lockhart, Allen, Gunatilake, Hobbs, & Taekman, 2012). Additionally, units conducting simulation-based training on management of shoulder dystocia have shown improved neonatal Apgar scores, decreased incidence of brachial plexus injuries in newborns, and decreased incidence of neonatal hypoxic–ischemic encephalopathy (Draycott et al., 2008). Simulation-based team training has shown improved collaboration between obstetrics and neonatology (Zabari et al., 2006). In our field of neonatology, simulation-based training has shown increased success rates in neonatal intubations after simulation training (Arnold et al., 2008), but there is a need for additional research to show the impact of simulation-based training in neonatal patient outcomes.

Simulation in Neonatal Care

Simulation provides an opportunity to practice high-risk patient care situations so that providers are more competent in their abilities to manage these situations. Because neonatal intensive care involves unexpected high-risk clinical situations, simulation is a tool to improve patient care outcomes.

Simulation-based training in neonatal care had its beginning in the Neonatal Resuscitation Program (NRP; Halamek et al., 2000; Murphy & Halamek, 2005). With studies showing that cognitive and technical skills achieved are typically retained for only 6 to 12 months, the goal of implementation of a simulation-based training curriculum was to improve learning and skills of healthcare providers caring for newborns requiring resuscitation at the time of delivery (Kaczorowski et al., 1998). It is not only recommended by national and international organizations including the International Liaison Committee on Resuscitation that oversee implementation of the NRP, but since its sixth edition, simulation-based training is now required (Perlman et al., 2010). In the seventh edition (Weiner, Zaichkin, & Kattwinkel, 2016),

TABLE 22.2

EXAMPLES OF HIGH-FIDELITY NEONATAL MANNEQUIN-BASED SIMULATORS

Features	SimNewB (Laerdal Medical)	Newborn Hal (Gaumard Scientific)	Premie Hal (Gaumard Scientific)	PEDI Blue Neonatal Simulator (Nasco)
Airway/ breathing	Realistic airway, normal and abnormal breath sounds, bilateral and unilateral chest rise, CO_2 exhalation	Realistic airway, normal and abnormal breath sounds, bilateral and unilateral chest rise	Realistic airway, normal and abnormal breath sounds, bilateral and unilateral chest rise	Realistic airway, bilateral chest rise
Cyanosis	Central, pulse oximetry	Central, pulse oximetry	Central, pulse oximetry	Peripheral and central
Circulation/EKG	Normal and abnormal heart sounds, central and peripheral pulses, EKG monitoring	Normal and abnormal heart sounds, central and peripheral pulses, EKG monitoring	Normal and abnormal heart sounds, central and peripheral pulses, EKG monitoring	None
Movement	All extremities: limp, tone, motion, seizure	Upper extremities: limp, tone, motion, seizure	None	None
Vocal sounds	Cry, grunt, stridor, cough, hiccup	Cry, grunt, stridor	Cry, grunt, stridor	None
Access procedures	Patent umbilical vein and arteries with blood flashback, bilateral intraosseous access	Patent umbilical vein with blood flashback, peripheral IV, bilateral intraosseous access	Patent umbilical vein with blood flashback, peripheral IV, bilateral intraosseous	Patent umbilical vein
Airway procedures	BVM, intubation, LMA, needle thoracentesis	BVM, intubation, LMA	BVM, intubation, LMA	BVM, intubation
Control	Wireless hand-held or tethered laptop	Wireless tablet PC	Wireless tablet PC	Tethered computer panel
Cost	$$$	$$$	$$$	$
Other	Interchangeable pupils, blood pressure	Gastric distention, bowel sounds, blood pressure	Premature newborn at 28 weeks	

BVM, bag-mask ventilation; IV, intravenous; LMA, laryngeal mask airway.

it does include simulated cases that are offered online. The incorporation of simulation-based methodology addresses the complex behavioral skills, such as effective teamwork and communication, that are essential in the resuscitation of the newborn. The NRP instructors are required to have the knowledge and skills needed to conduct simulation-based training: how to design simulation scenarios and debrief using reflective questions. Although the NRP has been a leader in embracing simulation since early on, it is only the beginning for the many potential uses and benefits in neonatal care.

There is a growing body of evidence that not only technical skills but also behavioral skills are improved with simulation-based training, ultimately improving patient care outcomes and decreasing medical errors (Andreatta et al., 2006, 2011; Barsuk et al., 2009; Draycott et al., 2008; Zabari et al., 2006). In the care of newborns, simulation-based training has been shown to improve provider success rates at endotracheal intubation, decreased incidence of hypoxic–ischemic encephalopathy, and improvement in Apgar scores (J. Arnold et al., 2008; Draycott et al., 2008).

Implementation of Simulation in Neonatal Care

The first step in the development of simulation-based neonatal activity is to determine the purpose of simulation activity. Five major categories in simulation can be used to help describe the purpose of simulation activity: (a) education, (b) competency and assessment, (c) research and development, (d) quality and patient safety, and (e) advocacy. Although simulation is an educational tool, it can be utilized for very different purposes beyond education. As a neonatal care provider is exploring and developing simulation training opportunities, it is vital to determine the purpose of the initiative in order to develop a useful and successful simulation initiative.

Simulation for Educational Purposes. Using simulations to provide training to meet the educational demands of neonatal

healthcare providers is the first category and most common use of simulation. Simulation-based education and training is primarily focused on delivering new knowledge/skills and/or providing practice and instruction to improve the learners' performance in a simulated event. It is important that all simulation-based educational activities are based on sound educational principles. (Please see the section Simulation for Competency and Assessment on simulation scenario design for key steps in this process.)

Simulation for Competency and Assessment. The goal of using simulation for assessment of skills and competency is growing. There is a need for development of validated simulation scenarios and assessment tools using validated and reliable measurement principles. Simulation has been shown to be helpful in demonstrating and evaluating competency in nursing training programs, advanced cardiac life support, advanced and emergency airway management, pediatric code resuscitation, CRM skills, laparoscopic surgical skills, and even bronchoscopy (Anderson, Murphy, Boyle, Yaeger, & Halamek, 2006; Calhoun, Rider, Meyer, Lamiani, & Truog, 2009; Konge, Arendrup, von Buchwald, & Ringsted, 2011; Lucisano & Talbot, 2012; Lutrell, Lenburg, Scherubel, Jacob, & Koch, 1999; Vaillancourt et al., 2011; Wayne et al., 2007).

Task trainers such as intubation trainers (Laedral), Lumbar Injection Simulators (3B Scientific, Tucker, Georgia), micro-preemie training baby simulator by Anatomy Warehouse (Evanston, IL), and Gaumard's (Miami, FL) PEDI® Blue Newborn Simulator offering CPR training and debriefing are just a few of the neonatal products available.

In anesthesia and surgical fields, simulation is an accepted means for maintenance of certification for physicians. Currently, other certifying bodies already utilize simulation in their certification processes such as the Medical Council of Canada, U.K. General Medical Council, National Board of Osteopathic Medical Examiners, and the U.S. Medical Licensing Examination (TJC, 2010). The disciplines within neonatology who are most advanced in adoption of simulation to assess competency and skills are neonatal nurses and advanced practitioners or neonatal nurse practitioners (NNPs; Cates & Wilson, 2011). National Certification Corporation (NCC), which offers certification for neonatal nurses, now has a module called *Simulation Enhancing Nursing Education & Practice* available for purchase (NCC, 2018).

Simulation Research and Development. There is a need to foster and develop research and quality improvement studies to advance the science of healthcare simulation (Issenberg, McGaghie, Petrusa, Lee Gordon, & Scalese, 2005). If possible, all simulation-based activities should have measurable and publishable outcomes. Needed areas of research include, but are not limited to:

1. Identification of which debriefing techniques and adjuncts best enhance learning
2. Identification of the optimal simulation educational approach based on the level of learner, skill of the faculty, and specific learning objectives
3. Development of "best practices" for simulation training in healthcare
4. Procedural or technical skills simulation research such as:
   a. Number of times needed for practice of a skill before competence is achieved
   b. Duration of time before procedural skills deteriorate
   c. Training in technical skills in simulation extrapolate to improve performance in skill on patients
   d. Validation of task trainers, virtual reality, and computer-based simulators
   e. Simulation training to decrease time from novice to expert
5. Use of simulation methodology as an assessment tool of technical and behavioral skills in healthcare providers
   a. Determination of the number and content of simulations required to assure an acceptable level of reliability
   b. Development and validation of reproducible scenarios with reliable and valid assessment tools for evaluating professional competence for the purpose of promotion, certification, or licensure
6. Development of reliable reproducible simulation-based scenarios for use across multiple institutions
7. Effects of fatigue on healthcare performance: team behaviors, decision making, communication skills, and error rates

Simulation for Quality and Patient Safety. Ultimately, all healthcare simulation activities have the potential to improve quality and patient safety. The best way to achieve this is to align simulation-based activities with national, local, and institutional patient safety and quality goals and needs. By qualitative research design and measurement, changes in patient care outcomes can be tracked and reported. Examples of this type of simulation include, but are not limited to:

1. In situ simulation to identify potential latent threats to patient safety in the clinical setting
2. Evaluation and testing of new hospital environments, technologies, equipment, or processes before being utilized in real patient care
3. Recreation of near misses and serious safety events to help identify causes and prevent future events

Advocacy in Simulation. Using simulation as a tool for advocacy for patient care is broad. It involves supporting the larger community with simulation-based activities. This can include:

1. Promoting simulation at a national or local level through media and public relations opportunities so that laypersons understand and might support healthcare simulation
2. Lobbying for healthcare legislature to support funding for healthcare simulation
3. Providing simulation-based education to laypersons, such as parents, so that they are better prepared to care for medical emergencies and crises at home or out of hospital

SCENARIO DEVELOPMENT

Just as in other more traditional curricular development models, simulation scenario design must be standardized and evidence based. It is important to realize that development of simulation educational events should be based on learning objectives and not on the features of mannequins or technology. Effective simulation scenario is essentially one where the learning objectives are achieved. Second, by incorporating real-life cases into scenarios, it not only improves the credibility of the cases for learners, but learners are also able to manage clinical problems and situations as they would in real-world practice. A series of steps are required to develop an effective and evidence-based scenario. For example, if one wanted to develop a scenario for educational purposes with the goal of training a healthcare team in how to manage a neonatal code, the process might look like this:

Step 1: Identification of the Purpose of the Scenario

Typically, when designing a scenario, it is recommended that the first step be to identify the purpose of the simulation: education, training, competency/assessment, research, or to address a patient

safety goal. Once you know the goal of the simulation session, it is easy to write learning objectives and determine a clinical case that can be created to meet the desired goal. In this case, the goal would be educational in nature.

Step 2: Identification of the Learning Objectives

The learning objectives should be determined based on the goal of the scenario. It is helpful to categorize learning objectives by their type: cognitive, technical, and behavioral. Although many simulation scenarios provide an opportunity to address many learning objectives, it is helpful to narrow the scope of the scenario to three or four at most so that the learners are able to synthesize these objectives.

Step 3: Identification of the Learners/ Participants

It is important to identify who will be the participants. Will it be a single or multidisciplinary team? How many learners per group? For this scenario, a learner group might consist of two neonatal nurses, one neonatal physician, one NNP, and one neonatal respiratory therapist. In general, the number of learners per simulation should reflect the appropriate number and type of providers for the clinical case.

Step 4: Identification of a Clinical Case to Create in Order to Achieve the Desired Learning Objectives

A patient clinical scenario should be developed that will allow the learning objectives to be met. The clinical situation must be realistic and appropriate to the level of the learners. For example, one might not want to choose management of congenital diaphragmatic hernia for a group of new nurses or residents; rather, a case of neonatal shock may be better aligned with their level of expertise. In this example case, one might choose a case of Group B streptococcal septic shock to address the needed learning objectives.

Step 5: Completion of a Scenario Design Template

Many simulation programs have developed and tailored their own simulation scenario design templates. Certain important pieces of information must be known ahead of time in order to conduct an effective simulation. Most simulation education instructors utilize a scenario design template or script that identifies all the necessary equipment and technology needed, the learners, the roles of instructors, the room setup, the expected scenario flow (a script like a play or movie), the appropriate mannequin physiological states based on actions of the learners, and the expected actions of the learners during a simulation. It is also very important to base the scenario and debriefing on the most recent evidence so that the educational experience is evidence based.

Step 6: Development of Debriefing Script Based on Learning Objectives

Although many topics discussed during the debriefing after a simulation scenario will be based on the performance and actions of the participants, it is important to keep the debriefing focused on the learning objectives. Time during a debriefing is limited, and although many teachable points will be raised during a simulation scenario, it is important to prioritize the discussion to the planned learning objectives. Therefore, it is often helpful to plan ahead with a few open-ended questions that will address the learning objectives. Some educators develop very detailed scripted debriefing questions to address these topics.

Step 7: Practice and Rehearsal of the Scenario

Every time a simulation scenario is run, the participants will likely act and perform differently. Therefore, it is very important to practice a scenario so that the scenario developers can ensure that the appropriate cues are available and that the learning objectives are achieved. When conducting a dress rehearsal, one often identifies medical equipment or auditory and visual cues that may be missing in order for the learners to be able to share the same mental model of the case as you intended.

Step 8: Implementation and Evaluation of the Simulation Scenario

As with any educational intervention, it is important to continuously re-evaluate the effectiveness of the intervention. Getting feedback from learners and instructors is important so that simulation scenarios can be continuously refined and improved.

NEONATAL APPS

A newer area of neonatal technology is the apps. These range from interactive drug calculators to apps that offer algorithms or infographics for common neonatal conditions, neonatal checklists to guide health professionals, and parent support apps such as those found at Support 4 NICU Parents (http://support4nicuparents.org/apps-for-nicu-parents). All of these apps are aimed at use of technology to support professionals and parents in providing care in the hospital and at home.

VIRTUAL CONSULTATIONS

Use of telemedicine is growing with neonatal specialists-physicians and nurses reaching out to provide consultations to community-based hospitals. These consults may be for assessments or for diagnostic reasons. They may be used to determine whether a baby needs to be transferred to a tertiary center or can remain in the birth hospital. Some of the early adopters of this technology are Arkansas Children's Hospital, Little Rock, Arkansas; Nationwide Children's, Columbus, Ohio; Children's Medical Center, Dallas; and Fauquier Hospital in Virginia. Telemedicine is being used after discharge to keep the babies in their homes with fewer hospital appointments (Robinson, Gund, Sjoqvist, & Bry, 2016).

SUMMARY

Simulation is a highly effective and innovative educational tool. It can be used for many purposes, including healthcare education, quality improvement, and patient safety. Although simulation can be a resource-intensive endeavor, when utilized appropriately, it can greatly improve healthcare provider performance and patient care outcomes. Simulation provides a mechanism for bringing the healthcare team together—students or practicing professionals to learn and practice the art of working together in a safe environment. This is another way that patient safety and quality will be improved through simulated interprofessional experiences. Use of technologies, whether through apps or virtual consults, is growing as is the evidence to support skill development/maintenance as well as impact on neonatal/family outcomes.

CASE STUDY

A sample of a simulation scenario in neonatal resuscitation.

Learning Objectives of the Scenario. By the end of the simulation session, learners should be able to:

- Cognitive
  1. Recognize the signs and symptoms of meconium aspiration syndrome in a neonate
  2. Develop a differential diagnosis of respiratory distress in a neonate
  3. Identify appropriate initial resuscitation and management steps in a newborn with meconium aspiration
- Technical
  1. Provide appropriate airway management skills for the neonate with meconium aspiration:
     a. Supplemental oxygen
     b. Tracheal intubation
     c. Positive-pressure ventilation
     d. Surfactant replacement
     e. Inhaled nitrous oxide
  2. Obtain umbilical venous and arterial access
  3. Provide intravenous (IV) fluid resuscitation and dextrose as indicated
- Behavioral
  1. Utilize appropriate teamwork and communication skills during a neonatal resuscitation, including:
     a. Identification of a team leader and other team roles
     b. Appropriate utilization of resources
     c. Effective communication, including closed-loop communication

Background for Learners of the Problem. This is a case of a newborn born with meconium aspiration syndrome who is to be managed by the NICU team following initial resuscitation.

■ Assessment: History and Physical Examination

History

- Baby girl is a 3,800-g estimated 38-week female born to a 16-year-old G1P1 with good prenatal care
- Maternal prenatal labs: mother: O+/− HIV—RPR pending HbsAg−, UDS: positive for marijuana
- Mother presented to L&D with loss of fluid approximately 24 hours prior to presentation, at 10 cm and +5 station
- Infant was born via precipitous spontaneous vaginal delivery with thick, foul-smelling meconium and fetal decels
- Mother developed fever to 102 at presentation
- At delivery, no spontaneous respirations noted, infant taken to warmer and suctioned below cords ×2 with return of thick meconium and started on bag-mask ventilation for 30 seconds with spontaneous respirations noted
- Heart rate was greater than 100 throughout resuscitation
- Peripheral IV placed at L&D and started on 40% oxygen via facemask with continuous positive airway pressure (CPAP) for desaturation and increased work of breathing
- Patient brought to NICU immediately without further intervention for initiation of respiratory support and prolonged rupture of membranes with chorioamnionitis; Apgar scores were 61, 85

■ Physical Examination Upon Presentation to NICU

- GENERAL: pale with thready pulses, poor peripheral perfusion
- VITAL SIGNS: baseline vital signs
- Temperature 98.3, HR 180, RR 78, BP 45/38, O_2 85% on 40% Fio_2 on FM with CPAP 8
- HEENT: AFOF, small caput, ears normal, palate intact, eyes open, pupils reactive to light; positive red reflex and normal facies
- RESP: lung fields bilaterally with coarse crackles and severe intracostal, subcostal, and substernal retractions noted; gasping respiratory effort on CPAP
- CV: rate regular with small II/VI systolic ejection murmur noted; poor peripheral perfusion, capillary blood refill time greater than 5 seconds, and thready pulses
- ABD: abdomen soft and nontender with no hepatosplenomegaly or masses; three-vessel cord; anus patent
- GENITOURINARY: normal female infant genitalia
- NEURO: decreased responses and tone
- EXTREMITIES: normal
- SKIN: pale with poor perfusion and mildly cyanotic; pronounced circumoral and acrocyanosis; no rashes or lesions

■ Differential Diagnoses

- Meconium aspiration syndrome
- Perinatal hypoxic–ischemic injury
- Shock
- Disseminated intravascular coagulation
- Sepsis
- Congenital cardiac defect

■ Diagnostic Tests

Laboratory Tests:

- CBC/differential: WBC 20.3, segmented cells 44; bands 30; hematocrit (Hct) 48%, platelet count 168,000/mm^3
- Glucose: 68
- Baby blood type and Coombs: baby: O+/−

Imaging Tests:

- Chest x-ray: bilaterally hazy with patchy areas of consolidation and atelectasis, hyperinflated to 10 ribs bilaterally, cardiac silhouette within normal limits

■ Simulation Scenario Setup and Logistics

Room Configuration (Setup). NICU inpatient room, infant warmer with neonatal high-fidelity mannequin on bed, covered up, no monitors on. Scenario starts with arrival of baby on CPAP from the labor and delivery room with transport team with portable warmer/isolette. Labor and delivery neonatal resuscitation team calls NICU when leaving L&D with brief handoff of patient to allow NICU team time to set up.

■ Equipment Needed

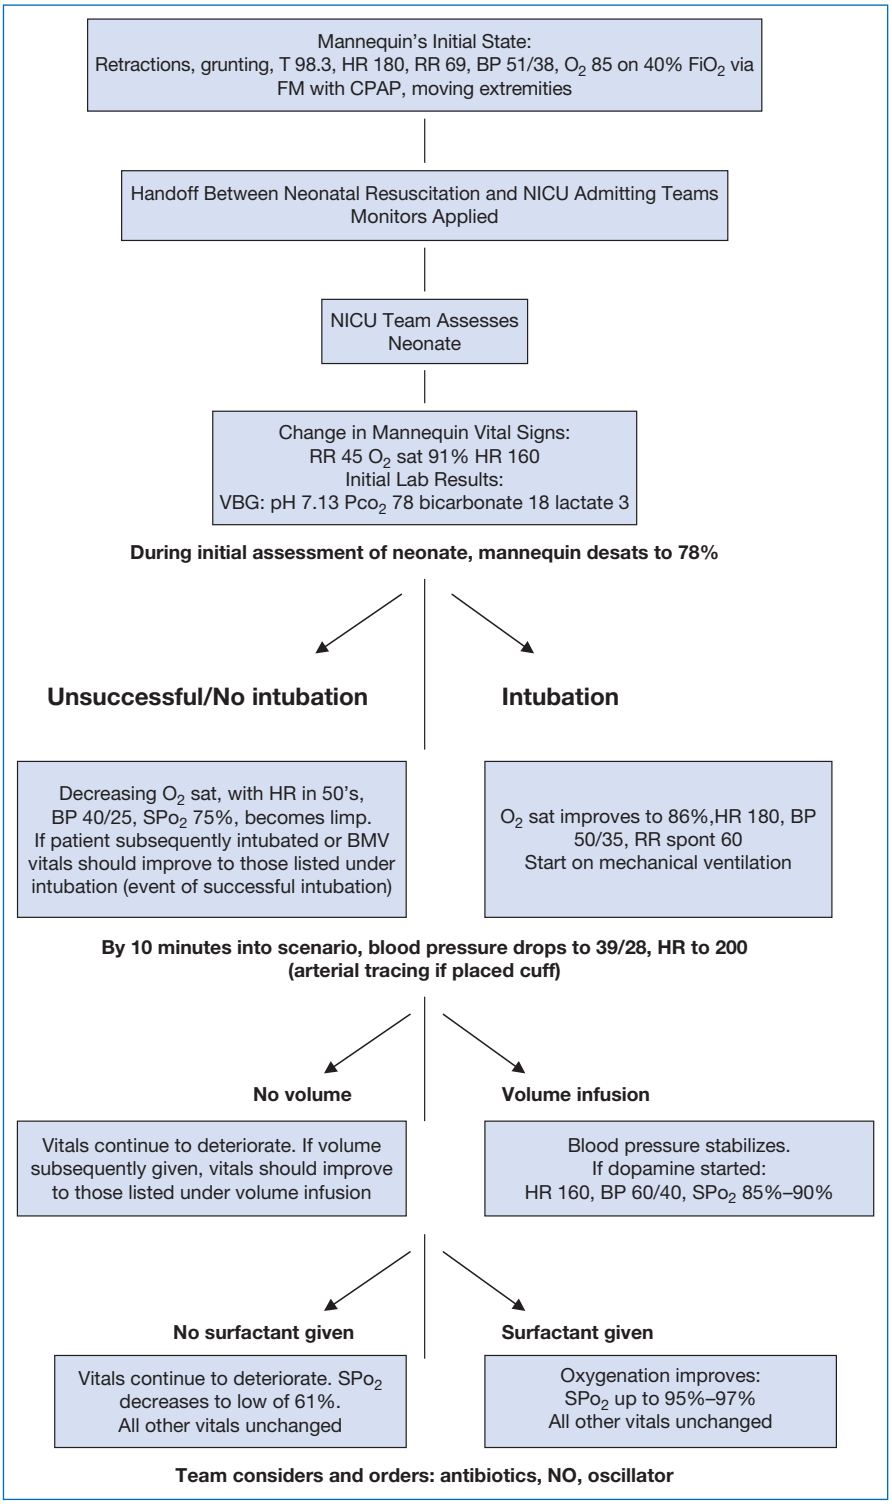
- High-fidelity neonatal mannequin with thick green moulage
- CPAP
- Ventilator (conventional and oscillator)
- Central-line access kit (umbilical)
- Neonatal crash cart
- Neonatal "fake" medications
- Airway supplies, including bag-mask and intubation equipment

■ Mannequins/Task Trainers/Confederates Needed

- High-fidelity neonatal mannequin: mannequin on admitting bed with a diaper and a hat only and some dark green thick moulage; peripheral intravenous (PIV) in place, CPAP on mannequin
- Low-fidelity neonatal mannequin: mannequin with hat and diaper on in transport isolette, attached to CPAP and Fio_2 at 40%, PIV in place
- Neonatal resuscitation team (confederate roles)
- Neonatal resuscitation team shows up with transport warmer/isolette with low-fidelity neonatal mannequin inside to start the scenario with a handoff to NICU admitting team.

■ Simulation Scenario Flow (Flow Chart)

Expected Scenario Flow. Neonatal resuscitation team (confederate team) arrives to bedside with transport warmer/isolette (low-fidelity



BMV, bag mask valve; BP, blood pressure; CPAP, continuous positive airway pressure; FiO_2, fraction of inhaled oxygen; FM, facial mask; HR, heart rate; NICU, neonatal intensive care unit; NO, nitric oxide; O_2, oxygen; RR, respiratory rate; T, temperature; VBG, venous blood gases.

mannequin), and report is given to NICU admitting team (learner team); transport team relays important information and background of neonate's course and history in the delivery room. After handoff to the admitting NICU team, the high-fidelity mannequin should be exposed (blanket removed), and the team should provide care to their new patient. The neonate should be placed on monitors. All appropriate providers should be in the room (nurses, physicians, respiratory therapists). The team should manage their patient until stabilized or 20 minutes of time has elapsed.

Expected Interventions of the Participants. The patient should be placed on monitors and vital signs assessed. Respiratory distress should be addressed first with noninvasive, then invasive ventilatory techniques. Recognition of possible meconium aspiration and sepsis should occur. The infant should be intubated and surfactant ordered. A chest x-ray should be obtained. Central access should be obtained, with appropriate labs sent and antibiotics ordered. Hypotension should be recognized and treated first with fluid resuscitation, then consider pressors. Failure of conventional ventilation should be recognized, and the team should consider inducible nitric oxide (iNO) and oscillator. The scenario ends when the following are achieved:

- Intubation
- Central-line access
- Fluid resuscitation
- Ordering and/or administration of surfactant, antibiotics, maintenance in vitro fertilization, iNO, and inotropes

Mannequin Operation: Scenario Flow Based on Participants' Interventions and Time

Debriefing. At the completion of the scenario, the instructor should lead a facilitative, reflective discussion of the learner's performance during the simulation. Concepts of a safe and confidential learning environment should be reinforced. The debriefing should focus on the learning objectives and issues that arose during the simulation such as things done well or not as well as desired by the team, questions the learners have based on the scenario, or other items of interest to the learners or the instructor. If possible, the debriefing should use video review of the scenario during the discussion. A typical debriefing lasts two to three times the duration of the simulation.

EVIDENCE-BASED PRACTICE BOX

Healthcare simulation is defined by David Gaba as "a technique—not a technology—to replace or amplify real patient experiences with guided experiences, artificially contrived, that evoke or replicate substantial aspects of the real world in a fully interactive manner" (Gaba, 2004). Healthcare simulation involves four important components: (a) the scenario: the story where a participant is immersed in a realistic clinical situation; (b) the simulator: a tool used to create a realistic physical space, equipment, and/or patient such as a mannequin; (c) the experience: suspension of disbelief and "near-life" experience during the scenario by the participants; and (d) the debrief: reflective discussion where the learning occurs.

Simulation is an educational opportunity where it is safe to make mistakes—there is no risk to patients. In fact, the goal of high-fidelity simulation encounters is often for participants to make mistakes. Simulation is an increasingly recognized tool to improve patient safety in healthcare. It provides an effective method to meet the needs of adult learners, while improving patient safety and outcomes through a safe environment, to improve and maintain skill proficiency. There is a growing body of evidence that clinician performance and patient care outcomes are improved with simulation-based training, ultimately improving patient care outcomes and decreasing medical errors (Andreatta et al., 2006; Andreatta, Saxton, Thompson, & Annich, 2011; Barsuk, Cohen, Feinglass, McGaghie, & Wayne, 2009). In obstetrics and gynecology, researchers have shown that team-based simulation training can result in decreased need for massive transfusion protocols in postpartum hemorrhage situations (Lockhart, Allen, Gunatilake, Hobbs, & Taekman, 2012). Additionally, units conducting simulation-based training on management of shoulder dystocia have shown improved neonatal Apgar scores, decreased incidence of brachial plexus injuries in newborns, and decreased incidence of neonatal hypoxic–ischemic encephalopathy (Draycott et al., 2008). Simulation-based team training has shown improved collaboration between obstetrics and neonatology (Zabari et al., 2006). Simulation-based training in newborn resuscitation has shown increased success rates in neonatal intubations after simulation training (Arnold et al., 2008), but there is a need for additional research to show the impact of simulation-based training in neonatal patient outcomes.

When developing and implementing simulation-based education, just as in other more traditional curricular development models, simulation scenario design must be standardized and evidence based. It is important to realize that development of simulation educational events should be based on learning objectives and not the features of mannequins or technology. An effective simulation scenario is essentially one in which the learning objectives are achieved. A series of steps are required to develop an effective and evidence-based scenario. It is important that all simulation instructors receive formal training in how to implement and debrief simulation scenarios. Debriefing is a challenge, and most literature supports the need for educators to be trained in effective debriefing principles. Debriefing requires learner self-reflection and facilitative feedback in a psychologically safe environment (Rudolph, Simon, Dufresne, & Raemer, 2006; Rudolph, Simon, Raemer, & Eppich, 2008). An educator must take time to develop an evidence-based scenario and practice before implementation to ensure that learning objectives are achieved. Simulation is a highly effective and innovative educational tool. It can be used for many purposes, including healthcare education, quality improvement, and patient safety. Although simulation can be a resource-intensive endeavor, when utilized appropriately, it can greatly improve healthcare provider performance and patient care outcomes.

CHAPTER 23

Pain in the Newborn and Infant

Marlene Walden and Carol Turnage Spruill

INTRODUCTION

Despite advances in neonatal pain assessment and management, nonpharmacologic and pharmacologic analgesic therapies continue to be underutilized to manage both acute and procedural pain (Carbajal et al., 2008; Committee on Fetus and Newborn and Section on Anesthesiology and Pain Medicine, 2016; Simons, van Dijk, Anand, et al., 2003). Untreated acute, recurrent, or chronic pain related to disease or medical care may have significant and lifelong physiologic and psychological consequences. As with all other medical conditions, the first step in the treatment process is the accurate diagnosis of the problem. Thus, pain assessment provides the foundation for all pain treatment. This chapter reviews the developmental neurophysiology of pain, discusses methods to assess pain in infants, highlights factors that influence the pain experience, and discusses evidence-based strategies for managing infant pain.

DEFINING PAIN IN INFANTS

Pain is defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage" (Merskey, 1979). The IASP definition also states that pain is always subjective and is learned through experiences related to injury in early life. This definition is problematic when considering infants who are incapable of self-report and who may not have had previous experience with injury. Anand and Craig (1996) proposed that pain perception is an inherent quality of life that appears early in development to serve as a signaling system for tissue damage. This signaling includes behavioral and physiologic responses, which are valid indicators of pain that can be inferred by others. Broadening the definition of pain to include behavioral and physiologic indicators, in addition to self-report, can benefit preverbal, nonverbal, or cognitively impaired individuals who are experiencing pain by providing objective pain assessment.

More recently, researchers have attempted to develop uniform definitions of prolonged, persistent, or chronic pain in the newborn (Anand, 2017). In a Delphi study conducted by van Ganzewinkel and colleagues, chronic pain in the newborn is characterized by pain that is not proximate to a procedure or event, occurs over a period of time, has no clear endpoint in sight, and often is not associated with a specific cause (van Ganzewinkel, Anand, Kramer, & Andriessen, 2014). Furthermore, an acute painful event may alter pain perception where subsequent non-noxious events are perceived as painful. Signs and symptoms may be nonspecific, further hindering the ability of caregivers to accurately assess chronic pain in the neonate (van Ganzewinkel et al., 2014).

Risk factors for pain along with a high index of suspicion should be used in determining whether an infant is in pain and is in need of appropriate pain-relieving treatment. The primary tenet is that pain in the newborn should be presumed in all situations usually considered to cause pain in adults and children, even in the absence of behavioral or physiologic signs (Agency for Health Care Policy and Research, 1992; National Association of Neonatal Nurses, 2012).

DEVELOPMENTAL NEUROPHYSIOLOGY OF PAIN

The basic mechanisms of pain perception in infants and children are similar to those of adults and include (1) transduction and transmission and (2) perception and modulation. However, because of neurophysiologic and cognitive immaturity, some differences exist. A brief review is presented here and emphasizes the developmental and maturational changes that occur during infancy and childhood (Fitzgerald & Howard, 2003).

Peripheral Transduction and Transmission

Noxious mechanical, thermal, or chemical stimuli excite primary afferent fibers that transmit information about the potentially injurious stimuli from the periphery to the dorsal horn of the spinal cord. A-delta (large, myelinated, and fast-conducting) and C (small, unmyelinated, and slow-conducting) fibers are primarily responsible for pain impulse transmission (nociception). However, these signals can be amplified or attenuated by activation of surrounding neurons in the periphery and spinal cord. For example, tissue injury causes the release of inflammatory mediators (e.g., potassium, bradykinin, prostaglandins, cytokines, nerve growth factors, catecholamines, substance P) that sensitize A-delta and C fibers and recruit other neurons (silent nociceptors) and result in hyperalgesia. Stimulation of A-beta fibers that signal nonpainful touch and pressure can compete with the transmission of nociception in the dorsal horn of the spinal cord, thus reducing the intensity of the perceived pain.

Central Mechanisms and Modulation

Neurotransmitters in the spinal cord either amplify (e.g., substance P, calcitonin gene-related peptide, neurokinin A) or attenuate (e.g., endogenous opioids, norepinephrine, serotonin, GABA [gamma-aminobutyric acid], glycine) pain information from the periphery. Central sensitization occurs when excitatory amino acids act on NMDA (*N-methyl-D-aspartate*) receptors to induce prolonged depolarization and windup.

Nociceptive sensory input reaches the thalamus through second-order neurons in the spinothalamic, spinoreticular, and spinomesencephalic tracts and is then widely distributed throughout the brain. The perception, emotional interpretation, and cognitive meaning of nociceptive stimuli occur within a distributive neuromatrix; no one "pain center" exists. The sensory-discriminative, affective-motivational, and evaluative dimensions of pain perception are mediated by past experience and the context of the painful event. For example, nociceptive stimuli activate areas of the limbic system thought to control emotion, particularly anxiety. Thus, differences in physiologic, biochemical, and psychologic factors influence the perception of pain, making it an individual phenomenon.

Descending modulation occurs when efferent projections from supraspinal areas such as the periaqueductal gray, raphe nucleus, and locus coeruleus release inhibitory neurotransmitters. The major neurotransmitters that mediate descending inhibition are norepinephrine, serotonin, endogenous opioids, GABA, and acetylcholine.

Neurodevelopment of Pain Perception

Infants, even prematurely born infants, have the neurologic capacity to perceive pain at birth (Fitzgerald & Howard, 2003; Simons & Tibboel, 2006; Walker, 2013). The peripheral and central structures necessary for nociception are present and functional early in gestation (between the first and second trimesters). Functional maturation of the fetal cerebral cortex has been demonstrated by (1) near-infrared spectroscopy and electroencephalogram (EEG) patterns that demonstrate alterations in cortical evoked potentials, (2) measurement of cerebral glucose use that shows maximal metabolic rates in sensory areas of the brain, and (3) well-defined periods of sleep and wakefulness that are regulated by cortical functioning from 28 weeks' gestation. The newborn infant possesses a well-developed hypothalamic–pituitary–adrenal axis and can mount a fight-or-flight response with the release of catecholamines and cortisol.

Research suggests that some differences in nociceptive processes between infants and adults exist. For example, pain impulse transmission in neonates occurs primarily along nonmyelinated C fibers rather than myelinated A-delta fibers. The peripheral and central nervous systems in the preterm are also immature, leading to lower thresholds for activation, excitation, and transmission of nociceptive stimuli. Furthermore, the dorsal horn neurons in the spinal cord have large, overlapping cutaneous receptive fields that, when stimulated, amplify nociceptive signaling and can evoke long-term excitability within the spinal cord (Anand, 2017). Descending inhibitory neurotransmitters are also lacking, leading to decreased modulation of pain in the preterm neonate (Fitzgerald & Howard, 2003). Thus, young infants may perceive pain more intensely than do older children or adults because their descending control mechanisms are immature and thus limit their ability to modulate the experience.

Long-Term Consequences of Pain

Although pain can serve as a warning of injury, the effects of pain are generally deleterious. Pain evokes negative physiologic, metabolic, and behavioral responses in infants. These responses include autonomic instability, pulmonary dysfunction, and hormonal stress (Goldschneider & Anand, 2003). Pain and stress contribute to an increased allostatic load of preterm neonates in the neonatal intensive care unit (NICU). *Allostatic load* is the resulting wear and tear on the body from repeatedly adapting to adverse situations (Grunau, Holsti, & Peters, 2006). Painful procedures may result in heightened pain sensitivity to routine handling as well as delayed recovery from noxious and routine caregiving procedures.

Learning about pain occurs with the first pain experience and may have effects on subsequent pain perception and responses. Memory of pain in infants is evident from differences in responses to painful vaccination in infants who had undergone unanesthetized circumcision in comparison with infants who were uncircumcised or who received analgesia during circumcision (Taddio, Goldbach, Ipp, Stevens, & Koren, 1995; Taddio, Katz, Ilersich, & Koren, 1997).

Research has suggested that pain syndromes may be related to early pain experiences. Grunau, Whitfield, and Petrie (1994) reported that parents judged their former extremely-low-birth-weight (ELBW) infants at 18 months to be less sensitive to pain and have higher somatization (pain of unknown cause) compared with parents of full-term infants. On the contrary, other research has failed to demonstrate differences in somatization of former ELBW infants at age 9 years (Whitfield, Grunau, & Holsti, 1997) or at ages 17 to 19 years (Grunau, Whitfield, & Fay, 2004). Further research is needed to learn about pain and its effects in infancy and beyond.

CLINICAL ASSESSMENT OF PAIN

Presently, no easily administered, widely accepted, uniform technique exists for assessing pain in infants (Duhn & Medves, 2004). Current pain methods have several limitations. First, most pain instruments were developed for neonates undergoing acute procedural pain such as heel sticks and may not accurately capture pain in neonates with persistent, prolonged, or chronic pain. Pain instruments also require caregivers to subjectively assess behavioral responses of the neonate to pain, which may result in interobserver variability and limit consistent pain assessments. Furthermore, behavioral pain responses may be absent or elusive in critically ill neonates who are pharmacologically paralyzed for medical treatment, infants at end of life (EOL), or in infants with neurologic impairments (Hall & Anand, 2014). While future directions in pain assessment may include technologies such as the use of near-infrared spectroscopy, heart rate variability, or palmar skin conductance, this specialized equipment may not be readily available at the bedside (Hall & Anand, 2014; Mele, 2018).

A multidimensional pain assessment tool that includes measurements for both physiologic and behavioral indicators of pain is preferable given the multifaceted nature of pain (National Association of Neonatal Nurses, 2012; Walden, 2001). Selection of an appropriate clinical pain assessment method should be based first on the developmental age of the infant and second on the type of pain experienced (e.g., for procedural pain or postoperative pain). Published validity and reliability should be considered when choosing a pain assessment tool.

Multidimensional Pain Tools

The most commonly used published multidimensional infant-specific pain assessment tools with psychometric data are listed in Table 23.1. The Premature Infant Pain Profile (PIPP), originally developed in 1996, has been demonstrated in numerous studies to be a valid and reliable measure of acute pain in

TABLE 23.1

MOST COMMONLY USED MULTIDIMENSIONAL PAIN ASSESSMENT TOOLS IN NEWBORNS

Pain Instrument	Population	Indicators	Forms of Validity	Reliability Data
Premature infant pain profile (Stevens et al., 1996, 2010)	Preterm and term neonates from 28 to 40 weeks	Gestational age Behavioral state Heart rate Oxygen saturation Brow bulge Eye squeeze Nasolabial furrow	Face Content Construct	Inter- and intrarater reliability >0.93
CRIES: Neonatal Postoperative Pain Assessment Score (Bildner & Krechel, 1996)	Neonates from 32 to 60 weeks	**C**rying **R**equires oxygen to maintain saturation 95% **I**ncreased blood pressure and heart rate **E**xpression **S**leep state	Face Content Discriminant Concurrent (r = 0.49–0.73)	Interrater reliability >0.72
Neonatal Infant Pain Scale (Lawrence et al., 1993)	Preterm and term neonates	Facial expression Cry Breathing patterns Arm movement Leg movement State of arousal	Face Construct Concurrent validity (r = 0.53–0.84)	Interrater reliability >0.92
Neonatal Pain Agitation and Sedation Scale (Hummel, Puchalski, Creech, & Weiss, 2008)	Preterm and term neonates	Crying/irritability Behavior/state Facial expression Extremities/tone Vital signs	Concurrent Discriminate	Interrater reliability >0.90

infants (Stevens, Johnston, Petryshen, & Taddio, 1996; Stevens, Johnston, Taddio, Gibbins, & Yamada, 2010). The PIPP was revised (PIPP-R) in 2014 to enhance validity and feasibility (Stevens et al., 2014). The PIPP has been tested in neonates ranging in ages from extremely preterm up to 40 weeks' postconceptional age. The PIPP incorporates two contextual factors that may account for the infant's less robust pain responses that may result from their immaturity or behavioral state. By scoring infants who are younger or those who are asleep higher on the PIPP, the adjusted scores do not penalize infants who are known to be less capable of mounting a robust response to noxious stimuli. The PIPP contains two physiologic indicators (i.e., heart rate and oxygen saturation) and three facial indicators (i.e., brow bulge, eye squeeze, and nasolabial furrow). While total scores vary between 18 and 21 depending on the infant's gestational age, scores between 7 and 12 usually signify mild to moderate pain requiring nonpharmacologic pain relief measures and scores greater than 12 indicate moderate to severe pain requiring pharmacologic pain intervention in addition to comfort measures.

The CRIES was originally developed to assess postoperative pain in infants between 32 and 60 weeks' gestational age (Krechel & Bildner, 1995), but studies have also documented its clinical utility in assessing procedural pain in preterm and term neonates (Ahn, 2006; Belda, Pallas, De la Cruz, & Tejada, 2004; Herrington, Olomu, & Geller, 2004). The CRIES is an acronym for the five parameters it measures: **C**rying, **R**equires oxygen to maintain saturation greater than 95%, **I**ncreased vital signs, **E**xpression, and **S**leepless. Total scores for the CRIES range from 0 to 10, with scores less than 4 indicative of mild pain requiring nonpharmacologic pain relief measures and scores greater than or equal to 5 consistent with moderate to severe pain requiring pharmacologic intervention in conjunction with comfort measures.

The Neonatal Infant Pain Scale (NIPS) was originally developed to assess procedural pain in preterm and term newborns (Lawrence et al., 1993), but studies also validate its utility with postoperative pain (Rouss, Gerber, Albisetti, Hug, & Bernet, 2007; Suraseranivongse et al., 2006). The NIPS examines five behavioral parameters (i.e., facial expression, crying, arms, legs, and state of arousal) and one physiologic parameter (i.e., breathing pattern). Total score ranges from 0 to 7. While the researchers of the NIPS do not provide guidelines for pain interventions on the basis of total score, all pain instruments in neonates are based on the premise of increasing pain intensity. Therefore, in tools without scoring guidelines for pain management, when pain scores reach the midrange of the total possible points for that tool (i.e., ~4 or greater with the NIPS), the clinician may infer that the infant is experiencing moderate to severe pain and pharmacologic intervention for that pain is warranted.

The Neonatal Pain Agitation and Sedation Scale (N-PASS), developed by Hummel et al. (2008), is a five-item scale that measures both pain/agitation and sedation in preterm and term neonates with prolonged pain postoperatively and during mechanical

ventilation. The N-PASS examines four behavioral items (crying/irritability, behavior state, facial expression, extremities/tone) and one physiologic indicator (vital signs). Total pain scores range from 0 to +10. Like the PIPP, the N-PASS includes gestational age as a contextual modifier of pain, thus adjusting the pain score to account for the preterm's limited ability to mount a robust pain response due to immaturity.

Sedation scores range from 0 to −10. Whereas a study by Hillman and colleagues reported that the N-PASS sedation score was significantly correlated with nursing bedside assessment, a study by Giordano and researchers found that the N-PASS reliably detected oversedation but failed to differentiate between levels of adequate sedation and undersedation (Giordano et al., 2014; Hillman, Tabrizi, Gauda, Carson, & Aucott, 2015). Further research is needed to determine optimal levels of sedation to maximize the ventilator benefits of the right sedation, while reducing the negative impact of oversedation on clinical outcomes.

Factors That Influence Pain

Pain is unique among neurologic functions because of the degree of plasticity in pain neurophysiology. Although structural and functional maturity is reached at an early age, anatomic and functional changes occur throughout life and are related to the effects of each pain experience. This plasticity means that the perception and meaning of pain are unique to each individual and are not determined by maturation alone but are influenced by many individual and contextual factors. Currently available methods to assess pain in infants do not adequately or quantitatively incorporate all aspects of the context of pain that influence the pain experience. Thus, the clinician must remain cognizant of the ways in which perception of pain may be positively or negatively influenced by these factors and subjectively incorporate them into the assessment of pain. These factors do not influence pain in isolation but are listed separately for clarity.

Behavioral State. The behavioral state of the infant, ranging from deep sleep to awake and crying, acts as a moderator of behavioral pain responses. The behavioral state of the infant immediately before the painful stimulus affects the robustness of the response. Infants in awake states demonstrate more robust reactions to pain than infants in sleep states. Infants in a drowsy or deep-sleep state will show less vigorous facial expression in response to heelstick than do infants who are alert or aroused before the heelstick (Grunau & Craig, 1987; Mathai, Naresh, & Sahu, 2011; Stevens, Johnston, & Horton, 1994).

Gestational Age. Gestational age affects infant pain responses, with younger infants displaying fewer and less vigorous behavioral responses to pain (Gibbins & Stevens, 2003; Stevens et al., 1994, 1996, 1999). In addition, preterm neonates may demonstrate unique behaviors in response to noxious stimuli. Several researchers have used the Newborn Individualized Developmental Care and Assessment Program (NIDCAP, Children's Hospital, Boston, MA) to examine responses of preterm neonates to a heelstick procedure and found that preterm neonates may uniquely respond to acute pain by increased flexion and extension of arms and legs, finger splay, fisting, frowning, and hand-on-face behaviors (Holsti, Grunau, Oberlander, & Whitfield, 2004; Walden et al., 2001).

Previous Pain Experience. Previous pain experience of preterm neonates may lead to alterations in pain signal processing. Infants who were subjected to more frequent painful procedures in the NICU had decreased behavioral and increased cardiovascular responses compared with infants who experienced less pain, even after controlling for gestational age–related differences in pain expression (Johnston & Stevens, 1996; Stevens et al., 1999).

Caregiver Handling. Term and healthy preterm newborns who were handled or immobilized before a heelstick procedure exhibited greater physiologic and behavioral reactivity, thus indicating that previous stress may result in greater instability in response to pain (Porter, Wolf, & Miller, 1998).

MANAGEMENT OF NEONATAL PAIN

Leaving pain untreated or undertreated is considered unethical due to the availability of validated assessment tools, multimodal treatment options, and abundance of research on neonatal pain (Carter & Brunkhorst, 2017). The goals of pain management in infants are (1) to minimize the intensity, duration, and physiologic cost of the pain experience; (2) to maximize the infant's ability to cope with and recover from the painful experience; and (3) to maintain a balance between pain relief and adverse effects of analgesics (Carbajal, Gall, & Annequin, 2004). Depending on duration and severity, pain may be successfully managed with nonpharmacologic comfort measures and/or pharmacologic therapies.

Prevention of Pain

Painful procedures in the NICU are unavoidable; therefore, it is vital that caregivers assist infants to cope with and recover from necessary but painful clinical procedures. Research suggests that increased neonatal procedural pain is associated with reduced white matter and impaired early brain development in very preterm infants (Brummelte et al., 2012). Therefore, strategies to prevent pain should be employed whenever possible, including grouping blood draws to minimize the number of venipunctures per day, establishing central vessel access when appropriate to minimize vein and artery punctures, and limiting adhesive tape and gentle removal of tape to minimize epidermal stripping.

Nonpharmacologic Comfort Management

Nonpharmacologic pain management is useful for short-term, mild to moderate pain in neonates and in conjunction with pharmacologic modalities for more severe pain (Committee on Fetus and Newborn and Section on Anesthesiology and Pain Medicine, 2016). Nonpharmacologic strategies are hypothesized to directly reduce pain by (1) blocking nociceptive transduction or transmission; (2) activating descending inhibitory pathways; or (3) activating attention or arousal systems that modulate pain. Nonpharmacologic strategies such as hand or blanket swaddling, breastfeeding, nonnutritive sucking (NNS), oral sucrose, and skin-to-skin contact may help minimize neonatal pain and stress while maximizing the infant's own regulatory and coping abilities (Carter & Brunkhorst, 2017).

Environmental Modifications. Infants who are sick or in pain will need changes in the environment to decrease stress and provide a healing atmosphere. These modifications generally include dim lighting, decreased noise, and reduced activity around the bedside (Carter & Brunkhorst, 2017).

Swaddling or Facilitated Tucking. Containment strategies to limit excessive, immature motor responses have been demonstrated to be effective in minimizing pain responses in preterm neonates. Swaddling is thought to reduce pain by providing gentle stimulation across the proprioceptive, thermal, and tactile sensory systems. Several studies have been conducted in the preterm population using either hand or blanket swaddling. A hand-swaddling technique known as "facilitated tucking" (holding the infant's extremities flexed and contained close to the trunk with hand flat on back or containing bottom and cupping the head) has been shown to

attenuate pain responses in preterm neonates by decreasing heart rates, increasing oxygen saturations, decreasing crying time and sleep disruption times, and reducing pain scores during heelstick procedures and endotracheal suctioning (Cignacco et al., 2012; Hartley, Miller, & Gephart, 2015; Obeidat, Kahalaf, Callister, & Froelicher, 2009; Wallace & Jones, 2017).

NNS. NNS is the provision of a pacifier into the mouth to promote sucking without the provision of breast milk or formula for nutrition. NNS is thought to produce analgesia through stimulation of orotactile and mechanoreceptors when a pacifier is introduced into the infant's mouth. NNS is hypothesized to modulate transmission or processing of nociception through mediation by the endogenous nonopioid system (Blass, Fitzgerald, & Kehoe, 1987; Field, 2017; Wallace & Jones, 2017).

NNS has been shown to reduce pain responses in both term and preterm neonates (Pillai Riddell et al., 2011) during immunizations (Liaw et al., 2011) and heelstick procedures (Liaw et al., 2010). A study by Stevens and colleagues found that pain relief was greater in infants who received both NNS and sucrose (Carter & Brunkhorst, 2017; Stevens et al., 1999). A study by Campos (1989) reported a rebound in distress occurred when the NNS pacifier was removed from the infants' mouths. Therefore, the efficacy of NNS is immediate but appears to terminate almost immediately on cessation of sucking (Campos, 1989).

Sucrose. Sucrose with and without NNS has been the most widely studied nonpharmacologic intervention for infant pain management. Sucrose is a disaccharide composed of fructose and glucose. A systematic review of 74 randomized controlled trials of full-term and preterm infants (N = 7,049) found that sucrose is safe and effective for reducing procedural pain in term and preterm neonates, particularly heelstick and venipuncture procedures and intramuscular injections (Stevens, Yamada, Ohlsson, Haliburton, & Shorkey, 2016). Although some additional benefit has been reported with doses up to 50%, doses of 24% sucrose or greater are most effective. A pain-reduction response is noted with dose volumes ranging from 0.05 to 2 mL of a 24% solution administered approximately 2 minutes before the painful stimulus (Stevens et al., 2016). This 2-minute time interval appears to coincide with endogenous opioid release triggered by the sweet taste of sucrose (Blass, 1994). The effect of sucrose appears to last approximately 4 minutes; therefore, repeated doses may be necessary if procedures are prolonged (Stevens et al., 2016). The use of sucrose in combination with other behavioral interventions such as NNS, skin-to-skin holding, and containment may enhance the analgesic effect of sucrose.

Although relatively few contraindications to the provision of swaddling and NNS for management of pain in neonates exist, the absolute safety of sucrose has not been determined. Rare instances of choking and decreased oxygen saturation, all resolving spontaneously, have been reported (Gibbins et al., 2002). Although a study by Willis and colleagues reported an association between sucrose and necrotizing enterocolitis (NEC), other research findings found no significant differences in incidence rates for NEC between infants who received repeated doses of sucrose over 28 days of life compared with control groups (Stevens et al., 2005; Willis, Chabot, Radde, & Chance, 1977). Sucrose should be used with caution in extremely preterm neonates, critically ill newborns, neonates with unstable blood glucose levels, and infants at risk for NEC. Furthermore, sufficient evidence of the safety of repeated doses of sucrose in neonates to recommend its widespread use for repeated painful procedures is lacking (Stevens et al., 2016). Johnston and colleagues reported that preterm infants less than 31 weeks' postmenstrual age who received repeated doses of sucrose for painful procedures showed poorer neurodevelopmental scores at 36 and 40 weeks (Johnston et al., 2002). However, a later study failed to demonstrate significant differences on neurobiologic risk status outcomes between preterm infants who received sucrose plus pacifier, water plus pacifier, or the standard care group (Stevens et al., 2005).

Seventy-one neonates between 24 and 32 weeks' gestational age were studied to determine the effects of sucrose and facilitated tucking alone and in combination. Sucrose is more effective than facilitated tucking alone though there is additional benefit during the recovery phase when sucrose and facilitated tucking are combined (Cignacco et al., 2012).

Skin-to-Skin Contact (Kangaroo Mother Care). Skin-to-skin contact, or kangaroo mother care, has been demonstrated to significantly reduce pain responses in term newborns and preterm neonates greater than 28 weeks' gestational age during heelstick and single painful procedures (Johnston et al., 2003, 2008, 2017). The study by Johnston et al. (2008) also showed that preterm neonates between 28 and 32 weeks' gestational age demonstrated a shorter time to recovery as compared with control neonates who were swaddled and lying prone in an incubator during the heelstick procedure.

Pharmacologic Management

Pharmacologic agents are often required to alleviate moderate to severe procedural, postoperative, or disease-related pain in neonates. Systemic analgesia, topical anesthetics, nonopioid analgesia, and adjunctive medications are reviewed. The most commonly used drugs for analgesia in neonates are listed in Table 23.2.

Opioids. Opioid analgesics are considered the gold standard for pain relief. Opioids are often the preferred choice to manage moderate to severe pain in neonates. Morphine and fentanyl are the most commonly used opioids in the NICU, although other drugs may also be used for pain control in the neonatal population. Opioids have (1) potent analgesic effects, (2) ability to produce sedation but no amnesic or hypnotic effects, (3) few hemodynamic side effects, and (4) availability of antagonist drugs such as naloxone to reverse adverse side effects (Walter-Nicolet, Annequin, Biran, Mitanchez, & Tourniaire, 2010). The most common adverse effects include respiratory depression, bronchospasm, reduced gastrointestinal motility, urinary retention, and pruritus.

Morphine. Morphine is the gold standard for opioid analgesia in critically ill and postoperative neonates. Morphine has a slower onset of analgesia due to lower lipid solubility, especially in preterm neonates. The onset of action is 5 minutes, and the peak effect occurs at 15 minutes (Walter-Nicolet et al., 2010).

Morphine has few effects on the neonatal cardiovascular system in the well-hydrated neonate. Hypotension, bradycardia, and flushing are part of the histamine response to morphine and can be decreased by slow intravenous bolus administration (over 10–20 minutes) and optimizing intravascular fluid volume (Anand, 2007). Although relatively uncommon, the effects of histamine release may also cause bronchospasm in infants with chronic lung disease (Anand, 2007). Decreased intestinal motility and abdominal distention may also occur, causing a delay in the establishment of enteral feeding in the preterm neonate (Anand, 2007). Tolerance of enteral feeds may be improved by priming the gut with small volumes of milk.

Compared with fentanyl, morphine is less likely to cause dependence or withdrawal. Close monitoring and individual titration of the amount and frequency of doses for all neonates receiving morphine therapy is essential (Anand, 2007).

TABLE 23.2

COMMONLY USED DRUGS FOR ANALGESIA IN NEONATES

Drugs	Routes	Dose	Administration Notes
Opioid Analgesics			
Morphine	Intermittent IV, intramuscular, subcutaneous Continuous infusion Oral/parenteral ratio	0.05–0.2 mg/kg 0.01–0.02 mg/kg/hour	Give over at least 5 minutes Repeat as required (usually every 4 hours) Give loading dose of 0.1–0.15 mg/kg over 1 hour Oral dose is 3 to 5 times IV dose; for treatment of opioid dependence, begin at most recent IV morphine dose equivalent and taper 10%–20% per day as tolerated
Fentanyl	Intermittent IV Continuous infusion	0.5–4 mcg/kg 1–5 mcg/kg/hour	Repeat as required (usually every 2–4 hours) Tolerance may develop rapidly after constant infusion Adjust weaning schedule on the basis of withdrawal symptoms
Nonsteroidal Anti-inflammatory			
Acetaminophen	PO	12–15 mg/kg	Give loading dose of 20–25 mg/kg Give loading dose of 30 mg/kg Maintenance intervals: Term infants: give every 6 hours Preterm infants older than or equal to 32 weeks' PCA: give every 8 hours Preterm infants younger than 32 weeks' PCA: give every 12 hours
Local/Regional Anesthetics/Analgesia			
Eutectic mixture of local anesthetics	Topical	1–2 g	Apply and wrap with occlusive dressing; allow to remain intact for 60–90 minutes; remove and clean before procedure to avoid systemic absorption; monitor for methemoglobinemia
Local/Regional Anesthetics/Analgesia			
Liposomal lidocaine cream (4%)	Topical	1 g	Use only on normal, intact skin; prepare the area by washing with mild soap and water; DO NOT use alcohol; apply a small amount of cream and gently massage into the skin, then apply the remainder of the dose in a 1/4-inch thick layer and cover with an occlusive dressing at least 30 minutes before the procedure; remove cream and cleanse area before beginning procedure
Lidocaine 1%[a]	Subcutaneous	0.2–0.5 mL	Epinephrine should never be added to the lidocaine because of its vasoconstrictive properties and the risk of ischemia and necrosis; infiltrate area using 25 G needle approximately 3–8 minutes before procedure

The effect of morphine therapy on neurologic outcomes of preterm neonates is unclear (Zwicker et al., 2016). Although two large randomized controlled trials (NEOPAIN [Neurologic Outcomes and Pre-emptive Analgesia in Neonates] and the EPIPAGE [Etude Epidemiologique sur lest Petits Ages Gestationalles]) suggest that morphine therapy does not have an adverse effect on neurologic outcomes (Anand et al., 2004; Roze et al., 2008), a subsequent study evaluating neurobehavioral outcomes at 36 weeks of neonates enrolled in the NEOPAIN trial suggested that morphine analgesia may result in subtle neurobehavioral differences in preterm neonates (Rao et al., 2007).

The effectiveness of morphine for acute pain caused by invasive procedures remains unclear. Several studies support the effectiveness of morphine analgesia for acute pain (Anand et al., 1999; Taddio et al., 2006), whereas other studies have found no significant analgesic efficacy (Carbajal et al., 2005; Franck, Greenberg, & Stevens, 2000; Saarenmaa, Huttunen, Leppaluoto, Meretoja, & Fellman, 1999; Simons, van Dijk, van Lingen, et al., 2003).

Fentanyl. Randomized clinical trials in neonates have found that fentanyl is approximately 13 to 20 times more potent than morphine (Saarenmaa et al., 1999). Fentanyl is probably the most widely used analgesic in neonates and offers two distinct advantages over morphine (Anand, 2007). First, fentanyl causes less histamine release than morphine and may be more appropriate for neonates with hypovolemia or hemodynamic instability, congenital heart disease, or chronic lung disease (Walter-Nicolet et al., 2010). Second, fentanyl blunts increases in pulmonary vascular resistance. This finding makes it potentially useful in managing pain in neonates with persistent pulmonary hypertension (Walter-Nicolet et al., 2010).

Fentanyl has a more rapid onset (3 minutes) and shorter duration of action (30 minutes) compared with morphine and must be administered as a continuous infusion or as an intravenous bolus every 1 to 2 hours. Accumulation of fentanyl in fatty tissues with extended use may prolong its sedative and respiratory depressant effects and may be responsible for the rebound increase in plasma levels observed following discontinuation of therapy in neonates (Anand, 2007).

Tolerance may develop rapidly with fentanyl, especially with continuous infusions compared with bolus dosing. In addition, dependence and withdrawal are more significant with fentanyl as compared with morphine (Franck, Vilardi, Durand, & Powers, 1998).

Rarely, fentanyl can significantly reduce chest wall compliance (stiff chest syndrome). This naloxone-reversible side effect can be prevented by slow infusion (as opposed to rapid bolus administration) or concomitant use of muscle relaxants.

Prevention of Opioid Withdrawal Symptoms. The rise in opioid use in the United States has resulted in a fivefold increase in neonatal abstinence syndrome (NAS) in NICUs around the country. The incidence of NAS has dramatically risen from 1.19 per 1,000 hospital births in 2000, to 5.63 per 1,000 in 2012 (Sanlorenzo, Stark, & Patrick, 2018). Treatment of these infants may be based on whether there was polydrug use, duration of exposure, use near the time of delivery, and severity of symptoms.

Neonates who require opioid therapy for an extended period of time may develop physical dependence and withdrawal. Rapid weaning of opioids may lead to withdrawal symptoms such as irritability, crying, increased respiratory rate, jitteriness, hypertonicity, vomiting, diarrhea, sweating, skin abrasions, seizures, yawning, stuffy nose, sneezing, and hiccups. The goals of clinical management of opioid withdrawal are (1) to reduce withdrawal symptoms to promote regular sleep cycles and (2) to reduce agitation caused by care interventions (Anand et al., 2010). The prevalence of opioid withdrawal is greater in infants after continuous infusions of fentanyl than continuous infusions of morphine (Franck et al., 1998). Dominguez and colleagues reported a 53% incidence in opioid withdrawal in neonates who received a minimum of 24 hours of fentanyl by continuous infusion. In this study, the most significant risk factors for opioid withdrawal were higher total dose and longer infusion duration. In all neonates with withdrawal, onset of withdrawal symptoms occurred within 24 hours of discontinuation of the fentanyl infusion (Dominguez, Lomako, Katz, & Kelly, 2003).

Data are insufficient to determine the optimal weaning rate of opioids to prevent withdrawal symptoms in neonates on opioid therapy (Hudak, Tan, Committee on Drugs and the Committee on Fetus and Newborn, & American Academy of Pediatrics, 2012). Ducharme, Carnevale, Clermont, and Shea (2005) reported that adverse withdrawal symptoms in children who received continuous infusions of opioids and/or benzodiazepines could be prevented when the daily rate of weaning did not exceed 20% for children who received opioids/benzodiazepines for 1 to 3 days; 13% to 20% for 4 to 7 days; 8% to 13% for 8 to 14 days; 8% for 15 to 21 days; and 2% to 4% for more than 21 days, respectively.

Buprenorphine is gaining recognition for decreasing treatment days and length of hospital stay (LOS) in opioid-exposed infants with NAS (Kocherlakota, 2014; Sanlorenzo et al., 2018). Buprenorphine is a partial mu opioid agonist and administration is sublingual. Studies comparing buprenorphine with morphine or methadone showed from 29% to 46% reduction in length of treatment (Hall, Rice, Folger, & Wexelblatt, 2018; Kraft et al., 2017).

Abstinence scoring methods commonly used in the care of the infant with prenatal drug exposure must be employed in assessing the infant during withdrawal from prolonged opioid use. The Modified Finnegan's Neonatal Abstinence Scoring Tool (Hudak et al., 2012) is the most commonly used tool for assessment of NAS in the United States. Challenges associated with scoring include conducting the assessment when an infant is hungry or sleeping or taking an infant away from parents to assess (Sanlorenzo et al., 2018). Scores may be higher when an infant is irritable with hunger, separated from parents, or awakened leading to unnecessary treatment.

A novel approach to scoring (ESC) was used in a quality improvement project to improve care of NAS patients. The components of the tool are very simple and easy to use clinically and include:

- E = Eat: able to eat 1 or more ounces each feeding
- S = Sleeping: able to sleep for 1 hour or longer when uninterrupted
- C = Console: can be consoled within 10 minutes or less when upset

Outcome measures were average LOS, morphine usage, and associated costs of treatment/LOS. A total of 287 infants were enrolled: 55 in the baseline period, 188 during the intervention period, and 44 in the postimplementation period. Length of stay decreased on average from 22.4 to 5.9 days. Morphine usage decreased from 98% to 14% and costs were reduced from $44,824 to $10,289. There were no reported adverse events and no infants had to be readmitted for NAS (Grossman et al., 2017).

Specific guidelines and/or intervention algorithms guide physicians and staff during opioid weaning and have been utilized successfully by many hospitals (Kocherlakota, 2014). A strict guideline is reported to significantly decrease opioid treatment days, decrease hospital stay, and result in less need for adjunctive drug therapy (Sanlorenzo et al., 2018). If it is possible to treat an infant with NAS outside the NICU, then keeping the mother–infant dyad together is a priority.

Methadone. Methadone is a synthetic opioid that produces prolonged analgesia and has good oral bioavailability, thus making it an attractive option to manage NAS (Hudak et al., 2012). When an infant is being weaned from opioid therapy to a longer-acting oral medication such as methadone, the starting dose of methadone should be calculated to provide a dose equivalent to the dose of opioid the neonate is receiving (Hudak et al., 2012). Further weaning should then be accomplished on the basis of frequent reassessment to ensure that the patient is free of pain and withdrawal symptoms. Studies are needed to further establish the pharmacokinetics and dosing requirements of methadone in neonates.

Topical Application of Local Anesthetics. Topical anesthetics are useful for the management of procedure-related pain in neonates. While EMLA cream ([eutectic mixture of local anesthetics],

lidocaine, and prilocaine; Astra Pharmaceuticals, London) has the best evidence for use in neonates, tetracaine 4% gel (Ametop; Smith & Nephew, London) and liposomal lidocaine cream (LMX 4%; Ferndale Laboratories, Michigan) have also been used in neonates.

EMLA Cream. EMLA cream is approved for use in infants at birth with a gestational age of 37 weeks or greater for a variety of clinical procedures. EMLA produces topical anesthesia when applied as a cream to the surface of intact skin and then covered with an occlusive dressing. The primary concern with the use of EMLA is methemoglobinemia caused by prilocaine toxicity. Neonates, particularly preterm neonates, are at increased risk because of a thinner stratum corneum and less active NADH-dependent (*NADH* dehydrogenase) methemoglobin reductase enzymes that result in higher plasma levels (Sethna & Koh, 2000). Neonates who have anemia, sepsis, hypoxemia, or metabolic acidosis and who are receiving other methemoglobin-inducing drugs such as acetaminophen, phenytoin, phenobarbital, or nitroprusside may also be at increased risk for development of systemic toxicity (Sethna & Koh, 2000). Although it is not routinely recommended for use in preterm neonates, one study found that a single dose of 0.5-g EMLA cream applied for 60 minutes to the intact skin of preterm infants older than 30 weeks' gestation did not result in significant increases in blood methemoglobin concentrations (Taddio, Shennan, Stevens, Leeder, & Koren, 1995). In addition to the risk of methemoglobinemia, local skin reactions have been noted with EMLA cream and have included blanching, redness, and transient purpuric lesions (Sethna & Koh, 2000). Policies and procedures regarding application of EMLA cream should be established to maximize pain relief while minimizing the potential side effects.

Three primary factors determine the effectiveness of EMLA cream: dose, size of application area, and duration of exposure (Sethna & Koh, 2000). The depth of penetration of EMLA is approximately 2 to 3 mm (Walter-Nicolet et al., 2010). The recommended dose in neonates older than 37 weeks is 1 to 2 g applied to the procedure site 60 to 90 minutes before the procedure and covered with an occlusive dressing (Anand, 2018). Multiple studies document the efficacy of EMLA in reducing pain associated with venipunctures and circumcisions (Anand et al., 2005). EMLA has also been documented to be effective in managing pain associated with lumbar puncture (Kaur, Gupta, & Kumar, 2003). EMLA has not been shown, however, to be effective in managing pain associated with heelstick procedures (Anand et al., 2005).

Tetracaine 4% Gel. Tetracaine 4% gel (Ametop; Smith & Nephew, London) has also been investigated in neonates for management of procedural pain. Tetracaine 4% gel produces anesthesia within 30 to 45 minutes of application and has duration of action between 4 and 6 hours (O'Brien et al, 2005). A meta-analysis of six randomized controlled trials comparing tetracaine with EMLA found tetracaine significantly reduced pain associated with intravenous cannulation compared with EMLA. However, tetracaine is ineffective in reducing the pain of heelprick and peripherally inserted central catheters in neonates (Lander, Weltman, & So, 2006). The most commonly reported local skin reaction is transient local erythema. Tetracaine gel is not recommended for use in preterm infants or full-term infants under 1 month of age (Hsu, 2018).

LMX 4%. Another topical local anesthetic currently used in pediatrics for management of procedural pain is liposomal lidocaine cream (LMX 4%; Ferndale Laboratories, Michigan). Several studies have evaluated the efficacy of LMX and EMLA and found a 30-minute application of LMX to be as effective as a 60-minute application of EMLA for producing topical anesthesia for peripheral intravenous access in older children (Eichenfield, Funk, Fallon-Friedlander, & Cunningham, 2002; Kleiber, Sorenson, Whiteside, Gronstal, & Tannous, 2002; Koh et al., 2004). Another study found LMX to be equally effective as EMLA in reducing the pain of circumcision in term newborns (Lehr et al., 2005). LMX may offer an improved risk–benefit profile compared with EMLA, considering the faster onset of action and no risk of methemoglobinemia. LMX does, however, contain an excipient of benzyl alcohol that is known to cause serious respiratory compromise, gasping respirations, metabolic acidosis, and death. Other medications used in the NICU contain benzyl alcohol, propylene glycol, and ethanol, and so providers must be careful when ordering these products to avoid the accumulation of benzyl alcohol and other preservatives capable of toxicity. Excipients are chemical additives to prolong shelf life of medications, increase absorption, manage release of active ingredients, and even enhance taste. Recent studies have shown that neonates in the NICU may be exposed to high levels of excipients, sometimes higher than recommended adult doses (Akinmboni, Davis, Falck, Bearer, & Mooney, 2018; Valeur, Hertel, Lundstrøm, & Holst, 2018). Further studies in neonates are needed to establish the safety and efficacy of LMX for management of procedural pain in neonates.

Nonopioid Analgesics

Acetaminophen. Acetaminophen, also known as paracetamol, is a nonopioid analgesic for short-term management of mild to moderate pain in neonates, but is ineffective for acute procedure-related pain. Acetaminophen has been commonly administered in neonates as an oral or rectal preparation. A study by Zuppa et al. (2011) reports the safety of intravenous administration of acetaminophen in neonates. When intravenous acetaminophen is administered concurrently with opioid analgesia, the effect is additive and allows a reduction in dosages of both drugs, resulting in fewer adverse side effects (Menon, Anand, & McIntosh, 1998; Ohlsson & Shah, 2016).

Little information is available on the pharmacokinetics of acetaminophen administration in neonates, especially administration by the rectal route. Peak concentrations of analgesic effect are reached approximately 60 minutes after an oral dose (Lexicomp, 2018). Elimination half-life is approximately 3 hours in term neonates, but can be as long as 11 hours in more preterm neonates requiring longer dosing intervals with decreasing gestational ages (Young & Mangum, 2011). Acetaminophen is metabolized almost entirely by hepatic conjugation, and elimination may be prolonged in neonates with liver dysfunction. Acetaminophen dosing according to tables with gestational age–related volumes is the safest way when working with preterm and term neonates (Lexicomp, 2018).

At therapeutic doses, acetaminophen is well tolerated and has a low toxicity. Because acetaminophen does not inhibit prostaglandin synthesis in tissues other than the brain, common side effects of nonsteroidal anti-inflammatory drugs—such as inhibition of platelet function, renal insufficiency, and gastrointestinal irritation—do not occur (Anand, Menon, Narsinghani, & NcIntosh, 2000). The primary concern of acetaminophen is liver damage, but this should not be a concern in neonates if standard doses are used (Lexicomp, 2018).

The use of acetaminophen in the first year of life has been reported to increase the risk of asthma, rhinoconjunctivitis, and eczema at 6 to 7 years of age (Beasley et al., 2008). A large Norwegian study provides additional evidence that prenatal and infant acetaminophen is independently associated with increased risk of asthma at 3 and 7 years (Magnus et al., 2016). In a multicenter, prospective, randomized, double-blind, parallel-group study of 300 children ages 12 to 59 months with mild, persistent asthma,

acetaminophen was no more likely to be associated with asthma exacerbation and the need for glucocorticoids than ibuprofen (Sheehan et al., 2016).

Further studies are needed to confirm these long-term adverse effects. Routine prophylactic use of acetaminophen at the time of vaccination is not recommended due to a potential reduction in antibody response (Prymula et al., 2009). In infants, paracetamol before vaccination may interfere with adequate immune responses to pneumococcal antigens, whereas ibuprofen weakens responses to pertussis and tetanus antigens. Antipyretics for fever prophylaxis before and during infant vaccination may need to be reconsidered (Wysocki et al., 2017).

Use of Adjunctive Drugs. In the NICU, the use of sedatives, alone or in combination with analgesics, is controversial. **Quality and Safety: Sedatives suppress the behavioral expression of pain, have no analgesic effects, and can even increase pain. Sedatives should only be used when pain has been ruled out.** When administered with opioids, sedatives may allow more optimal weaning of opioids in critically ill, ventilator-dependent neonates who have developed tolerance from prolonged opioid therapy. No research has been done to determine the safety or efficacy of combining sedatives and analgesics for the treatment of pain in infants. The most commonly administered sedatives in the NICU are benzodiazepines and chloral hydrate.

Benzodiazepines

Midazolam. Midazolam is a short-acting benzodiazepine that is frequently used as a hypnosedative in neonates. Safety concerns with the use of midazolam in neonates have been reported because of the large number of adverse neurologic effects associated with midazolam in term and preterm neonates. Severe hypotension, seizures, respiratory depression, and respiratory arrest have been reported in neonates following continuous infusions or rapid bolus administration (Lexicomp, 2018; Young & Mangum, 2011). Due to uncertainty about its safety, a Cochrane review concluded that data are insufficient to promote the use of intravenous midazolam infusions for sedation in neonates (Ng, Taddio, & Ohlsson, 2017).

Diazepam. Diazepam is not recommended for administration in neonates because of its very prolonged half-life (20–50 hours), its long-acting metabolites, and concern about the benzyl alcohol content. The dose of benzyl alcohol preservative in diazepam is, however, below the dose known to cause fatal toxicity in premature neonates (100–400 mg/kg/day). **Emergency Alert: Caution must be used to ensure other medications do not contain benzyl alcohol that could result in accumulation and higher doses that exceed the toxic amounts. Diazepam displaces bilirubin from albumin-binding sites, thereby increasing the neonate's risk of kernicterus** (Anand et al., 2000).

Chloral Hydrate. Chloral hydrate has been used in single doses to sedate neonates during pulmonary function, radiographic, and other diagnostic testing for which the patient must lie still. The onset of action is 10 to 15 minutes (Young & Mangum, 2011). Adverse effects include bradycardia, gastric irritation, and paradoxical excitement (Young & Mangum, 2011). Although clinically effective, concern has been raised about the potential carcinogenic effects of chloral hydrate administered to mice (Young & Mangum, 2011). The extremely long half-life of chloral hydrate increases the risk of toxicity with repeated administration. It is considered as inferior sedation to other options and comes with a high frequency of adverse reactions. Alternative sedatives (i.e., benzodiazepines) should be used when possible (Lexicomp, 2018).

MANAGEMENT OF SPECIFIC PAIN TYPES

Pain management techniques may vary on the basis of pain type and clinical situation. This section reviews special issues related to procedural pain, postoperative pain, preemptive analgesia for mechanical ventilation, and pain management at EOL.

Procedural Pain

It has been estimated that newborn infants, particularly those born preterm, are routinely subjected to an average of 61 invasive procedures performed from admission to discharge, with some of the youngest or sickest infants experiencing more than 450 painful procedures during their hospital stays (Barker & Rutter, 1995). Many of the procedures commonly performed in the neonate cause moderate to severe pain, with average pain scores of 5 on a 10-point scale (Simons, van Dijk, van Lingen, et al., 2003). Substantial numbers of failed attempts at procedures dramatically increase the number of painful procedures that neonates are subjected to. Simons and colleagues found that the percentages of failed procedures for insertion of central venous catheters, insertion of peripheral arterial catheters, and intravenous cannula insertion were 45.6%, 37.5%, and 30.9%, respectively (Simons, van Dijk, van Lingen, et al., 2003). **Quality and Safety: These frequent, invasive, and noxious procedures occur randomly in the NICU, and many times are not routinely managed with either pharmacologic or nonpharmacologic interventions (Carbajal et al., 2008; Johnston, Barrington, Taddio, Carbajal, & Filion, 2011).** Anand and the International Evidence-Based Group for Neonatal Pain (2001) provide guidelines for preventing and treating neonatal procedural pain. Strategies for the management of procedures commonly performed in the NICU are summarized in Table 23.3 (Anand & the International Evidence-Based Group for Neonatal Pain, 2001).

Local anesthesia may not be sufficient for procedures that affect deeper tissue, such as chest tube insertion or surgical cut down of vessels. Central analgesia is then required to prevent pain. For the nonventilated patient, in whom concern for the respiratory depressant effects of opioids exists, one-half the standard dose may be administered. The infant's respiratory status and responsiveness to pain stimuli can then be assessed before further drug administration. For the infant who is receiving opioid analgesics on a regular basis, a controlled infusion of a bolus dose may be required to provide adequate analgesia during an invasive procedure.

Postoperative Pain

Anticipating and planning is essential to managing postoperative pain. Adequate analgesia is important during the immediate postoperative period for the optimal recovery of the patient. Unrelieved pain can interfere with ventilation and delay weaning. In general, it is thought that the use of low-dose continuous infusions of opioid analgesics provides more constant, effective pain relief with less medication than repeated, intermittent scheduled doses of opioids (Spruill & LaBrecque, 2017). Analgesia is required as long as pain assessment scales along with nursing judgment indicate ongoing pain. Careful weaning may be needed following treatment, especially if the surgery was extensive.

Preemptive Analgesia for Mechanical Ventilation

Opioids are frequently used to sedate, promote respiratory synchrony, produce physiologic stability, and relieve pain or discomfort in ventilated neonates. However, a systematic review and meta-analysis of 13 studies on 1,505 infants concluded that there is insufficient evidence

TABLE 23.3

SUGGESTED MANAGEMENT OF PAINFUL PROCEDURES COMMONLY PERFORMED IN THE NICU

	Procedure	Gentle Technique	NNS ± Sucrose	Containment	Skin-to-Skin Holding	Topical Anesthetic	Opioids	Other/Notes
Mild	Tape removal	√	√	√				
	Endotracheal suctioning	√	√	√	√			
	Oro/nasogastric tube insertion	√	√	√	√			
	Umbilical catheterization	√	√	√				
	Intramuscular injection	√	√	√	√	√		
	Venipuncture/ arterial puncture	√	√	√	√	√		
	Heel lance	√	√	√	√			Use spring-loaded lancet Consider venipuncture for term and older preterm infants
Pain Intensity	Eye examination	√	√	√		√	√	Retinal surgery should be considered major surgery, and opioids should be provided
	Percutaneous/ arterial venous line placement	√	√	√		√	√	
	Endotracheal intubation	√		√			√	Use combination of atropine, morphine/ fentanyl, and nondepolarizing muscle relaxant
	Chest tube insertion	√		√		√	√	Consider subcutaneous infiltration of lidocaine
Severe	Circumcision	√	√	√		√		Dorsal penile nerve block or other regional block

Source: Data from Anand, K. J., & The International Evidence-Based Group for Neonatal Pain. (2001). Consensus statement for the prevention and management of pain in the newborn. *Archives of Pediatrics and Adolescent Medicine, 155*(2), 173–180. doi:10.1001/archpedi.155.2.173

available to recommend the routine use of opioids in mechanically ventilated neonates (Bellu, de Waal, & Zanini, 2010). These recommendations were attributed to failure to decrease pain scores during invasive procedures as well as the lack of overall benefits of morphine therapy on reduction of adverse outcomes such as death, intraventricular hemorrhage, and periventricular leukomalacia.

Pain Management at EOL

Compassionate care and relief of pain and suffering at EOL is a fundamental right of all individuals. Neonates who die as a result of a fatal neonatal illness deserve a good death. According to the Institute of Medicine, "a decent or good death is one that is: free from avoidable distress and suffering for patients, families, and caregivers; in general accord with patients' and families' wishes; and reasonably consistent with clinical, cultural, and ethical standards" (Committee on Palliative and End-of-Life Care for Children and Their Families, Board on Health Sciences Policy, & Institute of Medicine, 2003, p. 40). The quality of the dying process in the NICU is affected by a complex interaction of infant, parent, and caregiver factors (Fortney & Steward, 2014). In 2013, the American Academy of Pediatrics published a policy statement on pediatric palliative care and hospice care, yet significant variation remains in protocols addressing comfort care in pediatrics at EOL (American Academy of Pediatrics Section on Hospice and Palliative Medicine and Committee on Hospital Care, 2013; Haug et al., 2018). **Quality and Safety: Haug et al. (2018) reported that 45% of reporting institutions did not have neonatal comfort care guidelines and, of those reporting, 19% did not address pain symptom management.**

Pain assessment is extremely challenging in neonates at EOL. Caregivers must often consider risk factors for pain and rely on physiologic measures such as increases in heart rate and decreases in oxygen saturation to make pain management decisions. However, using a pain scale to measure pain in neonates at EOL remains a clinical standard as it provides an objective approach to assessing pain and facilitates improved communication about the infant's pain between professionals as well as with the infant's parents (Carter & Jones, 2013).

Pain management at EOL primarily centers on the provision of opioids to minimize pain and nonpharmacologic therapies to enhance the infant's comfort level (Walden, 2001). Continuous infusions of opioid therapy such as morphine and fentanyl are often required to manage pain at EOL and should be titrated to desired clinical response (analgesia). Opioid doses well beyond those described for standard analgesia are often required for infants who are in severe pain or who have developed tolerance (decreasing pain relief with the same dosage over time) after the prolonged use of opioids (Partridge & Wall, 1997). Physiologic comfort measures may palliate pain and distressing symptoms in infants at EOL and include reduction of noxious stimuli, organization of caregiving, and positioning and containment strategies (Walden, Sudia-Robinson, & Carrier, 2001).

A request for a palliative care consult often makes parents struggle with the decision as they often perceive this as "giving up" on their infant. Conversely, palliative care services may provide an added layer of support to parents and the healthcare team caring for an infant at EOL (Currie et al., 2016).

PARENTS

Nurses who care for the infant in pain must care for the infant's family as well. Parents have many concerns about their infants' pain and about the interventions used in the treatment of pain (Franck, Allen, Cox, & Winter, 2005; Gale, Franck, Kools, & Lynch, 2004). Several research studies have reported common barriers and facilitators of parental involvement in neonatal pain management (Franck, Oulton, & Bruce, 2012; Marfurt-Russenberger, Axelin, Kesselring, Franck, & Cignacco, 2016; Palomaa, Korhonen, & Polkki, 2016). Barriers often cited include parental emotional state, not wanting to be in the way, lack of knowledge, competing home and life requirements, medical equipment or health status of the infant, and unsupportive staff attitudes and paternalism toward parents. Parental suggestions for improving infant pain management have included increased education and advanced preparation on how to comfort their infant during painful procedures, increased use of standardized protocols for managing pain consistently, and family-friendly space and environment that supports parental presence and participation in their infant's pain relief (Franck et al., 2012; Marfurt-Russenberger et al., 2016; Palomaa et al., 2016).

A source of parental stress often occurs when there is a mismatch between parent and staff perceptions of the infant's pain (Gale et al., 2004). It is important to provide parents with consistent information about pain assessment and management. Debriefing with parents following a pain experience is a strategy that can be used to minimize disagreements between parents and nurses regarding pain intensity in the infant and may increase the potential for meaningful collaboration in improving the infant's pain care in the NICU.

Parents should be encouraged to participate in providing nonpharmacologic comfort measures to their infants during minor painful procedures. Several studies have shown that facilitated tucking by parents is an effective and safe pain management method during painful procedures in the NICU (Axelin, Lehtonen, Pelander, & Salantera, 2010; Axelin, Salantera, Kirjavainen, & Lehtonen, 2009; Axelin, Salantera, & Lehtonen, 2006). Depending on the nature of the medical procedure, increasing parental participation in providing comfort measures to their infant during painful procedures may help to moderate parental stress and optimize the parent–infant relationship (Miles & Holditch-Davis, 1997).

NEONATAL NURSE'S ROLE AND RESPONSIBILITIES

Provision of comfort and relief of pain are two primary goals of nursing care. To accomplish these goals, neonatal nurses must (1) prevent pain when possible, (2) assess pain in their neonatal patients who cannot verbalize their subjective experience of pain, (3) provide relief or reduction of pain through implementation of nonpharmacologic and/or pharmacologic measures, and (4) assist the infant in coping when pain cannot be prevented.

The effective management of infant pain requires nurses to collaborate with each other, with physicians, and with the infant's parents. Nurses must effectively communicate assessments and recommendations in an objective, concise manner and advocate for pain relief strategies with responsible healthcare team members. Neonatal nurses must remain informed about professional standards and clinical guidelines related to pain assessment and management in neonates. The nurse should also participate in ongoing pain education and review of new research and scientific developments.

SUMMARY

Pain in neonates is often assessed and managed inadequately in a large proportion of neonates in the NICU. It is clear, however, that caring for infants in pain requires attention not only to the immediate effects but also to the long-term developmental consequences of pain and pain treatment. Through ongoing research, objective assessment, effective collaboration, and systematic application of treatment plans, nurses will achieve greater comfort for individual patients and add to the body of knowledge in this rapidly evolving field.

CASE STUDY

■ **Identification of the Problem.** Term female infant with pain related to probable epidermolysis bullosa (EB) and extensive blistering of lower extremities

■ **Assessment: History and Physical Examination.** The term, 3,600-g female was born via vaginal delivery to a 19-year-old, unmarried, Hispanic, G2 P2, mother with minimal prenatal care. Maternal labs were unremarkable, including negative history for herpes. Maternal history positive for previous infant with confirmed EB. At birth, the infant was noted to have a vigorous respiratory effort at birth with Apgars 9 and 9 at 1 and 5 minutes of life, respectively. Significant bullous skin lesions were noted on the right lower leg and left ankle. She was transferred to the NICU for care.

Once in the NICU, she was placed in a dual radiant warmer/incubator bed and placed on continuous cardiorespiratory monitoring. An umbilical venous line was placed. Blood was sent for complete blood count (CBC) with differential and blood culture. Intravenous fluids were started along with small feedings of expressed breast milk or formula.

Physical examination on admission to the NICU was:

- Vital signs: heart rate 172; respiratory rate 38; temperature 97.6 axillary; blood pressure 68/47 MAP 54
- General: term-appearing infant with signs of pain and distress with handling
- HEENT: anterior fontanelle soft, flat, and large; sutures approximated; normocephalic; red reflex deferred; nares patent; mucous membranes moist and pink
- RESP: bilateral lung sounds clear and equal; respirations unlabored and of normal rate; no retractions, grunting, or nasal flaring
- CV: regular rate and rhythm. S_1 and S_2 present without murmur; strong and equal brachial and femoral pulses; capillary fill time less than 3 seconds
- ABD: soft and slightly rounded; normal bowel sounds; no hepatosplenomegaly
- Genitourinary: female genitalia appropriate for gestation; anus patent and appropriately positioned
- NEURO: Normal tone and activity; good grasp, suck, Moro; irritable with crying and facial grimacing
- SKIN: pink and warm; significant skin lesions on the right lower leg and left ankle
- Extremities: normotonic; full range of motion of all extremities; spine straight, midline without deformity

■ **Diagnoses**

- Term infant with probable EB
- Pain related to skin lesions

■ **Diagnostic Tests**

- CBC: WBC 13.2; Hgb 17; Hct 47.5; Plt 60; Segs 67; Lymphs 15; Monos 4; Eos 0; Bands 12
- Glucose 93
- Chromosome panel: pending
- Will need skin biopsy and other tests as determined by consultations with Genetics and Dermatology for final diagnosis

■ **Development of Management Plan for Pain**

1. Use CRIES to assess for pain with vital signs and before, during, and after procedures or dressing changes.
2. Strategies for prevention of pain: Vital signs per monitor. Reduced frequency of BPs to every day to reduce friction to the skin. If nasogastric tube is needed for feedings, secure with nonadhesive methods such as TubiFast or silicone tape for fragile skin.
3. Dysphagia may occur secondary to pain, oral blistering, and scarring. Use a Haberman or Lamb's nipple to reduce oral friction with nippling. Consult with pharmacy regarding oral topical anesthetic to be administered before nippling.
4. Protect skin by using dressings on bony prominences, egg-crate mattresses, sheepskins, and moist healing environment; avoiding tape; and avoiding trauma. Use petrolatum-based emollients covered with antibiotic ointments and nonstick dressings (e.g., Mepitel® dressings). Wrapping gauze, cotton mesh, or self-adhering elastic wrap (e.g., Coban™) around the dressing can protect and reduce friction.
5. Remove dressings carefully using gentle technique. Consider removing during bathing.
6. Reduce frequency of NICU interventions such as temperature taking, blood pressures, weighing, and so on.
7. Use mittens for the baby's hands and feet.
8. Administer fentanyl pro re nata (PRN) for CRIES scores of 5 or above. Consider weaning to an oral opioid when intravenous access is no longer needed.
9. Administer fentanyl before dressing changes and procedures anticipated to be of moderate to severe pain intensity.
10. Consult Dermatology and Wound Care for further recommendations to maintain skin integrity and manage open wounds.
11. Educate parents on how to provide protective, prophylactic, and therapeutic care for their infant with EB.

EVIDENCE-BASED PRACTICE BOX

Reducing Pain Associated With Screening for Retinopathy of Prematurity

Infants born less than 1,500 g or less than 32 weeks are routinely subjected to necessary ophthalmologic screening for retinopathy of prematurity (ROP). Screening examinations are a significant source of pain and discomfort and are associated with physiologic instability in preterm neonates. Dempsey and McCreery (2011) published a Cochrane systematic review to determine the effect of instillation of topical anesthetic eye drops on pain responses of preterm neonates undergoing ROP screening. Only two randomized crossover studies were identified for inclusion in the analyses. The authors concluded that the administration of proparacaine eye drops at least 30 seconds before the examination was associated with a reduction in pain scores, but was not effective in eliminating pain. The authors recommended that future studies should address the role of both nonpharmacologic and pharmacologic interventions, including different

(*continued*)

EVIDENCE-BASED PRACTICE BOX (*continued*)

local anesthetic agents, NNS, sucrose, and swaddling to reduce pain associated with this common procedure.

Investigators in a double-blind randomized controlled trial of 60 preterm infants gave topical anesthetic drops, then compared breast milk, sucrose, and distilled water before and after ROP exam. Due to the shorter recovery time with breast milk, they recommend breast milk over sucrose for pain management of ROP eye exams. The breast milk group also had lower mean heart rates and higher oxygen saturations than the sucrose group (Taplak & Erdem, 2017).

CHAPTER 24

Fetal Therapy

Taryn M. Edwards and Tamara M. Meeker

INTRODUCTION

Fetal therapy includes any intervention (invasive and/or noninvasive) performed to improve the health of children by intervening before birth to correct or treat a prenatally diagnosed abnormality. These therapies include ultrasound-guided needle procedures (fetal blood sampling, intrauterine blood transfusion, shunts, balloon valvuloplasty or septostomy, and radiofrequency ablation), fetoscopic procedures (posterior urethral valves [PUVs], photocoagulation, umbilical cord occlusion, tracheal occlusion, and amniotic band release), open fetal surgery (OFS; myelomeningocele [MMC] repair, lobectomy, and teratoma resection), and *ex-utero* intrapartum treatment (EXIT; Moon-Grady et al., 2017). This chapter will provide a historical overview of fetal therapy, the importance of a multidisciplinary approach, fetal diagnoses amenable to fetal therapy, and care of the maternal–fetal dyad before, during, and after intervention.

HISTORICAL OVERVIEW

The history of fetal therapy started over three decades ago when practitioners met to discuss this emerging field. The overall goal of this meeting was to change the outcomes for diseases like hydrocephalus, obstructive uropathy, and pulmonary hypoplasia (Moon-Grady et al., 2017). Initial experiments related to fetal therapy focused on how to safely and effectively gain access to the uterus. Next, the fetal surgical approaches needed to be studied, which were initially performed on animal models, such as dogs, rabbits, primates, and lambs (Deprest et al., 2010).

In 1963, Sir William Liley made medical history when he became the first doctor to give a fetus a blood transfusion before birth (McMann, Carter, & Lantos, 2014). The significance of his achievement was not only a major advancement in the management of erythroblastosis fetalis but also the first real demonstration that the fetus is accessible to skilled diagnosis and treatment. The story of modern fetal surgery started with Dr. Harrison at the University of California, San Francisco (UCSF). In 1981, a multidisciplinary team at UCSF became the first group to clinically attempt correction of urinary tract obstruction in utero by placing a catheter into the fetal bladder to bypass the obstruction and prevent pulmonary hypoplasia or renal failure (Deprest et al., 2010). See Table 24.1 for additional fetal therapy hallmark cases.

TABLE 24.1

TIMELINE IN THE EVOLUTION OF FETAL THERAPY

Year	First	Open vs. MIS
1963	Fetal transfusion	MIS
1981	Vesicoamniotic shunt placement	MIS
1982	Fetal surgery	Open
1984	Lung lesion resection	Open
1987	Fetal thoracoamniotic shunt placement	MIS
1990	Laser ablation for TTTS	MIS
1992	Sacrococcygeal teratoma debulking	Open
1995	EXIT procedure	Open
1997	Fetoscopic repair of myelomeningocele	MIS
1997	"Fetendo" tracheal clipping for CDH	MIS
1997	Fetoscopic release of amniotic band	MIS
2001	Fetoscopic balloon tracheal occlusion for CDH	MIS

CDH, congenital diaphragmatic hernia; EXIT, *ex-utero* intrapartum therapy; MIS, minimally invasive surgery; TTTS, twin-to-twin transfusion syndrome.

Source: With permission from Graves, C. E., Harrison, M. R., & Padilla, B. E. (2017). Minimally invasive fetal surgery. *Clinics in Perinatology, 44*(4), 729–751. doi:10.1016/j.clp.2017.08.001

ETHICAL CONSIDERATIONS

Since the fetus became a patient over three decades ago, there has been an increase in overall acceptance to this ever-changing patient population. Given that fetal interventions are motivated by beneficence, ethical considerations must include maternal autonomy and decision making (American College of Obstetricians and Gynecologists [ACOG] Committee on Ethics & American Academy of Pediatrics [AAP] Committee on Bioethics, 2011; Titus & Moodley, 2012). Any fetal intervention has implications on maternal health, without actual benefit to the mother; therefore, these interventions cannot be performed without her informed consent. The goals of the treatment and any conflicting data or paucity of data should be disclosed at that time (Titus & Moodley, 2012). A thorough unbiased discussion that includes the risks and benefits to the fetus as well as the risks and benefits of obstetric and neonatal care without fetal intervention should be had at that time. Maternal risk is primarily related to the high incidence of preterm labor and its corresponding morbidity, risk of infection, and bleeding. There is an increased risk of uterine rupture after hysterotomy (Al-Refai, Ryan, & Van Mieghem, 2017), which is associated with significant maternal morbidities and mortalities that place subsequent pregnancies at risk (ACOG Committee on Ethics & AAP Committee on Bioethics, 2011).

In addition to uterine rupture, pulmonary edema after fetal intervention can be due to generous volume overload during OFS, fluid resorption after laser ablation for twin-to-twin transfusion syndrome (TTTS), or from tocolytic use especially when different classes of tocolytics are used together (Al-Refai et al., 2017). **Emergency Alert: Complications of OFS include placental abruption, chorioamnionitis, and possible need for blood transfusion.** Fertility is not affected and the miscarriage rate in subsequent pregnancies is comparable with baseline. Risks to the fetus include intrauterine demise, bleeding depending on the intervention, failed intervention requiring repeated attempts, and premature birth.

Maternal–Fetal Imaging

Ultrasonography is an essential adjunct to prenatal diagnostic procedures that has laid the groundwork for fetal therapy that is performed today. This method of imaging is used to confirm the fetal gestational age and number, malformations, fetal well-being, and aid in procedures like amniocentesis, chorionic villus sampling, and percutaneous umbilical blood sampling. In addition, it is used to determine placenta location and blood flow to the fetus. Although prenatal diagnoses are primarily made by ultrasound, ultrafast fetal MRI has been helpful in ruling out alternative diagnoses (Khalek & Johnson, 2013). Fetal MRI may be more sensitive than ultrasound due to high soft-tissue contrast (Euser, Meyers, Zaretsky, & Crombleholme, 2016). The advantages of MRI include the use of multiple planes for reconstruction and a large field of view, making the visualization of complicated anomalies easier. For the most accurate diagnosis and detailed anatomy, imaging should include the following: high-resolution 3D and 4D ultrasound, MRI, and echocardiography (Rintoul, Ades, & Adzick, 2018).

Multidisciplinary Team Approach

Quality and Safety: For maximum benefit, candidates for fetal surgery should be identified and referred before 23 weeks' gestation. This allows the multidisciplinary team to evaluate the maternal–fetal dyad and perform appropriately timed interventions. After 30 weeks' gestation, manipulation of the uterus is associated with a higher risk of premature rupture of the membranes (PROM) and preterm labor; thus, delivery of the fetus and treatment of the malformation with standard postnatal care becomes a more reasonable approach (Kiatano, 1999). When fetal therapy is the chosen treatment, the clinical case must be broken down into six phases: diagnosis, information and decision making, perioperative and postoperative care, home care and follow-up, delivery, and neonatal period. Each phase involves distinct and important nursing input and responsibilities.

Once the mother is referred to a fetal treatment center, the family is given information about the reason for the referral and the evaluation process. For many families, this is the most difficult time, and the nurse should provide appropriate and sufficient information about the process to help families cope during this stressful situation. The nurse must recognize that the family is experiencing the loss of a normal pregnancy and experiencing anxiety of an uncertain future. The diagnostic phase includes maternal evaluation, including physical examination as well as blood work. Fetal evaluation includes imaging via 3D or 4D ultrasound, ultrafast MRI, and genetic testing. The information collected during this phase will determine whether the maternal–fetal dyad is a candidate for fetal therapy. See Box 24.1 for inclusion and exclusion criteria for fetal therapy.

Given the complexity of fetal therapy, a multidisciplinary team approach is needed to care for the mother and fetus. This team should include a perinatologist, neonatologist, pediatric surgeon (cardiologist, urologist, neurosurgeon, fetal), sonographer, anesthesiologist, operating room and perinatal nurse specialists, social work, and a nurse coordinator who can serve as a liaison with the family

At the time of delivery, the multidisciplinary team for the mother includes obstetric and/or operating room nurses, certified nurse midwife, obstetrician, and anesthesiologist. For the newborn, the team includes neonatologist, surgical advance practice nurse, neonatal nurses, and neonatal respiratory therapist. These team members have advanced knowledge in fetal therapy procedures and are certified neonatal resuscitation providers (Neonatal Resuscitation Program [NRP]).

Box 24.1

CRITERIA FOR FETAL THERAPY

Maternal Exclusion Criteria

- Maternal age <18 years
- History of cervical insufficiency and/or short cervix <20 mm on transvaginal ultrasound
- Placenta previa
- Other serious maternal medical condition
- Previous spontaneous singleton delivery <37 weeks' gestation
- Maternal–fetal Rh alloimmunization
- Uterine anomaly
- Psychosocial limitations
- Inability to comply with travel and follow-up

Fetal Inclusion Criteria

- Singleton with no additional fetal anomalies related to primary diagnosis
- Normal karyotype
- Ultrasound evidence of cardiac dysfunction and/or hydrops
- Gestational age <32 weeks

Procedures

One of the best-known forms of fetal therapy is transplacental passage of maternal medications, like corticosteroids, antiarrhythmic drugs, and intravenous immunoglobulins (Al-Refai et al., 2017). Steroids have been used in treating fetal conditions like congenital adrenal hyperplasia, lung maturation, and experimentally in the treatment of anti-Ro/La antibody-mediated fetal heart block (Al-Refai et al., 2017). Persistent fetal tachyarrhythmias, like supraventricular tachycardia and atrial flutter, will often lead to fetal hydrops and demise. Antiarrhythmic agents, like digoxin, flecainide, or sotalol, have been administered to healthy pregnant women without adverse cardiac events being reported for the mother. Lastly, intravenous maternal administration of immunoglobulins treats fetal alloimmune thrombocytopenia (Al-Refai et al., 2017). Although medical interventions can be performed for amenable fetal conditions, there are other conditions where surgical interventions may be needed.

Minimally invasive fetal surgery (MIFS) and procedures have become popular options due to the rise in popularity of adult laparoscopic surgery and the development of size-appropriate fetoscopic instruments. Minimally invasive procedures can be used to treat prenatal diagnoses such as congenital diaphragmatic hernia (CDH), lower urinary tract obstruction (LUTO), TTTS, intravenous fetal blood transfusion for anemia, and cardiac anomalies such as aortic stenosis (Saracoglu, Saracoglu, & Kafali, 2016; Wenstrom & Carr, 2014). As with OFS and the EXIT procedure, MIFS and procedures require an experienced, multidisciplinary team approach; many members of the team meet weekly to discuss upcoming cases and corresponding imaging (Graves et al., 2017). The minimally invasive fetal teams typically include members of the following disciplines: fetal/pediatric surgery, obstetrics, maternal–fetal medicine (MFM), anesthesia, cardiology, urology and obstetric/perinatal, operating room, and neonatal nursing.

Closed fetal procedures are performed under ultrasound guidance, employ the use of a needle or a trocar, either of which is inserted through the maternal abdominal and uterine walls, and are usually limited to one access point (Nassr, Erfani, et al., 2017). Needle-based procedures are percutaneous umbilical blood sampling, balloon valvuloplasty, shunt placement (thoracoamniotic or vesicoamniotic), and radiofrequency ablation (Hoagland & Chatterjee, 2017). Closed fetal procedures are performed under local and/or regional (epidural or spinal) anesthesia (Nassr, Erfani, et al., 2017; Wenstrom & Carr, 2014). The procedures are typically performed percutaneously; however, it can be performed via a small laparotomy giving better access to the uterus (Nassr, Erfani, et al., 2017; Wenstrom & Carr, 2014). The benefit of greater exposure to the uterus becomes important for the surgeons when the case is particularly difficult, or the fetal position needs to be changed or maintained.

The importance of real-time ultrasound imaging during minimally invasive fetal procedures cannot be underscored enough. Ultrasound is used to ensure safe entry to the uterus, as well as identify placental position, fetal position and well-being, fetal cardiac function, and umbilical artery blood flow. In the situation of an anterior placenta, curved instruments can be utilized to avoid the placenta while under ultrasound guidance (Graves et al., 2017).

The fetoscopic approach is the second mode of minimally invasive fetal procedures and is utilized for ablation of PUVs, amniotic band release, tracheal occlusion, laser photocoagulation for TTTS, and umbilical cord coagulation (Hoagland & Chatterjee, 2017). Fetoscopy is performed in a manner similar to that of the closed procedures. Real-time ultrasound guidance is used to ensure safe access to the uterine cavity and is used as an adjunct to the fetoscope to visualize the fetus and its well-being throughout the procedure (Graves et al., 2017). Depending on the procedure and number of ports required, the mother can have from one to several small incisions on her abdomen or a small laparotomy as with the closed procedures. To optimize visual clarity in the uterus when the amniotic fluid is not clear, an amnio-exchange with warmed saline can be used during the procedure to improve visualization of the fetus (Graves et al., 2017). Complications of fetoscopic procedures are bleeding, membrane separation, chorioamnionitis, amniotic fluid leakage, PROM, premature labor, premature birth, and intrauterine fetal demise. PROM and premature labor are the most common complications of MIS and lead to significant fetal morbidity in the form of oligohydramnios, lung hypoplasia, chorioamnionitis, and premature birth (Graves et al., 2017). Additionally, the number of access sites on the maternal abdomen and the size of the fetoscopic instruments have been linked to fetal morbidity with larger diameter instruments significantly decreasing gestation age at birth (Graves et al., 2017). Minimally invasive procedures, as they relate to specific diagnoses, will be discussed elsewhere in the chapter.

Fetal Surgery

Since its introduction in the mid-1960s, fetal therapy, specifically fetal surgery, has evolved to meet the needs of life-threatening fetal diagnoses with continued focus on decreasing the risk to the mother for said procedures. In addition to its primary applications (urinary obstruction and fetal anemia), diagnoses amenable to fetal interventions include MMC, TTTS, cervical neck masses, lung lesions, sacrococcygeal teratoma (SCT), and CDH (Wenstrom & Carr, 2014). As fetal surgical techniques have been validated with randomized controlled trials (RCTs) and now have evidence-based rationales, several aspects of the process require further study, identifying the optimal maternal–fetal dyad, optimal timing for the fetal intervention, and prevention of premature labor and global membrane separation following the procedure (Wenstrom & Carr, 2014). Through rigorous science, scientists and fetal surgeons have identified fetal diagnoses amenable to fetal intervention, extensively studied the natural history of each of the diagnoses, tested potential fetal interventions in animal models prior to humans, and safely carried out such interventions in humans on the fetus, itself, now recognized as a patient (Graves et al., 2017; Upadhyaya & Lander, 2013). Additional work utilizing a minimally invasive approach, developed by modeling laparoscopic surgical approaches and instruments, has further decreased fetal morbidity and mortality as well as decreased maternal risk (Graves et al., 2017). Table 24.2 highlights the milestones in both open and minimally invasive fetal procedures.

Open Fetal Surgery

OFS has long been reserved for the most severe cases in which the life of the fetus is in peril with one exception; the fetus with MMC. The procedure itself is similar to the EXIT procedure described next. The mother is anesthetized with general endotracheal anesthesia in addition to epidural anesthesia. In the case of OFS, the epidural serves two functions, both intraoperative and postoperative pain management for the mother (Moldenhauer & Adzick, 2017). Depending on the fetal position and more importantly the placental position, the hysterotomy will either be anterior or posterior (after the uterus is exteriorized). Regardless of the location of the hysterotomy, it will be performed in the fundus (Moldenhauer & Adzick, 2017). The hysterotomy begins with electrocautery followed by the uterine stapling device to ensure a bloodless operative field and control of the membranes (Harrison & Adzick, 1993; Moldenhauer & Adzick, 2017). The uterus is irrigated continuously

TABLE 24.2

FETAL CONDITIONS AMENABLE TO IN-UTERO TREATMENT

Condition	Intervention
Fetal Therapy: Medical Treatment	
Rh sensitization (anemia)	Red cell transfusion (into umbilical vein)
Pulmonary immaturity	Betamethasone (transplacental)
Vitamin B_{12} deficiency	Vitamin B_{12} (transplacental)
Carboxylase deficiency	Biotin (transplacental)
Supraventricular tachycardia	Digoxin, flecainide, or similar drug (transplacental)
Heart block	Betamimetics (transplacental)
Hypothyroidism	Thyroxine (transplacental)
Adrenal hyperplasia	Steroids
Intrauterine growth restriction	Protein calories (transamniotic)
Severe combined immunodeficiency syndrome	Stem cell transplantation into umbilical vessel
Congenital cystic adenomatoid malformation	Maternal steroid administration
Sickle cell disease	Gene therapy
Fetal Therapy: Surgical Treatment	
Urinary tract obstructions	Closed procedure (i.e., percutaneous catheter placement or fetal bladder cystoscopy)
Twin reversed arterial perfusion	Closed procedure (interruption of blood flow to the abnormal fetus by ablating blood vessels)
Twin-to-twin transfusion syndrome	Closed procedure (laser ablation of intertwin vascular connections)
Diaphragmatic hernia	Closed procedure (i.e., temporary tracheal occlusion with a balloon)
Myelomeningocele	Open procedure (i.e., open repair of spinal defect)
Sacrococcygeal teratoma	Closed procedure (i.e., interruption of blood flow to the tumor by ablating/sclerosing vessels) or open procedure (i.e., resection or debulking of tumor)
Pleural effusion	Closed procedure (i.e., placement of thoracoamniotic catheter for decompression)
Aortic stenosis (hypoplastic left heart syndrome)	Closed procedure (i.e., balloon valvuloplasty)
Hypoplastic left heart syndrome with intact atrial septum	Closed procedure (i.e., balloon septostomy)
Pulmonary atresia	Closed procedure (i.e., balloon valvuloplasty)
Congenital high airway obstruction syndrome	Closed procedure (laser ablation of obstruction) and/or open procedure (delivery via *ex-utero* intrapartum treatment procedure after establishment of fetal airway while on placental bypass)

with warmed lactated Ringer's (LR) or warmed normal saline solution (NSS) to maintain fetal buoyancy, fetal thermoregulation, and uterine distension (Moldenhauer & Adzick, 2017). Although receiving maternal anesthesia via the placenta, the fetus is given additional sedation and a neuromuscular blockade drug (NMBD) for paralysis, as NMBDs do not cross the placenta (Bouchard et al., 2002; H. L. Hedrick et al., 2005; Hirose et al., 2004; Laje et al., 2012). **Quality and Safety: Atropine is administered to the fetus to prevent fetal bradycardia** (Bouchard et al., 2002; H. L. Hedrick et al., 2005; Hirose et al., 2004; Khalek & Johnson, 2013; Laje et al., 2012). The fetus is monitored during the procedure via pulse oximetry and sterile fetal echocardiography as maternal general anesthesia acts as a fetal myocardial depressant (Khalek & Johnson, 2013; Moldenhauer & Adzick, 2017). Additionally, intravenous access is obtained in the fetus for medication and volume administration. For example, premedicating with volume is required for fetal lung lesion resection as removal of a large lesion from the fetal chest can precipitate a rapid decline in fetal cardiac output (Khalek & Johnson, 2013). Once the fetal surgery is complete, and regardless of the defect, the uterus is closed in two layers to make the closure watertight and the LR or NSS is infused until the final suture is placed to return the amniotic fluid levels to normal and allow for intra-amniotic antibiotic to be infused; the infusion catheter is then removed and an omental flap is placed over the sutured hysterotomy to help further seal it (Khalek & Johnson, 2013; Moldenhauer & Adzick, 2017). The laparotomy is then closed, the mother is recovered, and her care then follows a postoperative protocol (Nassr, Erfani, et al., 2017; Peranteau et al., 2014). As with the EXIT procedure, delivery of the pregnancy affected by OFS and all subsequent pregnancies should avoid active labor and be delivered by cesarean delivery to prevent uterine rupture (Graves et al., 2017; Moldenhauer, 2013; Nassr, Erfani, et al., 2017). The timing of a pregnancy subsequent to OFS should be at least 2 years (Nassr, Erfani, et al., 2017).

EXIT Procedure

Ex-utero intrapartum therapy (or treatment), also referred to as an EXIT procedure, is the process of performing a lifesaving intervention on the fetus via an open uterine incision while the mother is deeply anesthetized; the uterus is relaxed and distended and the fetus is partially delivered but remains on placental bypass (Mychaliska et al., 1997). The purpose of the EXIT procedure is to stabilize the fetus prior to birth when there is an anatomic defect that will significantly increase the chance of morbidity and mortality and interfere with the fetus' successful transition to extrauterine life. Initially developed for the establishment and securement of an airway in a fetus that had a prior in-utero tracheal occlusion for CDH, the EXIT procedure can and has been used for the following congenital anomalies: cervical or oropharyngeal teratoma, mediastinal teratoma, cervical lymphangioma, laryngeal atresia, congenital high airway obstruction syndrome (CHAOS), tracheal web, severe subglottic stenosis, facial tumors, resection of large lung lesions, and cannulation for extracorporeal membrane oxygenation (ECMO; Bouchard et al., 2002; Hirose et al., 2004; Laje et al., 2012; Moldenhauer, 2013; Mychaliska et al., 1997).

While the EXIT procedure results in a cesarean-like birth, there are some important distinctions to differentiate one procedure from the other. Once a prenatal diagnosis is made that has proven amenable to the EXIT procedure, a referral must be made to a tertiary center with an established and highly experienced MFM and fetal/pediatric surgery group. The maternal/fetal dyad must first be assessed for appropriateness for the procedure. The prenatal diagnosis must be confirmed utilizing advanced diagnostic techniques such as high-resolution fetal sonography, ultrafast fetal MRI, and fetal echocardiography (Moldenhauer, 2013). Adjuvant testing may include karyotyping and further genetic testing, where indicated. A comprehensive multidisciplinary team is essential in the diagnosis, planning, and execution of the EXIT procedure and should include high-risk obstetricians and MFMs, fetal/pediatric surgeons, anesthesiologists, radiologists, pediatric cardiologist, neonatologists, nurses of varying specialties, advanced practice nurses, social workers, case managers, and potentially an ECMO team (Bouchard et al., 2002; Hirose et al., 2004; Laje et al., 2012; Moldenhauer, 2013). A substantial amount of teaching is required by the multidisciplinary team to help the family understand not only the diagnosis but also the procedure itself including all risks and potential outcomes. **Emergency Alert: Diverging from any of the aforementioned practice recommendations may lead to suboptimal outcomes or even death for both the mother and the fetus.**

The procedure itself involves a very large multidisciplinary team in the operating room that must operate in seamless coordination with each other, especially considering the time constraint, the significance of the procedure, and the size of the patient and corresponding surgical field. Prior to the procedure, the placenta must be mapped and its margins clearly delineated. If the placenta is anterior, options for hysterotomy include classic cesarean incision, fundal incision, or even posterior uterine incision (Bouchard et al., 2002; H. L. Hedrick et al., 2005; Hirose et al., 2004; Laje et al., 2012; Moldenhauer, 2013; Noah et al., 2002). Placental mapping can be difficult in the setting of polyhydramnios that often accompanies airway obstruction (Bouchard et al., 2002; H. L. Hedrick et al., 2005; Mychaliska et al., 1997). In such cases, an amnioreduction can be performed. To start, the mother is positioned supine and slightly in left-lateral decubitus. This facilitates offloading the gravid uterus from the inferior vena cava, which in turn will promote hemodynamic stability in the mother throughout the case (Bouchard et al., 2002; Hirose et al., 2004; Moldenhauer, 2013). The mother is endotracheally intubated and placed under deep general anesthesia to promote uterine relaxation. This is accomplished with inhaled halogenated anesthesia and adjuvant tocolytics, as needed (Bouchard et al., 2002; Hirose et al., 2004; Laje et al., 2012; Moldenhauer, 2013; Mychaliska et al., 1997). Maternal monitoring is standard for a patient under general anesthesia. After abdominal incision, the placenta is again mapped to confirm its position in the uterus and the fetus' position is confirmed with sterile ultrasonography. At this point, an amnioreduction can be performed. The uterus is entered with the use of a specifically designed uterine stapler that discharges absorbable staples and creates a hemostatic, bloodless incision as well as controls the membranes (Harrison & Adzick, 1993). The uterus is continually observed and palpated for contractions. If contractions are detected, additional tocolytics are utilized (Hirose et al., 2004; Moldenhauer, 2013). Through the hysterotomy, the fetus is partially delivered, typically head and neck or head and chest, depending on the location of the defect, diagnosis, or indication for the procedure. To replace lost amniotic fluid, a continuous infusion of warmed NSS or warmed LR solution is infused into the uterus (Bouchard et al., 2002; H. L. Hedrick et al., 2005; Hirose et al., 2004; Laje et al., 2012; Moldenhauer, 2013). This continuous infusion serves several purposes. First, the fetus is kept warm and buoyant and, most importantly, the uterus remains distended and staves off contractions and placental separation. The fetus is continually monitored during the procedure with pulse oximetry and sterile fetal echocardiography and given additional analgesia, although likely sedated via maternal anesthesia, and also given neuromuscular blockade as these

drugs do not cross the placental barrier (Bouchard et al., 2002; H. L. Hedrick et al., 2005; Hirose et al., 2004; Laje et al., 2012). Establishment of the fetal airway is paramount and performed first in all cases due to potential complications and potential need to emergently abort the procedure. Exogenous surfactant is administered when indicated for appropriate preterm gestational age. Peripheral intravenous access is established in the fetus first and later umbilical venous and arterial catheters can be placed, as timing allows. During an EXIT procedure, the fetal surgeon can perform a variety of procedures including laryngoscopy, bronchoscopy (rigid and flexible), orotracheal intubation, tracheostomy, resection of masses or lung lesions, and ECMO cannulation (Hirose et al., 2004; Moldenhauer, 2013). In certain cases, a tracheotomy can be performed followed by orotracheal intubation over a sterile feeding tube or guidewire introduced in a retrograde manner (Bouchard et al., 2002; Laje et al., 2012). Once the indicated intervention is completed and barring any complications, the umbilical cord is clamped, the cord is cut, and the fetus is delivered and given to the awaiting specialized neonatal team for further resuscitation. If additional surgical procedures are necessary, they can be performed once the infant is stabilized. An infant undergoing an EXIT procedure is not assigned Apgar scores, as they are sedated and pharmacologically paralyzed prior to delivery. In ideal conditions, a fetus can remain on placental bypass without complications for approximately 60 minutes, although a procedure time of 150 minutes has been described in the literature (H. L. Hedrick et al., 2005; Hirose et al., 2004; Moldenhauer, 2013). After the fetus is delivered, the hysterotomy and maternal abdomen are both closed and the mother is awoken from anesthesia. Post-EXIT care of the mother is similar to that of a cesarean delivery (Moldenhauer, 2013).

Maternal outcomes following an EXIT procedure are similar to those of women following standard cesarean delivery with regard to blood loss, need for blood product transfusion (low), recovery time, infection rate, and hospitalization (H. L. Hedrick et al., 2005; Hirose et al., 2004; Moldenhauer, 2013; Noah et al., 2002). After an EXIT procedure, secondary to the inherently required large hysterotomy (H. L. Hedrick et al., 2005), active labor must be avoided in subsequent pregnancies and future deliveries should occur via scheduled cesarean delivery. Future fertility is not adversely affected (Hirose et al., 2004; Moldenhauer, 2013).

Anesthesia and Analgesia for Fetal Procedures/Surgery

When anesthesia is administered for fetal surgery or fetal procedures, it is important to remember that two (or more, in the case of multiparity) patients are simultaneously being anesthetized. The risks of anesthesia during pregnancy are multifocal as they relate to the physiologic changes of the mother, which, in turn, cause alterations in pharmacokinetics and pharmacodynamics, and possible adverse effects on the fetus (Box 24.2). Therefore, anesthetizing a pregnant woman during major surgery requires specially trained anesthesiologists who can provide the necessary level of anesthesia and pain management for the maternal–fetal dyad while ensuring the mother's safety and minimal side effects for both patients. Meticulous attention must be paid to perioperative fluids, administration of inhaled halogenated anesthetic gases, the titration of vasopressors and inotropic agents, and accurate assessment of pulmonary vascular permeability as maternal fluid volume overload and pulmonary edema can occur rapidly (Duron et al., 2014; Saracoglu et al., 2016; Saracoglu, Saracoglu, Alatas, & Kafali, 2015). The following must be taken into consideration by the anesthesiologist when anesthetizing the maternal–fetal dyad:

- Decreased peripheral vascular resistance (cardiac output increases with no increase in blood pressure, resulting in a decrease in peripheral vascular resistance)
- Decreased functional residual capacity and an increase in alveolar ventilation (which speeds up induction with inhalation anesthetics)
- Increased oxygen consumption (decreased functional residual capacity combined with increased oxygen consumption predisposes pregnant women to hypoxia)
- Hypotension as a result of aortocaval compression (lying supine, a pregnant woman in the second and third trimesters experiences reduced blood flow back to the heart because of aortocaval compression by the gravid uterus)

The compression of the major abdominal vessels by the gravid uterus when the mother lies supine not only causes maternal hypotension but also causes uterine hypoperfusion. It is for this reason the mother must be tilted slightly on the operating table to ensure the absence of aortocaval compression.

Pregnant women are also more sensitive to inhaled anesthetics because of elevated endorphin levels, and therefore require less inhaled gas (Duron et al., 2014; Saracoglu et al., 2015). Regional anesthetics also require adjustment. The increase in intra-abdominal pressure and venous shunting of blood in the mother enlarges the epidural veins, which decreases the epidural space and decreases the analgesic requirement (Saracoglu et al., 2015).

Maintaining the stability of the fetal cardiovascular system is the most important step in anesthesia management during fetal surgery (Liu et al., 2013). If fetal bradycardia is detected by the surgeons, the surgeon responds by repositioning the fetus to relieve cord compression and the anesthesiologist must respond immediately by raising the maternal blood pressure, increasing maternal oxygenation, and administering tocolytics (Hoagland & Chatterjee, 2017). There are threats to this stability from maternal

Box 24.2

MATERNAL PHYSIOLOGIC CHANGES DURING PREGNANCY AFFECTING ANESTHESIA ADMINISTRATION

- Increased cardiac output (50%–100%)
- Increased plasma volume (40%–55%)
- Increased RBC volume (20%–30%)
- *Relative* anemia and hypoalbuminemia (plasma volume increase > RBC volume increase)
- Decreased serum oncotic pressure
- Decreased blood pressure
- Decreased peripheral vascular resistance
- Increased oxygen consumption
- Altered coagulation; tendency toward hypercoagulopathy
- Increased susceptibility to thromboembolic events
- Increased endorphin and progesterone
- Decreased functional residual capacity
- Increased susceptibility to hypoxia
- Increased pulmonary vascular permeability
- Increased gastric acid secretion
- Decreased LES tone
- Displacement of the pylorus, stomach, LES, and diaphragm
- Increased risk of aspiration during intubation and resultant aspiration pneumonia

LES, lower esophageal sphincter; RBC, red blood cell.

anesthesia and fetal blood loss. Maternal inhalation anesthesia has a direct inhibitory effect on the fetal myocardium depressing its function as well as vasodilation (Liu et al., 2013). This negative effect is only exaggerated the longer the fetus is exposed to inhaled agents. Another threat to the fetal cardiovascular stability is fetal blood loss. Due to the small circulating fetal blood volume (100–110 mL/kg), even the smallest amount of blood loss can lead to hypovolemia, resulting in profound fetal hypotension (Hoagland & Chatterjee, 2017; Liu et al., 2013). Due to the immaturity and the lack of sensitivity of fetal regulatory mechanisms, the fetus is unable to adequately increase its heart rate, cardiac output, and blood pressure to accommodate these stressors. This is what makes fetal acidosis, hypotension, and bradycardia such common and significant threats to fetal well-being during fetal procedures. Fetal oxygenation depends on the maternal arterial oxygen content. If the mother's partial pressure of arterial oxygen, partial pressure of arterial carbon dioxide, and uterine blood flow are maintained within normal limits, fetal anoxia is least likely to occur. Fetal acidosis can occur quickly and it is vital to avoid when at all possible (Saracoglu et al., 2015). Other causes of fetal anoxia are maternal hypotension, which causes a decrease in uterine blood flow, as well as uterine vasoconstriction caused by anxiety, insufficient anesthesia, or vasoactive drugs.

Maternal anesthesia and analgesia for open fetal procedures includes regional anesthesia (epidural or spinal) and deep endotracheal general anesthesia. Regional anesthesia augments general anesthesia intraoperatively and serves as analgesia postoperatively. Deep general anesthesia is important to maintain uterine relaxation throughout the procedure.

Fetal analgesia during fetal procedures or fetal surgery, whether open or MIS, is a multimodal approach. During open procedures, the fetus receives maternal anesthesia via placental transfer. Additional analgesia is given to the fetus despite this transfer to guarantee a pain-free procedure for the fetus. Neuromuscular blockade must be administered directly to the fetus as these drugs do not cross the placental barrier. Typically, a combination of atropine (to prevent fetal bradycardia), fentanyl (half-life of >12 hours in the fetus), and neuromuscular blockade to decrease fetal movement during the procedure is utilized (Nassr, Erfani, et al., 2017). In the setting of fetal bradycardia, additional medications, crystalloid fluids, or blood products can be administered intravenously to the fetus to maintain or regain hemodynamic stability. For minimally invasive procedures, the fetus does not receive anesthesia or analgesia from maternal local or regional drugs. In these cases, the aforementioned combination of medications is administered intramuscularly directly to the fetus. Depending on the procedure performed, the complexity of the procedure, and the instruments required to accomplish said procedure, immobility of the fetus is not always required (Graves et al., 2017). It should be noted that minimally invasive procedures performed on noninnervated fetal tissues (the placenta and umbilical cord) do not require fetal anesthesia or analgesia (Graves et al., 2017; Hoagland & Chatterjee, 2017).

Perioperative and Postoperative Care

Perioperative management of the mother includes the use of tocolytics (magnesium sulfate infusion, indomethacin, and nifedipine). Given the fluid shifts that occur during and after fetal surgery, patients are encouraged to orally hydrate the night before the procedure so that fluids can be restricted intraoperatively and postoperatively. This reduces the risk of pulmonary edema in the immediate postoperative period (Moldenhauer & Adzick, 2017).

After the procedure, the mother remains in the hospital for approximately 4 days. During that time, daily ultrasounds and echocardiography are performed to assess fetal well-being and the quiescence of the uterus. The current tocolytic regime begins with indomethacin to the mother before surgery and over the next several days. Indomethacin is the drug of choice because it inhibits the synthesis of prostaglandins released during uterine manipulation. The mother is discharged on activity restrictions (like modified bed rest), oral nifedipine, and extensive teaching on signs and symptoms of preterm labor. She will come back once or twice weekly for fetal evaluation (i.e., nonstress test [NST]) and ultrasound (i.e., amniotic fluid index). If rupture of membranes, chorioamniotic separation, or preterm labor occur, the mother will be rehospitalized, placed on bed rest, and continuously monitored.

Diagnoses

Congenital Anomalies

Cardiac. Indications for fetal cardiac intervention include critical aortic stenosis, hypoplastic left heart syndrome (HLHS) with intact atrial septum, and pulmonary atresia with intact ventricular septum (Nassr, Erfani, et al., 2017). Critical aortic stenosis presents during the second trimester and is identified by echocardiography. The echocardiography will reveal left ventricle dilation with progressive dysfunction; this evolves into HLHS. The goal of fetal intervention is to prevent progressive left ventricular dysfunction and ultimately HLHS. Under continuous ultrasound guidance, a needle is aligned with the left ventricular outflow tract, the trocar is removed, and a guide wire with a preloaded balloon is advanced through the aortic valve. Once the wire is in the correct position, the balloon is inflated, and the valve is dilated. The balloon is then deflated and removed (Nassr, Erfani, et al., 2017).

Fetuses with HLHS with intact atrial septum will be hypoxemic at birth due to increased left atrial pressures resulting in lung disease (Rintoul et al., 2018). They will have severe metabolic and respiratory acidosis resulting in a high mortality rate. Fetal treatment for HLHS with intact atrial septum involves an atrial septostomy with or without stent placement. Pulmonary atresia with intact ventricular septum results in right ventricle hypoplasia. The goal of fetal intervention is to restore biventricular circulation by performing a pulmonary valvuloplasty (Rintoul et al., 2018).

Congenital Cystic Adenomatoid Malformations. Congenital cystic adenomatoid malformations (CCAM) is a developmental abnormality of the fetal lung parenchyma that occurs in every 1:15,000 to 1:25,000 live births (Derderian et al., 2015; Euser et al., 2016). In normal pulmonary development, the HOXB-5 gene is present during the pseudoglandular phase and then decreases over time, specifically during the canalicular phase. PDGF-B becomes predominant in the canalicular phase and decreases in the saccular phase. As these lung lesions grow, they can be large enough to obstruct the esophagus, which leads to polyhydramnios and increases the risk of preterm labor and birth (Khalek & Johnson, 2013). The lesion can also cause significant mediastinal shift resulting in pulmonary hypoplasia, impaired venous return, cardiac failure, and hydrops (Khalek & Johnson, 2013).

There are several classification systems utilized to describe these lung lesions, with the modified Stocker classification being the most common (Pogoriler, Swarr, Kreiger, Adzick, & Peranteau, 2017). Although there are five classifications that fall under the modified Stocker, types I and II are the most common. Type I refers to large cysts (macrocystic) and type II refers to small cysts (microcystic). Macrocystic lesions are described as lung lesions with one or more cysts greater than 5 mm. These lesions often grow throughout pregnancy and are amenable to aspiration and thoracoamniotic shunt (TAS) placement (Derderian et al., 2015; Peranteau et al., 2016). TAS placement can decrease the CCAM volume by 50% to 80%, ultimately reducing the intrathoracic mass effect (Khalek &

Johnson, 2013; Peranteau et al., 2015). Postshunt placement complications include premature rupture of membranes, preterm labor, chorioamniotic membrane separation, and infection (Khalek & Johnson, 2013). Chest wall deformities are a known risk when a TAS is placed early in gestation (18–20 weeks) and should be discussed during the fetal consult. In addition, there is a risk of shunt occlusion, malfunction, or dislodgement (Peranteau et al., 2015). Microcystic lesions, cysts that are less than 5 mm, generally plateau or decrease in size after 26 to 28 weeks' gestation and are amenable to prenatal betamethasone administration (Derderian et al., 2015; Macardle et al., 2015).

Antenatal betamethasone has become the standard of care for fetuses with a microcystic or mixed lesion whose CCAM volume ratio (CVR) is 1.6 or more (Derderian et al., 2015; Khalek & Johnson, 2013; Peranteau et al., 2016). The CVR is calculated by multiplying the CCAM length, width, height, and a constant of .52 and dividing it by the head circumference (Euser et al., 2016).

$$\frac{\text{Length (cm)} \times \text{height (cm)} \times \text{width (cm)} \times .52}{\text{Head circumference}}$$

Studies have shown that CVR of 1.6 or more increases the risk of the fetus developing hydrops. Although the mechanism of action for antenatal steroids is unknown, it is hypothesized that betamethasone downregulates several genes that are related to abnormal lung development. For fetuses with CCAM, HOXB-5 and PDGF-B remain persistently elevated and it is theorized that steroids stop these elevations and impede CCAM growth (Derderian et al., 2015).

For those symptomatic lesions that are unresponsive to steroids, OFS may be performed. If significant mediastinal shift is present, recommendations include EXIT procedure with lobectomy while on placental bypass or elective cesarean delivery and immediate lobectomy after birth (Khalek & Johnson, 2013). If the fetus is asymptomatic, postnatal resection of the lesion is recommended given the risk of lobe infections or malignancy (Pogoriler et al., 2017). Histology reports have included cases of myxosarcoma, embryonal rhabdomyosarcoma, pleuropulmonary blastoma, and bronchoalveolar carcinomas (Khalek & Johnson, 2013). Once a lobectomy has been performed, the remaining normal ipsilateral lung continues to grow to fill the chest and there are no residual respiratory problems (Khalek & Johnson, 2013).

Congenital Airway Malformations and Neck Masses. CHAOS is a complete or near-complete airway obstruction typically caused by laryngeal or tracheal atresia, but in rare cases can be caused by isolated tracheal stenosis, mucosal web, severe micro- or retrognathia, subglottic stenosis, or extrinsic compression by a large cervical mass (e.g., teratoma or lymphangioma; M. H. Hedrick et al., 1994; Lim et al., 2003). CHAOS is uniformly fatal if not treated with a fetal intervention (including EXIT procedure). To date, no fetus has survived CHAOS without fetal intervention (Ryan, Somme, & Crombleholme, 2016). Regardless of the etiology, the pathophysiology of fetal upper airway obstruction is such that it prevents egress of the fluid produced in the lungs to the amniotic space. This fluid is usually produced under a pressure that favors movement out through the fetal mouth and is partly aided by fetal breathing movements. Sonographic findings of CHAOS include a bilaterally flattened or everted diaphragm, large, overdistended (fluid-filled), echogenic lungs that compress the mediastinum, dilated large airways distal to the obstruction, and fetal ascites or hydrops that result from compression of the heart and great vessels (M. H. Hedrick et al., 1994). If hydrops does not develop in utero, a fetus with CHAOS may be delivered via the EXIT procedure, which maintains the baby on placental support until an airway is established via orotracheal intubation or tracheostomy (Mychaliska et al., 1997). Approximately one-third of fetuses with CHAOS will spontaneously perforate the atresia into the larynx or the esophagus, allowing for egress of lung fluid, reducing the compression on the mediastinum and resolution of fetal hydrops (Rintoul et al., 2018). If the atresia does not spontaneously perforate, in the setting of hydrops, a fetoscopic laser can be used to perforate the laryngeal or tracheal atresia, allowing for resolution of the hydrops prior to the EXIT procedure; laser perforation of the atresia does not negate the need for delivery via EXIT. Use of the EXIT procedure in CHAOS cases can offer an improved prognosis and the potential for excellent long-term outcome of these fetuses that otherwise would not survive.

Extrinsic causes of upper airway obstruction that can present prenatally are epignathus, epulis, mandibular hypoplasia, large cervical teratoma, large lymphatic malformations, thoracic teratomas, and space occupying lung lesions (Ryan et al., 2016). If there is upper airway obstruction, regardless of the etiology, these fetuses should be delivered via the EXIT procedure for the safest transition to extrauterine life and best possible outcomes. During the EXIT procedure, fetal surgeons can perform laryngoscopy, bronchoscopy (rigid and flexible), orotracheal intubation, tracheostomy, and even resection of the obstructing mass. Once the airway is obtained and ventilation is established, the fetus can be delivered and transitioned to the awaiting neonatology team in a controlled manner for proper resuscitation and stabilization.

Congenital Diaphragmatic Hernia. CDH occurs when the diaphragm fails to close and the abdominal contents migrate into the chest through the hernia. CDH occurs in every 1:2,500 live births; left-sided lesions are more common than right-sided, and bilateral lesions are rare (Deprest et al., 2005; Peralta, Jani, Van Schoubroeck, Nicolaides, & Deprest, 2008). Given the herniation of abdominal contents into the chest cavity, the lungs develop with fewer alveoli, thickened alveolar walls, increased interstitial tissue, and diminished alveolar space and gas-exchange surface area (Deprest et al., 2005). Also, the pulmonary vasculature is abnormal. There are fewer vessels per lung volume, medial hyperplasia, and peripheral extension of the muscle layer into the smaller intraacinary arterioles, and adventitial thickening. Based on these two developmental abnormalities of the lung, CDH is associated with high postnatal mortality due to pulmonary hypoplasia and/or pulmonary hypertension (Deprest et al., 2005; McHugh et al., 2010; Peralta et al., 2008). CDH can be associated with chromosomal anomalies, as well as syndromes (Deprest et al., 2005).

The evolution of high-resolution ultrasound and fetal MRI have made the diagnosis of CDH possible prenatally, as well as determining lung-to-head ratio (LHR; Deprest et al., 2005; Victoria, Danzer, & Adzick, 2013). This is calculated by measuring the lung area (length 1 × length 2) and dividing that number by the head circumference. The main limitations of LHR are its dependence on gestational age, the variability in measurements, and compression of contralateral lung from visceral organs (Victoria et al., 2013). Given these limitations, observed compared with expected (O/E) LHR was developed to correct for gestational age. Fetuses with an O/E LHR less than 15% have extreme pulmonary hypoplasia, which is associated with poor survival rate. Infants with an O/E LHR of 15% to 25% have severe pulmonary hypoplasia and a predicted survival rate of 20%. Those with an O/E LHR of 26% to 35% have moderate pulmonary hypoplasia and an expected survival rate of 30% to 60%. Lastly, fetuses with an O/E LHR between 36% and 45% will have mild pulmonary hypoplasia and have a survival rate of greater than 75% (Victoria et al., 2013).

Historical fetal intervention included OFS to repair the hernia and tracheal clip to improve lung growth. Both modalities resulted in poor outcomes, especially for those fetuses where the liver is

herniated into the chest. During OFS, reduction of the liver into the abdomen kinks the umbilical vein and leads to fetal death (Deprest et al., 2005). Most recently, fetal research has been focused on fetoscopic endoluminal tracheal occlusion (FETO) that prevents egress of lung fluid, which increases lung tissue stretch and triggers lung growth, reversing the development of pulmonary hypoplasia (Deprest et al., 2005; Peralta et al., 2008). The timing of FETO is important, in addition to the duration of occlusion, as the goal is to balance alveolar type I and II cells, surfactant synthesis, and total alveolar phospholipid content. The balloon is placed between 26 and 28 weeks' gestation and removed around 34 weeks' gestation, allowing for vaginal delivery or referral back to a hospital closer to home (Figure 24.1). An important complication of FETO is rupture of membranes and the risk for preterm delivery. If the balloon is in place or is unable to be deflated prior to delivery, an EXIT procedure should be performed. In the case where a delivery is imminent and an EXIT procedure cannot be executed, surgery staff specialty trained in balloon retrieval must be present at the delivery for immediate retrieval via bronchoscopy prior to resuscitation.

With the advancements in obstetrics and neonatology, interventions like prenatal corticosteroid administration, high-frequency oscillatory ventilation (HFOV), surfactant administration, inhaled nitric oxide (iNO), and ECMO have positively impacted the postnatal survival of newborns with CDH (Deprest et al., 2005; McHugh et al., 2010).

Myelomeningocele. Routine maternal serum alpha-fetoprotein (MSAFP) screening that is outside the normal range alerts healthcare providers to directly sonograph the fetal spine. The ultrasonographer will also evaluate the head for frontal bone scalloping (lemon sign), for abnormality of the cerebellum (banana sign), for Arnold-Chiari II malformation (hindbrain herniation), and for hydrocephaly. Neural tube defects can occur either as a flat defect without a fluid-filled sac covering (myeloschisis), with a membranous covering (meningocele), or membranous covering with extrusion of the spinal cord into the fluid-filled sac (MMC). MMC is the most common congenital central nervous system anomaly that occurs in 3.4:10,000 live births (Adzick et al., 2011; Farmer et al., 2018). MMC occurs when the neural tube fails to close during the fourth week of gestation. It is characterized by a fluid-filled sac that contains the spinal cord and nerves (Moldenhauer & Adzick, 2017). This results in hydrocephaly, hindbrain herniation, and damaged nerves that lead to long-term morbidity and mortality (Moldenhauer & Adzick, 2017). Survivors have paralysis, bowel dysfunction, and bladder dysfunction, and the majority have Arnold-Chiari II malformation. This malformation includes hindbrain herniation, brainstem abnormalities, low-lying venous sinuses, and a small posterior fossa (Adzick et al., 2011). Given this constellation, hydrocephalus and developmental brain abnormalities have been well documented, in addition to the effects on motor, cranial nerve, and cognitive functions (Adzick et al., 2011).

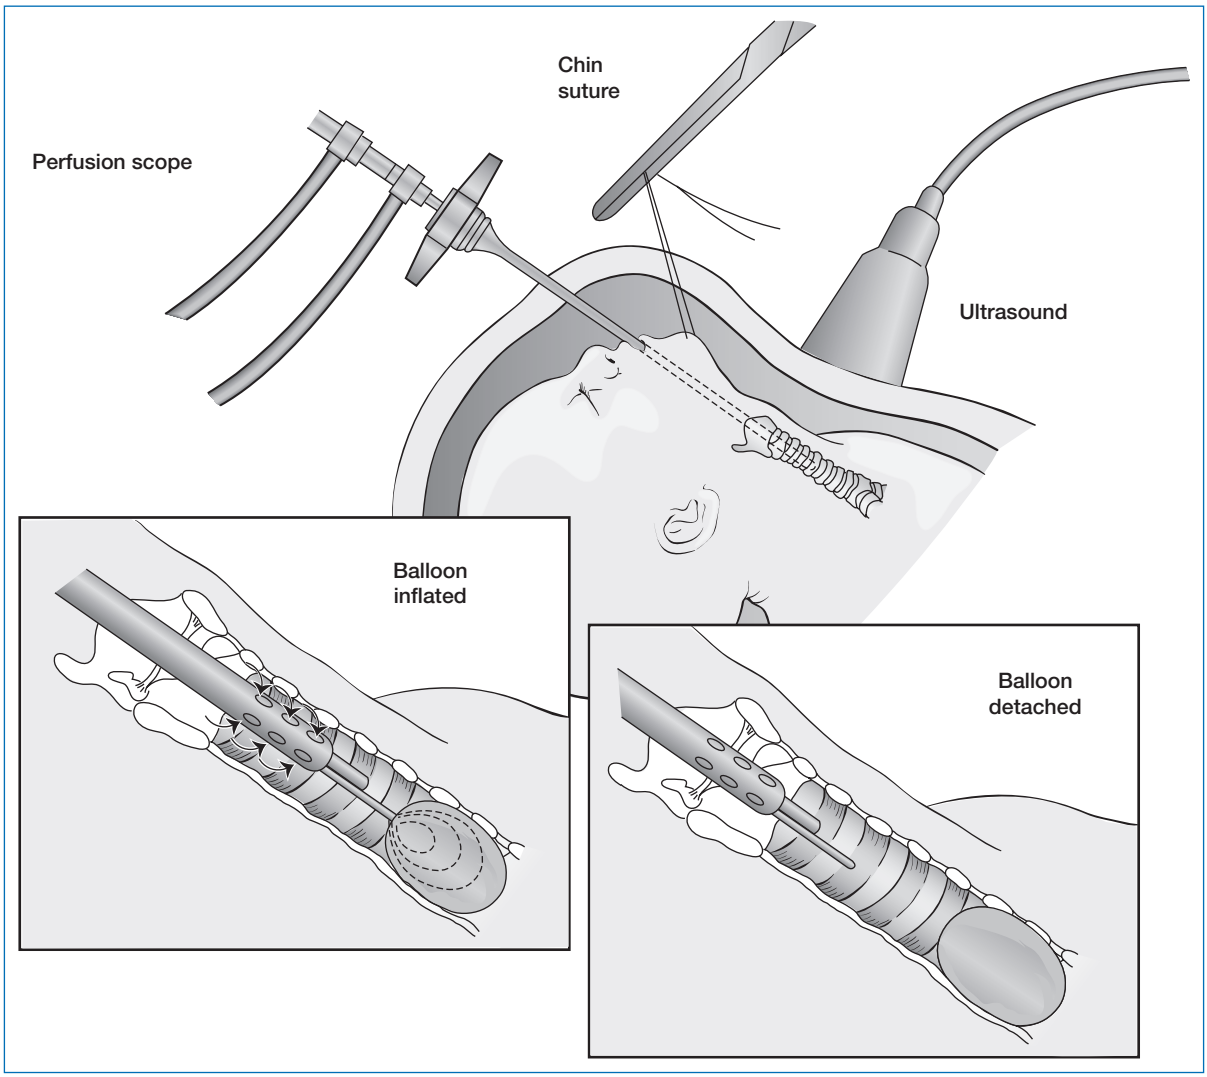

FIGURE 24.1 Fetal tracheal occlusion with balloon.

Initial attempts at in-utero MMC closure were performed endoscopically by covering the neural placode with a split-thickness skin graft (Moldenhauer & Adzick, 2017). Given that the outcomes were poor, OFS techniques were then explored. In 2003, the Management of Myelomeningocele Study (MOMS) trial was started and sponsored by the National Institutes of Health. This trial was a prospective, multicenter randomized trial that compared prenatal and postnatal MMC closure. There were strict inclusion and exclusion criteria to ensure the safety of both the mother and the fetus (Adzick et al., 2011).

The MOMS trial found that children in the prenatal surgery group were more likely to walk independently due to improved motor function, had decreased need for ventriculoperitoneal (VP) shunt placement when fetal repair occurred between 20 and 24 weeks' gestation, and improved psychomotor and mental development (Farmer et al., 2018; Moldenhauer & Adzick, 2017; Tulipan et al., 2015). Although prenatal surgery does not seem to impact the need for clean intermittent catheterization, it has significantly impacted bladder trabeculation, vesicoureteral reflux, and open bladder neck (Moldenhauer & Adzick, 2017).

Maternal–fetal complications of prenatal MMC closure include chorioamniotic membrane separation, spontaneous membrane rupture, oligohydramnios, and spontaneous labor. Like other fetal therapies and interventions, there is an increased incidence of maternal pulmonary edema, uterine dehiscence, and need for blood transfusion at the time of delivery (Moldenhauer & Adzick, 2017; Tulipan et al., 2015). Preterm delivery, with an average gestational age of 34 weeks, and central apnea, regardless of gestational age, were identified in the neonatal period (Moldenhauer & Adzick, 2017).

Obstructive Uropathy. Fetal LUTO is a serious condition in the fetus with significant risk for morbidity and mortality in the neonatal period if left untreated (Haeri, 2015). Hallmark presentation on ultrasound is a dilated bladder with a thickened wall and bilateral hydroureteronephrosis (Graves et al., 2017; Haeri, 2015). The severe forms of the condition lead to a distended/dilated urinary system with resultant renal dysplasia and oligohydramnios that results in pulmonary hypoplasia and deformation of the facies and distal extremities. The incidence of significant LUTO is 1 in 500 pregnancies, but is likely underestimated, with 10% of cases associated with trisomies 13, 18, or 21 (Haeri, 2015; Wu & Johnson, 2009). There is a strong male predominance (Clayton & Brock, 2014; Wu & Johnson, 2009). The etiology for LUTO is typically PUVs or urethral atresia. The natural history of obstructive uropathy is variable and depends on fetal gender, severity, and gestational age at onset of the obstruction (Wu & Johnson, 2009). Outcomes of the diagnosis and subsequent treatment of LUTO rely on two major factors: degree of pulmonary hypoplasia and degree of renal disease (Wu & Johnson, 2009). When suspected, fetal urinary anatomy is followed closely with ultrasound for evidence of dilatation and the amniotic fluid volume must also be closely monitored for oligohydramnios. When anomalous signs are present, vigilant prenatal testing should ensue to determine candidacy for fetal intervention. Genetics should be thoroughly evaluated as should fetal urine samples for electrolyte concentrations and renal morphology. Fetal urine samples are obtained by needle aspiration under ultrasound guidance. Two or three samples should be obtained 24 to 48 hours apart as the initial sample(s) contain stagnant urine that can skew chemistry results (Haeri, 2015). If the severity of the individual fetal obstruction is suitable for fetal intervention and the family consents, fetal intervention is planned. The three options for fetal intervention are vesicoamniotic shunt (most common), valve ablation, and fetal vesicostomy (Haeri, 2015).

Vesicoamniotic shunting (VAS) is a closed, minimally invasive fetal procedure performed with ultrasound guidance under local maternal analgesia. Due to oligohydramnios, an amnioinfusion is required prior to the start of the procedure (Haeri, 2015). Fetal analgesia and neuromuscular blockade are administered either IV via the umbilical vein or IM in the fetal deltoid. A double pigtail catheter is deployed via needle with the distal end in the fetal bladder and the proximal end in the amniotic space. This allows the fetal bladder to drain, decreases dilation of the urinary system, staves off renal dysplasia, and resolves oligohydramnios. Shunt displacement is a common complication of this procedure and occurs in more than 40% of clinical cases, sometimes necessitating a repeat procedure (Wu & Johnson, 2009).

Fetal cystoscopy is an experimental treatment that can both diagnose the cause of the obstruction and relieve it (in the case of PUV). Fetal cystoscopy is a fetoscopic procedure performed in conjunction with ultrasound guidance. Amnioinfusion is not required with this procedure, but more regional maternal analgesia is required (Haeri, 2015). Fetal anesthesia is similar to that used in VAS. For the procedure, a trocar is inserted into the fetal bladder and the fetoscope is advanced through the trocar toward the urethra. If a membrane-like obstruction of the urethral lumen is noted, PUV can be confirmed and the valves can be ablated with laser ablation, hydroablation, or guidewire ablation (Graves et al., 2017). If the obstruction does not appear membrane-like, urethral atresia is confirmed and no attempt to ablate the obstruction is made.

Fetal vesicostomy is accomplished with OFS. This procedure is not regularly performed due to a paucity of data coupled with maternal and perinatal morbidity (Haeri, 2015). Despite the efforts of scientists studying the condition or the surgeons treating it, long-term survival and long-term renal function remain disappointing. In recent studies, 2-year survival rates ranged from 35% to 54% (Graves et al., 2017) and it has been elucidated that prenatal treatment of LUTO does not negate the need for dialysis or renal transplant (Graves et al., 2017; Haeri, 2015; Nassr, Shazly, et al., 2017; Wu & Johnson, 2009).

Sacrococcygeal Teratoma. SCT is the most common germ cell tumor in neonates and children occurring in 1 in 30,000 to 45,000 live births (Yao, Li, Zheng, Dong, & Xiao, 2014). SCT arises from the coccyx and is composed of tissues from all three germ layers (endoderm, mesoderm, and ectoderm; Partridge et al., 2014; Van Mieghem et al., 2014; Yao et al., 2014). SCTs are classified by the Altman classification system, with Altman type I being completely external and Altman type IV completely internal. Altman types II and III have both internal and external components, with type II a little more external and type III a little more internal. Type IV tumors, because they are completely internal, can be missed on prenatal imaging. Also, because they are all internal, type IV SCTs can have considerable mass effect on surrounding structures. The bladder, rectum, and large and small bowel can be displaced or distorted due to the teratoma. This becomes important in the postnatal period, as voiding and stooling can be negatively affected. Even after the internal teratoma is resected, residual effects of the prior displacement can remain. SCTs, regardless of type, are composed of mature or immature tumor elements on pathologic examination and rarely may contain malignant elements (Partridge et al., 2014). Teratomas with mature elements are the least likely to recur and have the lowest potential for malignancy. Immature elements have an increasing risk for both recurrence and malignant transformation. Evidence of yolk sac elements has the highest malignancy potential and these infants are usually treated with chemotherapy in the neonatal intensive care unit (NICU) or early in infancy.

An internal cystic teratoma does not exert the same mass effect on surrounding structures as a solid teratoma would by virtue of the cysts' ability to be compressed. Solid, vascular SCTs, on the other hand, can exhibit significant mass effect when

internal. Solid, vascular SCTs also create a vascular "steal" of blood whether internal or external, which increases the workload of the fetal heart (Van Mieghem et al., 2014; Yao et al., 2014). The fetal heart has to pump blood to the body of the fetus as well as to the low-resistance vascular bed of the SCT, causing high-output cardiac failure in the fetus that can lead to hydrops and, in extreme cases, maternal mirror syndrome and placentomegaly (H. L. Hedrick et al., 2004; Van Mieghem et al., 2014). For example, "normal" fetal combined cardiac output (CCO) is 400 mL/kg/minute. Fetuses with a CCO greater than or equal to 750 mL/kg/minute are at greatest risk for developing hydrops. Polyhydramnios is another common sonographic finding with SCT. Polyhydramnios increases maternal discomfort, creates marked distension of the uterus, and puts the pregnancy at risk for preterm labor and premature delivery. The etiology of polyhydramnios in the setting of SCT is not fully elucidated, but it is believed to be linked to placentomegaly.

OFS has historically been the treatment of choice for pregnancies complicated by SCT and its sequelae, including polyhydramnios, high-output cardiac failure, and hydrops. It is important for best outcomes to intervene on the fetus early in the development of hydrops (Rintoul et al., 2018). Once hydrops is diagnosed, absence of fetal intervention carries a mortality rate of 100% (H. L. Hedrick et al., 2004). The goal of OFS for SCT is to debulk the external component of the teratoma and ligate the large vascular connections, thereby cutting off the tumor's blood supply and ideally reversing the high-output cardiac failure and hydrops (H. L. Hedrick et al., 2004). During OFS, no attempt is made to resect the internal component (if one exists) or to remove the coccyx. Resection of the remaining teratoma and removal of the coccyx happens in the postnatal period when the neonate is stabilized and prepared for surgery. By definition, the teratoma is not definitively resected until the coccyx is removed. Failure to remove the coccyx results in a 30% to 40% risk of recurrence. There are also minimally invasive fetal interventions employed to ameliorate the complications of SCT and to prolong the pregnancy such as amnioreductions and cyst aspiration (H. L. Hedrick et al., 2004). Others include vascular coiling, embolization, sclerotherapy, monopolar cautery, laser ablation, and radiofrequency ablation (Van Mieghem et al., 2014). The latter group of interventions has been associated with thermal injury to the fetus after laser ablation or RFA, extratumoral spread of the embolizing or sclerosing agents, and hemorrhage (Graves et al., 2017; Van Mieghem et al., 2014).

Infants with SCT are followed closely in the postnatal period and in the long term (usually up to 3 years) with laboratory studies (alpha-feto protein levels), careful physical examination and imaging for recurrence, and malignant transformation (H. L. Hedrick et al., 2004; Padilla et al., 2017). Risks for recurrence and malignant transformation are tumor spillage at time of resection, failure to remove the coccyx, yolk sac pathology, and incomplete resection of the tumor (Padilla et al., 2017). Long-term functional sequelae of SCT, whether debulked prenatally or not, are constipation, fecal incontinence, urinary incontinence, neurogenic bladder, vesicourethral reflux, and sexual dysfunction. Partridge et al. (2014) determined that higher risks for long-term functional sequelae increased with higher Altman typing and with prenatal imaging evidence of gastrointestinal or urologic obstruction. A longitudinal study conducted in 2007 found that functional sequelae of SCT improve over time and the adults studied had complications similar to their age-matched controls (Cozzi et al., 2008). Despite the data and complications described here, survival for infants with SCT is rather high with up to 50% of prenatally diagnosed SCTs following uneventful antenatal, perinatal, and postnatal courses (Nassr, Erfani, et al., 2017).

Fetal Conditions

Amniotic Band Syndrome. Amniotic band syndrome is a rare prenatal complication that occurs in 1:1,200 to 1:15,000 live births (Javadian et al., 2013). The cause remains unknown, but it is hypothesized that there is a primary defect or early disruption of the amnion that results in the mesodermal matrix production, resulting in band development (Derderian, Iqbal, Goldstein, Lee, & Hirose, 2014). The syndrome can lead to fetal demise if there is umbilical cord strangulation or a deformity of a limb or even limb amputation (Graves et al., 2017; Javadian et al., 2013). The presentation, severity, and outcome depend on the location of the bands and timing of damage. Utilization of ultrasound to monitor blood flow to the affected limb and/or umbilical cord entrapment is important to determine the timing of fetal intervention. Ultrasound findings include, but are not limited to, distal limb edema, abnormal doppler flow, and visualization of the band (Graves et al., 2017). The fetal intervention includes using fetoscopy for amniotic band release (Graves et al., 2017; Javadian et al., 2013). Derederian et al. (2014) found that after fetoscopic release of the band, there was improved blood flow, in addition to limb preservation and function verified in the postnatal period.

TTTS and Twin Reversed Arterial Perfusion (TRAP). TTTS is the most common severe and most challenging complication of monochorionic twin pregnancies (Crombleholme, 2003). The incidence of TTTS is between 10% and 15% of monochorionic pregnancies and accounts for 17% of mortality in twin gestations despite its low incidence (Rintoul et al., 2018). TTTS is a complication of monochorionic diamniotic twins characterized by vascular anastomoses at the placental level (chorioangiopagus) that results in an imbalance of flow from one twin to another. This unequal sharing of the monochorionic placenta usually can be visualized on ultrasound; insertion of the smaller (or donor) twin's umbilical cord often is marginal or velamentous, whereas the larger (or recipient) twin's cord inserts into the placenta centrally. The aberrant vascular communications result in a net shunting of blood that can be detected by Doppler ultrasonography. The vessels in question are unpaired, resulting in flow from the donor fetus to the recipient fetus. Doppler studies demonstrate the characteristic pulsatile arterial blood flow on the donor's side, whereas a continuous venous flow is noted on the recipient's side. Other sonographic evidence of TTTS is severe oligohydramnios or anhydramnios in the sac of the donor twin (also known as the "stuck twin") and polyhydramnios, pulmonary hypertension, and hypertrophic cardiomyopathy caused by chronic hypervolemia noted in the recipient twin.

Initial criteria for diagnosing TTTS in utero was based on the criterion derived from neonatal standards for twin birth weight discordance and hemoglobin levels. This was later proven unreliable when the validity of this criterion could not be validated when comparing with values for monochorionic twins without evidence of TTTS and samples of dichorionic twins (Crombleholme, 2003). More recently, the severity of the condition may be assessed using the Quintero staging system (Table 24.3). Not only does this staging system mirror the progression of disease, but it has also been shown to be important in establishing the prognosis (Quintero et al., 1999). Laser photocoagulation is offered for stages II to IV and stage I on a case-by-case basis. Typically outcomes for type I when comparing expectant management and photocoagulation are similar (Nassr, Erfani, et al., 2017). If left untreated, TTTS is lethal and carries perinatal mortality rates as high as 80% or 90% (Graves et al., 2017; Wenstrom & Carr, 2014).

Original treatment proposals for TTTS included intertwin membrane microseptostomy designed to restore amniotic fluid volume equality without the need for repeated amnioreduction

procedures. An investigation of this therapy seemed to suggest microseptostomy was more successful than serial amnioreductions as defined by survival. The study was small and uncontrolled, and its results could not be duplicated by a second retrospective single-institution series comparing serial amnioreductions with microseptostomy. The original investigators then performed and reported results from a multicenter, prospective, randomized clinical trial that again compared microceptostomy with amnioreductions and confirmed the former was not superior to the latter when comparing survival rates (Crombleholme, 2003).

De Lia, Cruikshank, and Keye (1990) first described laser photocoagulation of intertwin vessels for the treatment of TTTS. The results reported similar survival rates when compared with the amnioreduction versus microseptostomy study but superior results when comparing neurologic outcomes (De Lia, Kuhlmann, Harstad, & Cruikshank, 1995). Later, selective laser photocoagulation was proposed and attempted. Selective laser photocoagulation differed from the original nonselective photocoagulation in that the selective procedure did not photocoagulate all vessels crossing the intertwin membrane but, rather, only photocoagulated direct arterial-arterial and veno-venous connections as well as any unpaired artery leading to a cotyledon that had a corresponding vein leading to the other twin's umbilical cord (Crombleholme, 2003). In cases of severe TTTS, selective fetoscopic laser photocoagulation of the communicating vessels (see Figure 24.2) has now become the surgical standard of care after a large European study comparing laser photocoagulation with serial amnioreductions was stopped early for efficacy of laser photocoagulation (Graves et al., 2017; Nassr, Erfani, et al., 2017; Senat et al., 2004; Wenstrom & Carr, 2014). Amnioreductions are still performed for maternal comfort and to improve fetal perfusion by reducing the distending pressure at the uteroplacental interface.

Fetoscopic umbilical cord coagulation is a procedure reserved for the most severe TTTS cases when the recipient twin shows sonographic signs of irreparable cardiomyopathy and who is not expected to survive (Crombleholme, 2003). The premise for this approach posits that cord coagulation and sacrifice of the recipient twin will stop progression of the syndrome, allow for delivery later in gestation for the donor twin, and improve the outcomes for the donor twin, particularly neurologically speaking. During this procedure, the cord of the recipient twin is coagulated, but the vascular communications between the donor twin and the placenta within the recipient twin's space are preserved. There are reports of restored fetal growth of the donor twin, normalization of amniotic fluid volumes, and a donor twin that is neurologically intact at time of delivery; albeit premature (Crombleholme, 2003). For these difficult cases, cord coagulation may be the best chance of survival for at least one of the twins. Other methods of selective fetal reduction include ultrasound-guided bipolar cord coagulation and radiofrequency ablation.

Another disorder of monochorionic twin gestation is TRAP sequence. With TRAP, one twin, who is acephalic and acardiac,

TABLE 24.3

QUINTERO STAGING SYSTEM FOR TWIN-TO-TWIN TRANSFUSION SYNDROME

Quintero Staging System	
Stage I	The fetal bladder of the donor twin remains visible sonographically.
Stage II	The bladder of the donor twin is collapsed and not visible by ultrasound.
Stage III	Critically abnormal fetal Doppler studies noted. This may include absent or reversed end-diastolic velocity in the umbilical artery, absent or reverse flow in the ductus venosus, or pulsatile flow in the umbilical vein.
Stage IV	Fetal hydrops present
Stage V	Demise of either twin

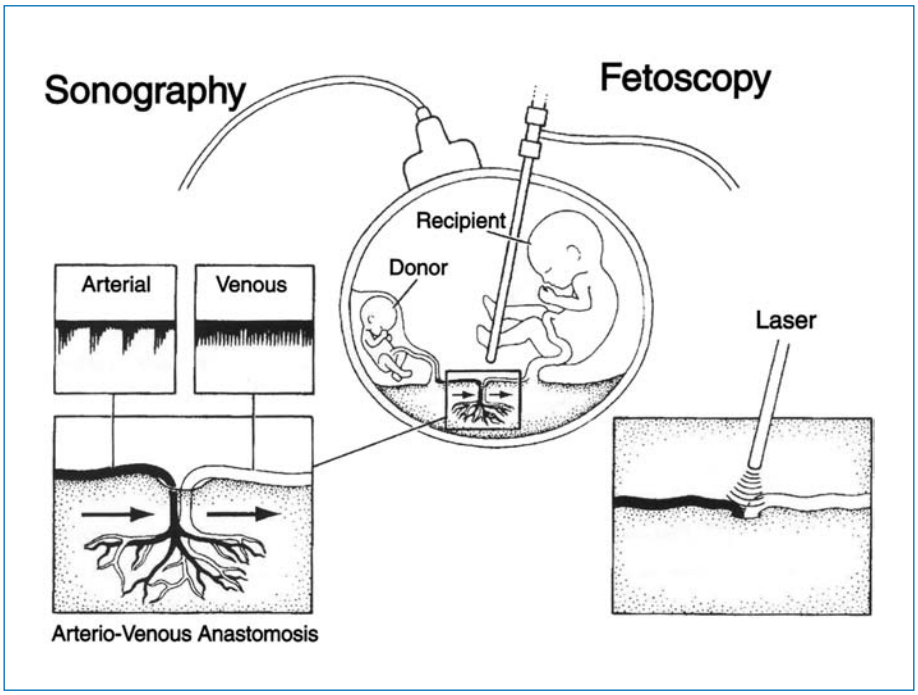

FIGURE 24.2 Fetoscopic laser ablation of the placental intertwin vessels.

is connected to the co-twin in a parasitic fashion. The second twin, or "pump twin," is anatomically normal with normal vascular connections to the placenta. The anomalous twin receives its blood supply from direct vascular connections to the normal twin, which, left untreated, will result in high-output cardiac failure and increased mortality in the "pump" twin. To save the normal twin and increase outcomes and overall survival, blood flow to the anomalous twin must be permanently interrupted. Methods of interrupting flow between the twins affected by TRAP are those outlined earlier for selective fetal reduction.

FETAL THERAPY: NEW HORIZONS

Today, organizations like the North American Fetal Therapy Network (NAFTNet) and the International Fetal Medicine and Surgery Society (IFMSS) support education and research for fetal diagnoses and therapies, in addition to promoting collaboration among fetal therapy centers around the world. IFMSS has an international registry that tracks the number, type, and outcome of fetal surgical attempts.

Further research for fetuses with MMC should be built upon the research studies that showed placenta-derived mesenchymal stem cells significantly improve motor function. Furthermore, transamniotic stem cell therapy and basic fibroblast growth factor sponges have been studied in rodent models for coverage of the MMC defect (Farmer et al., 2018; Moldenhauer & Adzick, 2017). NAFTNet has also sponsored the development of the Fetal Myelomeningocele Consortium and outcomes registry that will provide a way to track outcomes and guide future research (Moldenhauer & Adzick, 2017).

Surgeons at Texas Children's are experimenting with performing minimally invasive fetoscopic procedures by removing almost all of the amniotic fluid and instilling CO_2 into the uterus, thus creating a larger operative space. By doing so, these surgeons posit that larger, more complicated surgeries (such as MMC repair) can be performed, negating the need for OFS that carries higher risk of maternal morbidity (Nassr, Erfani, et al., 2017). It is their hope that this new approach will better anchor the fetal membranes to the uterine wall and prevent premature rupture of membranes and chorioamniotic separation that often comes with fetoscopic repair of MMC (Nassr, Erfani, et al., 2017). Critique of this experimental approach includes the risk of inducing fetal acidosis with the instillation of CO_2 into the uterine environment. Surgeons evaluating the procedure have not found this to be a complication to date, but theorize fetal acidosis can be avoided with maternal hyperventilation. The same group at Texas Children's also theorizes gastroschisis may be another fetal diagnosis that will benefit from fetal intervention. They suggest identifying complicated gastroschisis early and either covering or closing the defect will prevent some or all of the morbidity associated with the diagnosis of gastroschisis (Nassr, Erfani, et al., 2017). A multicenter group from UCSF, the University of California (UC), Berkeley, and Caltech are currently researching the production and use of a biocompatible adhesive that would be used to seal the fetal membranes prior to performing fetal interventions to prevent PROM (Table 24.5). They are modeling their adhesive after the adhesive properties of mussels' attachment to wet rocks (Graves et al., 2017).

TABLE 24.4

FETAL ANATOMIC DEFECTS AND ASSOCIATED EFFECTS ON DEVELOPMENT

Anatomic Defect	Effect on Fetal Development
Congenital cystic adenomatoid malformation	Pulmonary hypoplasia Hydrops fetalis
Sacrococcygeal teratoma	High-output cardiac failure Hydrops fetalis
Laryngeal atresia/ congenital high airway obstruction syndrome	Pulmonary hypoplasia Hydrops fetalis
Twin-to-twin transfusion syndrome	Vascular steal Growth restriction (donor) High-output cardiac failure (donor) Hydrops fetalis (recipient) Hypertrophic cardiomyopathy (recipient) Pulmonary hypertension (recipient twin)
Twin reversed arterial perfusion	Vascular steal Hydrops fetalis Hypertrophic cardiomyopathy Note: all effects on "pump" twin
Myelomeningocele	Paraplegia Hydrocephalus
Lower urinary tract obstruction	Renal dysplasia Pulmonary hypoplasia (due to oligohydramnios) Deformation of distal extremities and facies (due to oligohydramnios)
Congenital diaphragmatic hernia	Pulmonary hypoplasia Pulmonary hypertension
Aortic stenosis	Hypoplastic left heart

SUMMARY

The primary goal of this chapter has been to describe fetal treatment and, in particular, fetal surgery. As this field rapidly evolves, expands, and broadens the options for treatment, more neonatal healthcare professionals will be approached by both colleagues and patients with questions on fetal intervention, including surgery. In this redefined clinical milieu, neonatal nurses must have a basic understanding of this area of medicine, including its associated technology and perhaps even the new ethical considerations it poses. This chapter recognizes the critical, complex, and often difficult role nurse specialists fulfill in fetal treatment, acting as both patient advocate and fetal treatment team representative. The responsibilities are complex, and the nurse specialist who fulfills them must be able to weigh, balance, interpret, and act on a variety of issues from a multifaceted, informed perspective. This chapter, then, is an acknowledgment of the talent, intellect, skill, and compassion that nursing professionals bring to the field of fetal treatment.

CASE STUDY

■ **Identification of the Problem.** A 31-year-old gravida 3, para 1, currently at 23 to 2/7 weeks, whose singleton gestation is complicated by a fetal MMC. The patient's amniocentesis results revealed a normal karyotype (46XX).

■ Assessment: History and Physical Examination

- Past medical history: unremarkable
- Surgical history: none
- Obstetric history: full-term normal spontaneous vaginal delivery (NSVD) 2 years ago (healthy male), followed by early first trimester spontaneous abortion (SAB)
- Meds: prenatal vitamins, Claritin, 1,600 mcg folic acid
- Allergies: NKDA (no known drug allergies)
- Social history: works as an accountant; her husband (present at today's visit) is employed as a police officer
- Family history: the patient's cousin may have had spina bifida, but the patient is unsure and at present has not been able to obtain records

■ Review of Systems

- GENERAL REVIEW OF SYSTEMS: negative
- CONSTITUTIONAL: she is oriented to person, place, and time; vital signs are normal; she appears well developed and well nourished
- HEAD: normocephalic and atraumatic
- EYES: conjunctivae and extraocular movement are normal; pupils are equal, round, and reactive to light
- NECK: normal range of motion; neck supple
- CARDIOVASCULAR: normal rate, regular rhythm, normal heart sounds, and intact distal pulses
- PULMONARY/CHEST: effort normal and breath sounds normal
- ABDOMINAL: soft; bowel sounds are normal
- GENITOURINARY: uterus gravid
- MUSCULOSKELETAL: normal range of motion
- NEUROLOGIC: she is alert and oriented to person, place, and time, she has normal reflexes
- SKIN: skin is warm and dry
- PSYCHIATRIC: she has a normal mood and affect; her behavior is normal; judgment and thought content normal

■ Diagnostic Tests

1. Fetal echo: Structurally and functionally normal
2. Obstetric ultrasound: Appropriately grown fetus with normal amniotic fluid volume. A severe Chiari II malformation is noted;

there is ventriculomegaly measuring 17 mm on each side; the level of the defect is felt to be at L1 to L2, and there is also the finding of syringomyelia (syrinx). There is concern of no visible normal spinal cord below the level of the syrinx (just neural elements). The placenta is anterior, and the cervical length appears normal.

3. MRI: Small posterior fossa, and downward descent of the cerebellar tonsils down to the level of C4, and a lumbar MMC, consistent with Chiari II malformation. Abnormal T2 hyperintensity is noted in the spinal canal in the lower cervical region extending to the lower thoracic cord, concerning for syrinx.
4. Laboratory tests: B+, Rh positive, antibody screen negative; Hct = 42.3, Hgb = 13.5, rubella immune, VDRL (venereal disease research laboratory) negative, HBsAg negative, and chlamydia and gonorrhea negative

■ **Working Diagnosis.** Pregnancy complicated with fetus with MMC

■ Development of Management Plan

Counseling. Discussed maternal and paternal history, the diagnostic findings, and the potential management options. Reviewed the MOMS trial that studied prenatal versus postnatal repair of MMC (Adzick et al., 2011). Reviewed the benefits of prenatal MMC repair seen in that trial, particularly the 40% reduction in need for shunting (primary outcome). Discussed the secondary outcomes of a potential decrease in ambulatory deficits, such as the need for a brace, or other motor functions such as bladder and bowel control. Patients who underwent prenatal repair appeared to have a benefit equivalent to a two-level improvement in location of the lesion (e.g., deficits associated with a L2 lesion would potentially be closer to those normally seen with an L4 lesion). Discussed the risks of prenatal surgery, most significant of which are preterm birth and maternal risks such as those associated with a uterine hysterotomy.

Regarding Preterm Birth. Based on the MOMS trial results, there was an 80% incidence of preterm birth in patients who had the prenatal fetal surgery repair, compared with a 15% preterm birth in the nonsurgery or postnatal group. While this amounts to a fivefold higher risk of delivering preterm, if the patient elects prenatal surgery versus postnatal surgery, it is important to examine this more specifically by severity of the gestational age at the time of such a preterm birth. The greatest increased risk is in delivery under 30 weeks' gestation because in patients who elected to have a postnatal repair, there were no births under this gestational age, whereas 12.8% of patients who had the prenatal repair delivered at less than 30 weeks. Overall, statistically 45% of patients who undergo prenatal surgery deliver at less than 34 weeks, whereas only 5% of patients who have a postnatal repair deliver at less than 34 weeks.

Risk involving the hysterotomy is potentially high and necessitates close surveillance. Of the 76 patients analyzed in the first publication of the MOMS trial who had prenatal surgery, 35.5% had thinning or dehiscence of their hysterotomy scar. For this reason, it is imperative that patients who undergo prenatal surgical repair receive very close monitoring for contractions and are evaluated immediately if they complain of discomfort.

Other maternal risks include leakage of amniotic fluid through the hysterotomy site, which would lead to oligohydramnios and the potential need for long-term hospitalization for the remainder (or significant portions) of the pregnancy. For some patients, leakage of amniotic fluid is painful and inflammatory and leads to significant discomfort during the remainder of the pregnancy. Less common risks include other general operative risks such as bleeding, the need for blood transfusion, anesthetic complications, infection, blood clots, and complications resulting from any of the medications necessary to stabilize the patient postoperatively.

■ **Pregnancy Management Options.** Three management options:

The patient can elect to undergo a pregnancy termination. Legally this can be performed up to 24 weeks' gestation.

The patient can elect to have standard postnatal repair. It is recommended that she undergo elective cesarean delivery at 39 weeks' gestation in the same center prepared to offer postnatal MMC repair. Pregnancy recommendations are monthly growth scans antenatally as well as weekly NST beginning at 32 weeks.

The patient can elect to undergo prenatal repair. This would be scheduled prior to 26 weeks' gestation. If the patient is over 24 weeks' gestation at the time of surgery, there is the option of antenatal corticosteroids if she would choose to undergo an emergent cesarean delivery in the event of fetal distress. The patient understands that regardless of fetal status, she would have to have a cesarean delivery for this pregnancy (even in the event of an intrauterine fetal death [IUFD]), as the fresh scar cannot undergo labor. For the prenatal surgery she would need both regional anesthesia (epidural) and general anesthesia. In the immediate postoperative period, the patient would be on IV magnesium and indomethacin. Once she no longer needed magnesium, the patient would begin oral nifedipine, which would continue until delivery. The usual postoperative course ranges between 4 and 5 days of inpatient hospitalization, followed by 2 to 3 weeks of local outpatient follow-up. If the patient has an uncomplicated outpatient postoperative course, she may be cleared to return home under the direct management of a perinatologist. Written guidelines for pregnancy management would be provided. Most importantly, as noted earlier, the patient should not be allowed to tolerate significant contractions or labor. She would need to be retocolyzed in the event of preterm labor and delivered by cesarean section if labor was unstoppable. Preterm premature rupture of membranes (PPROM), in the absence of contractions, can be managed as per usual protocol. Barring any other complications, the patient would have to undergo cesarean delivery by 37 weeks.

Regarding future pregnancies: There is no increased risk of infertility. There is also no option of vaginal birth after cesarean section, and all future pregnancies should be managed similar to having had a prior *classical scar* and should be delivered by early cesarean section. After a pregnancy involving a prenatal MMC repair, the uterus has a double scar (prenatal surgical hysterotomy plus delivery hysterotomy), which increases her risk in future pregnancies. It is advised that the patient adhere to a minimum interpregnancy interval of 16 months, and that, due to the double scar, future pregnancies be delivered at 36 weeks by repeat cesarean.

■ **Outcome.** Patient elected prenatal repair of fetal MMC. Surgery was performed the following week.

EVIDENCE-BASED PRACTICE BOX

Based on its most recent statistics, the Centers for Disease Control and Prevention (CDC, 2018) reports that birth defects affect 1 in 33 babies and are the leading cause of infant mortality in the United States, more so than low birth weight and prematurity, sudden infant death syndrome (SIDS), and maternal complications. Affected babies who survive are at increased risk for developing lifelong physical and cognitive challenges. Lifelong costs associated with birth defects, for example, and annual hospital stays are a significant stressor on families and the healthcare system alike. Fortunately, advances in fetal diagnosis allow clinicians to both accurately identify most complex anomalies prenatally and, more often, stratify the severity of the birth defect. In many instances, because diagnosis can be made in the second trimester, clinicians can provide families information that enables them to make more informed decisions about the pregnancy and the delivery plan and to plan and prepare for the future.

Over the past four decades, fetal intervention for congenital anomalies has evolved from a mere concept to a full-fledged medical specialty. The strategy of fetal intervention is to ameliorate or reverse some of the progressive physiologic organ damage that occurs from a particular defect. Operative techniques used in fetal surgery, such as open hysterotomy, fetal endoscopy, and image-guided percutaneous procedures, were developed and tested extensively in animal models first, before clinical application. These advances in surgical techniques paralleled and complemented those in fetal imaging, prenatal diagnosis, and maternal tocolysis. In a relatively short time, fetal intervention has become an important option for the treatment of fetuses who would otherwise not survive gestation or who would endure significant morbidity and mortality after birth.

The evolution of fetal surgery from research hypothesis to medical specialty was not without many trials and tribulations. The fetal therapy community quickly learned that justification for in-utero intervention based on anecdotal experience and retrospective studies of registry data was insufficient. Prospective controlled trials to determine the safety and efficacy of fetal interventions were necessary. As a result, in the mid-1990s, UCSF conducted the first NIH-sponsored trial examining open fetal surgical repair for CDH without herniated liver (Harrison et al., 1997). Upon completion of the trial, data suggested that fetal surgery for CDH, although physiologically sound and technically feasible, did not improve survival over standard postnatal treatment.

Three trends have dominated the field of fetal surgery. First, an emphasis has been placed on prospective RCTs instead of retrospective clinical trials to determine efficacy and effectiveness. The evolution of the interventions themselves represents a strategic shift from anatomic repair of a congenital anomaly to physiologic manipulation of the developmental consequences (e.g., from open in-utero repair of the diaphragmatic defect in CDH to temporary tracheal occlusion to promote lung growth). Finally, innovation in techniques represents a movement toward developing minimally invasive procedures. These overarching themes emphasize the objective of a multidisciplinary team of obstetricians, surgeons, perinatologists, nurses, anesthesiologists, and sonologists to promote maternal safety while improving outcomes for patients with fetal anomalies.

Many fetal treatment centers around the world have and are conducting clinical trials for fetal intervention. These centers have formed a cooperative and collaborative global community committed to reporting outcomes from fetal intervention, whether good or poor. These collaborations have already resulted in the successful completion of multicenter RCTs for TTTS and MMC. It is the dedication of these multidisciplinary teams that has helped establish fetal surgery as a medical specialty.

Prenatal screening, genetic testing, and improved imaging capabilities provide families more information earlier in their pregnancy. Potential parents are often not prepared for a poor prenatal diagnosis. Understandably, they react with fear and grief. All involved subspecialties have a very important, defined role. Clinicians have both the privilege and an ethical obligation to deliver services to families by educating parents about all their options, supporting them through the decision-making process, providing appropriate informed consent, and delivering competent and compassionate care. Providing care and support to the family faced with this news is of concern to all nurses who participate in their care. Nurses can be key planners/coordinators in the multidisciplinary team and have great potential to facilitate a healing environment for families facing the unexpected.

PARENT VOICES

Crystal Duffy

When I think back on the fetal surgery performed to save my babies' lives prior to their birth, I think of how blessed I was not only to live in a time with these advanced medical technologies but also lucky to have been geographically close to one of the few centers in the country specializing in twin-to-twin transfusion syndrome.

I attribute my babies' successful fetal surgery to advanced medical technology, dedication from a team of talented surgeons, and the faith and hope from both parents.

CHAPTER 25

Surgical Considerations in the Newborn and Infant

Kaye Spence

INTRODUCTION

Caring for an infant with a surgical condition is an exciting challenge that requires knowledge of pathophysiology and current neonatal care practices, training to recognize and respond to complications, and an ability to extend supportive care to the family. Optimum outcome is achieved through the skills of a multidisciplinary team that includes neonatal nurses, neonatologists, pediatric surgeons, radiologists, anesthesiologists, respiratory therapists, and parents. The members of this team must work together, guided by the knowledge that all principles of neonatal care, as well as additional considerations related to surgical care, apply in each case. This chapter outlines the special considerations of the newborn infant who undergoes surgical procedures in the newborn period and shortly after.

ANTENATAL CONSIDERATIONS

Neonatal surgery has been inextricably linked to the field of obstetrics with neonatologists and surgeons, along with fetal medicine specialists, obstetricians, and midwives working together to characterize the development and well-being of fetuses with congenital malformations (Cass, 2011). Many congenital surgical defects are diagnosed in utero through routine prenatal screening, providing time for education and emotional support for the family. Women are transferred to a high-risk birth unit with skilled fetal–maternal specialists with access to a neonatal surgeon. If possible, a tour of the neonatal intensive care unit (NICU) should be arranged before delivery for the prospective parents as meeting the team and knowing their roles can help reduce a parent's anxiety (Wilpers, Kennedy, Wall, Funk, & Bahtiyar, 2017). It is recommended that the parents meet with members of the surgical and neonatal teams to discuss the findings and probable prognosis for their infant. Information given to the family should include the natural history of the abnormality, timing of surgery, anticipated surgical outcomes, possible long-term sequelae, and any other possible problems that may be involved with the neonate's course (Lakhoo, 2012). There have been many changes over the past decades in the care and management of newborn infants requiring surgery. Important areas of advancement have been in newborn intensive care and postoperative care. Another area of advancement has been in antenatal diagnosis and the early referral to NICUs for information and education regarding the expected course of treatment and the outcomes of surgical care for newborn infants. For more information on fetal surgery, please see Chapter 24, Fetal Therapy.

TRANSPORTATION OF INFANTS FOR SURGERY

Infants requiring surgery should be born in an appropriate tertiary perinatal center, adjacent to pediatric surgical facilities, in accordance with best practice. Pregnancies complicated by birth defects have variable rates of antenatal diagnosis and may require surgical repair in the newborn period. The success of antenatal transfer is dependent on the complexity of the antenatal diagnosis, and with regionalization of maternal and neonatal services the healthcare of women outside specific urban areas are not disadvantaged. For some specific conditions, such as congenital heart disease, transferring the mother for delivery to a high-risk center is preferred (Calisti et al., 2012) so that an expedited transfer from the birth unit to the NICU can occur in a matter of minutes. Advantages of antenatal referral of infants with congenital anomalies requiring surgery include:

1. Improved neonatal outcomes
2. The opportunity for parents to discuss the following issues with experienced staff:
   - Options for birth
   - Anticipated care of the baby
   - Likely neonatal outcomes
3. The reassurance of access to the best available obstetric and neonatal care
4. Women may also experience a reduction in stress and anxiety as an emergency transfer of the baby resulting in separation of mother and baby is avoided (Wilpers et al., 2017).

Approximately 80% of neonates with an antenatal diagnosis of a congenital anomaly require admission to a NICU and major surgery. Emergency transport services retrieve neonates to tertiary referral centers for intensive care, diagnostic workup, or surgery. If birth occurs at an appropriate tertiary perinatal center, the potential for an emergency neonatal retrieval to a pediatric facility is avoided. The mortality rate is falling for neonates who have surgery in the first 28 days (Tauro, Walker, Halliday, Jatana, & Trivdi, 2018).

It is desirable for each maternity unit to have a policy on antenatal referral of mothers with babies known to have a congenital

abnormality, likely one that would require surgery. The policy should emphasize antenatal consultation with the appropriate fetal, surgical, and other consultants (e.g., genetics, cardiac) in the preferred facility. It should note that the decision to make an antenatal maternal referral should take into account patient and clinician preferences. The policy should include options and processes for antenatal referral for more detailed fetal assessment and a plan for the optimal place of delivery. This referral will usually occur in mid-pregnancy. **Quality and Safety: If surgery or other critical therapy is likely to be required soon after birth, this plan should include delivery at a perinatal center with direct access to appropriate pediatric surgical services.** For women in nonurban locations, transfer to a tertiary care centre around 34 weeks' gestation may be desirable.

SURGICAL NEONATAL INTENSIVE CARE UNITS

Criteria for neonatal surgical units have been established in several countries to ensure that acceptable standards are met for infants who require surgery during the neonatal period. There are identified requirements for surgical services that provide operations and general anesthesia for newborn infants. These requirements relate to adequate training for the consultant surgeon and anesthetist with sufficient caseloads to maintain skills (McAteer et al., 2013). In addition, adequately trained and experienced staff to care for the infant postoperatively need to be available in dedicated newborn surgical units.

There are arguments for and against large regional specialist pediatric centers being established for neonatal surgery. Benefits of regionalization include pooling of expertise, appropriate consultants, support services, and staff training. Disadvantages include children and their families having to travel long distances for care and the loss of expertise at a local level. However, the availability of a neonatal emergency transport service can provide expertise and support for transferring neonates to regional neonatal surgical intensive care centers (Fullerton et al., 2016).

There are trends in some countries to ensure that surgical neonatal intensive care units (SNICUs) are located in children's hospitals with a co-located perinatal center. This practice enables the women to deliver with a high-risk obstetric team as well as having a specialist pediatric/neonatal surgical team present to attend to the infant's well-being.

Staffing

The majority of the nursing staff in SNICUs require skills and competence in neonatal intensive care as well as the specific management of neonatal surgical patients. Recommendations for staffing ratios vary; however, most infants will require dedicated nursing staff in the immediate postoperative period. During this period many infants will be unstable, and vigilant observation and assessment are required to avert postoperative complications. In addition, the families require additional support and explanation of many of the unique procedures seen in infants who have undergone surgery. A dedicated in-service program that includes a multidimensional approach to various conditions, altered pathophysiology, care paths, techniques, and procedures as well as counseling skills is recommended (Gallagher, 2013). A wide range of subspecialists, including cardiologists, gastroenterologists, endocrinologists, geneticists, infectious disease specialists, respiratory specialists, and anesthetists, as well as allied health professionals, are involved in the SNICU; this requires a coordinated effort of team meetings and communication. Nurses are in key positions to coordinate the information and develop care plans to ensure continuity when multiple specialist teams are involved. The combined skills of the pediatric surgeon, pediatric anesthetist, neonatologist, and neonatal nurse together with the resources available in a regional pediatric center will continue to contribute to the improvements in survival and quality of life of infants requiring neonatal surgery. However, there does need to be continuing debate on the surgical advances for infants with congenital malformations. Issues such as long-term outcomes and future quality of life need to be considered by the team together with the families. Other issues such as resources and cost-effectiveness of the treatments need to be part of the community debate for future healthcare programs; according to present evidence, neonatal surgery yields good value for money and contributes to equity in health.

Family

Families will seek out information about their infant's prenatally diagnosed condition (Usui, Kamiyama, Tani, Kanagawa, & Fukuzawa, 2011) and require open and honest communication from the healthcare team regarding prognosis, treatment options, and outcomes. Decisions on the management and treatment of the infant require a team approach that includes parents, nurses, obstetricians, pediatric surgeons, neonatologists, nurse practitioners, and radiologists. Supportive services should be provided to the family as indicated to reduce some of the stressors of having their newborn infant undergo surgery (Diffin, Spence, Johnston, & Badawi, 2012). Providing opportunities for kangaroo care prior to the operation may help alleviate some stressors and it has been shown that with an opportunity to breastfeed prior to surgery can improve breastfeeding rates postoperatively for cardiac infants (McKean et al., 2017).

Parents want comprehensive information, especially during the waiting periods. Parental coping may be greatly enhanced by timely updates from the operating room (OR) while the parents are waiting for their infant in surgery. It is also important for the surgeon to speak with the parents immediately after surgery to discuss findings and the infant's condition. Once the infant is back from the OR, the parents are encouraged to visit in a timely manner to reduce anticipatory stress. The nurse will discuss the infant's current condition, the equipment used, and anticipatory care in the short term.

In the postoperative period, parents need to be able to negotiate their parental role with the staff members caring for their infant and are supported in their attempts to advocate for their infant. Parents are also encouraged to participate in their child's care to the extent that it is comfortable for them. This participation means that parents must be provided with adequate information and guidance regarding their role to enable them to cope and use informal support structures to help allay their anxiety (McFadyen et al., 2011).

CLASSIFICATION OF NEONATAL SURGERY

Neonatal surgery is defined as surgery performed on infants who

- Are less than 28 days old
- Weigh less than 2,500 g regardless of age
- Require care in a NICU regardless of age or weight

Approximately 0.6% of newborn infants undergo surgery in the first 4 weeks of life (Badawi et al., 2003). Some of the most common types of surgical procedures performed are gastrointestinal, cardiovascular, hernia, genitourinary, and neurosurgical.

Neonatal surgery can be classified into three groups for ease of management. Group 1 includes those infants with a life-threatening

condition for whom a surgical operation is necessary within the first day of life, such as congenital diaphragmatic hernia, gastroschisis, or esophageal atresia with fistula and critical congenital cardiac malformations. In group 2 are those infants with an obvious abnormality but for whom a surgical operation may be deferred for days or months, such as exomphalos minor or cleft lip. Group 3 includes infants who have an obvious abnormality whose management may consist of interventions after due consideration, such as myelomeningocele.

PREANESTHETIC EVALUATION

Anesthetizing a preterm or critically ill neonate requires constant vigilance, rapid recognition of events and trends, and swift intervention. The anesthetic considerations in the preterm neonate are based on the physiologic immaturity of the various body systems, the associated congenital disorders, and possible poor tolerance of anesthetic drugs and considerations regarding use of high concentrations of oxygen. The preoperative assessment should include consultation with the parents, including the description of postoperative respiratory support. A complete examination is undertaken, with special attention to the appearance of the upper airway and the possibility of difficult intubation (Taneja, Srivastava, & Saxena, 2012). Preterm and ex-premature infants can have dramatic responses with wide variability to narcotics and inhaled anesthetics.

Preoperative investigations include hemoglobin, hematocrit, and platelets, and the coagulation profile should be within acceptable limits. Serum electrolyte, glucose levels, arterial blood gas, and chest x-ray will aid in intraoperative management and stabilization (Taneja et al., 2012). A blood cross-match must be available so that a transfusion can be given if the blood loss exceeds 10% of blood volume during surgery.

PREPARATION FOR SURGERY

From the time of delivery, the goal is to reduce the likelihood of morbidity and mortality by continually assessing the infant and the responses to treatments instituted. Preparation for surgery starts with discussions with the family and gaining informed consent. The consent process is the responsibility of the surgical team; however, it is good practice for the nurse to be present when these discussions take place. If the parents are from a non–English-speaking background, then an interpreter needs to be present. Often nurses are asked to clarify issues that were discussed, and nurses are in a unique position to communicate misunderstandings back to the surgical team.

Quality and Safety: Many of the neonatal surgical procedures are performed on emergency operative lists; therefore, the preparation needs to be coordinated and the many teams involved aware of the infant's condition prior to surgery. The anesthetist holds a key role in this coordination with multiple subspecialists, and the nurse is pivotal in ensuring the documentation is complete and the family informed and available. Each institution needs to have a clear and comprehensive system of evaluating infants during the preoperative period to ensure effective use of operating time and to avoid undue delays and stress on the infant and family. An understanding of neonatal physiology is necessary to enable the team to provide appropriate care in three areas of homeostasis—temperature regulation, fluid and electrolyte balance, and acid–base balance (Taneja et al., 2012). In addition, specific practices for preparation for transfer to the OR are described in this chapter. Each area is discussed in relation to the preparation of the infant for surgery.

Temperature Management

Heat loss can occur during transfer to the imaging department and the OR due to the infant's high ratio of surface area to body weight. It remains important to maintain the core body temperature close to 37°C to minimize oxygen consumption. In the OR, a low ambient temperature increases heat loss by both convection and radiation. It is ideal that the OR be warmed to 28°C to 30°C for neonatal patients. The infant may be transferred on an open-care bed with a radiant warmer and cover; some surgeons will operate on these beds to minimize the stress of heat loss. The infant undergoing surgical procedures where the organs are exposed is at particular risk of heat loss.

Quality and Safety: Prevention of hypothermia in the surgical neonate is imperative in the preoperative period. Maintaining a neutral thermal environment is a constant challenge. In a neutral thermal environment, metabolic activity is minimal because body temperature is kept stable. Oxygen consumption is reduced, and acidosis is prevented. Any prolonged deviations from the neutral thermal environment further stress the infant's already limited thermoregulatory abilities. Strategies such as wrapping the infant's head and limbs in cotton webbing can be useful in reducing some of the inevitable heat loss.

Heat loss occurs through evaporation, conduction, convection, and radiation. Evaporative heat loss occurs with exposure of the intestinal contents of a ruptured omphalocele or gastroschisis. In the case of an encephalocele or a myelomeningocele, the unprotected spinal cord may allow heat loss. The exposed bladder mucosa in exstrophy of the bladder also contributes to heat loss. This type of heat loss can be prevented by applying warm dressings to the defects and then covering these areas with plastic wrap. Do not use saline-soaked dressings as this can add to the evaporative heat loss.

Conductive heat loss occurs with direct skin contact with a cold surface, such as cold or wet linens, an operating table, radiographic plates, or an unwarmed bed. To prevent this type of heat loss, linens should be prewarmed as the bed or incubator is warmed. Operating or radiography tables can be warmed with heat lamps before and during procedures. Linens that become wet should be replaced with dry, warmed linens; radiographic plates and scales should be covered with warmed linens before the infant is placed on them.

Heat loss by convection occurs when air blows over the infant. Use of warmed oxygen in head hoods (boxes) and ventilators can reduce this type of heat loss. Also, it is essential that the incubator door not be open for prolonged periods. Insertion of nasogastric tubes, placement of intravenous lines, radiographic studies, physical examinations, and phlebotomy procedures should be performed through the incubator portholes to reduce heat loss. An additional heat source may be placed over the incubator when the door must be open.

Heat loss by radiation is the most difficult to control. This type of heat loss occurs during transportation of the neonate in cold hallways or in the cold OR. To prevent this cold stress, the infant should be covered with warmed linens or wrapped during transport. ORs should be prewarmed to well above the "comfortable" temperature. Nursing care that focuses on the thermoregulatory process of the neonate is vital to the prevention of complications related to poor temperature control. It is also beneficial to use warmed solutions for suctioning and dressing changes. Frequent monitoring of the infant's temperature is extremely important. Consistency in the method of measuring temperature and appropriate documentation are also essential.

Fluid and Electrolyte Balance

Adequate fluid volume is required to ensure the perfusion of all organ systems. An inadequate vascular volume interferes with the oxygen supply to peripheral tissues, resulting in cellular damage and acidosis. Precision in fluid management is essential; there is little margin for error. Particular care needs to be taken to ensure excessive volumes are not delivered with additional drugs used during the anesthesia. All fluid losses must be measured accurately to ensure adequate replacement. Estimation of insensible fluid losses is essential, including those caused by humidification through ventilation and radiant heating. Unexpected fluid losses and inadequate fluid replacement delay preoperative stabilization of the neonate's condition.

Infants with an esophageal atresia may have continuous losses of saliva suctioned from the esophageal pouch that needs to be considered in the fluid balance. The large exposed intestinal area seen with a ruptured omphalocele or gastroschisis results in large volumes of fluid losses. Replacement of these losses may involve up to twice the normal maintenance fluids of a neonate. If a membranous sac protects an omphalocele, the fluid requirement is less.

Gastrointestinal obstructions cause fluid losses from vomiting, aspiration, and the suctioning required for gastric decompression. Infants with open neural tube defects also have increased fluid losses. A leaking myelomeningocele requires increased fluid administration to keep up with the loss of cerebrospinal fluid.

Peritonitis, such as occurs with intestinal perforations in necrotizing enterocolitis, midgut volvulus, or ruptured meconium ileus, causes third spacing of fluid (capillary leak syndrome) or fluid shifts into the bowel, necessitating increased fluid replacement. Third spacing of fluids, or capillary leak syndrome, is the result of trauma to the gastrointestinal system. The capillary membrane's permeability is changed. This phenomenon may be due to natural fibronectin, a glycoprotein secreted by epithelial cells in the pulmonary and gastrointestinal trees. It is secreted in response to stimulation of the immune system to heal a wound. Fibronectin alters capillary permeability, shifting fluid and resulting in a "leaky capillary" and the third spacing of fluid. The body's compensatory response to any gastrointestinal trauma, then, can result in a movement of fluid across this "leaky" membrane. Fluid moves out of the vascular compartment and into the tissues, and the infant develops generalized edema. Abdominal swelling exerts pressure on the thoracic cavity, increasing the work of breathing. Gas exchange and ventilation are compromised as a result of (a) the pressure; (b) the decreased circulation; (c) the increased workload of the heart, which delivers oxygen to the tissues; and (d) the increasing loss of the buffer system through the mechanisms of diminished kidney perfusion and gastric losses.

The numerous conditions that affect the surgical neonate may result in imbalances of serum electrolytes, especially sodium and potassium. Fluid losses and inadequate intake result in hypokalemia and hyponatremia.

Hyperkalemia occurs with acidosis, excessive potassium intake, and renal failure. Renal failure may result from genitourinary obstructions or from sepsis and poor perfusion, as is seen with necrotizing enterocolitis with perforation or peritonitis.

The causes of hypernatremia are generally iatrogenic. An excessive intake of sodium occurs with the administration of hypertonic solutions, intravenous flushes with normal saline or heparinized normal saline, or sodium bicarbonate for treatment of acidosis. **Emergency Alert: Return to a fluid and electrolyte balance is needed to improve the neonate's ability to tolerate any necessary operative procedure and to reduce the likelihood of complications.**

Maintenance of Glucose Levels

Fluctuation in the glucose level is a major indication of stress and infection. Preoperative hyperglycemia can result from sepsis or excessive intravenous administration of glucose. Hypoglycemia may result from a multitude of problems. For example, reduced glycogen stores are seen in premature infants and in infants with intrauterine growth restriction. Excessive insulin production occurs in the infant of a diabetic mother and with sudden or prolonged cessation of glucose infusions, as may occur with difficult or delayed insertion of intravenous lines. Abnormalities in glucose metabolism are evident with sepsis, shock, and asphyxia, as well as with various central nervous system (CNS) abnormalities. **Emergency Alert: Glucose infusions must be carefully titrated to provide adequate hydration while the serum glucose is slowly restored to an acceptable concentration, avoiding extremes in the serum glucose level.**

Acid–Base Balance

A variety of factors can alter the acid–base balance in the surgical neonate. Major conditions that can result in acidosis include inadequate respiratory support and fluid or electrolyte imbalances. The effects of sepsis and tissue necrosis are also significant causes of acidosis. Acidosis in the surgical neonate can be of the respiratory, metabolic, or mixed type.

Respiratory acidosis could occur with decreased ventilation, resulting in an increased partial pressure of carbon dioxide (P_{CO_2}) and a decreased pH. An overproduction of acids may occur with any condition that causes a decrease in oxygenation or perfusion. Impaired kidney function, such as that which occurs in acute renal failure or renal tubular necrosis, reduces elimination of hydrogen ions, contributing to the development of metabolic acidosis. Bicarbonate losses are increased with severe diarrhea, intestinal fistulas, vomiting, and gastric drainage, resulting in metabolic acidosis.

Poor tissue perfusion causes acidosis, as is seen with multiple gastrointestinal anomalies that are accompanied by large fluid losses. These anomalies include tracheoesophageal fistula with esophageal atresia, ruptured omphalocele and gastroschisis, bowel obstruction, and necrotizing enterocolitis. Adequately replenishing fluid or blood volume usually corrects this metabolic acidosis. When necrosis or perforation occurs, however, the acidosis may not be correctable until the necrotic bowel has been removed and any resulting sepsis treated.

Drugs

The role of prophylactic antibiotics for neonatal surgery remains controversial. However, with suspected gastrointestinal obstruction, antibiotics may be needed to treat peritonitis or enterocolitis. The progression of necrotizing enterocolitis may be slowed with vigorous antibiotic therapy. Treatment of omphalocele and gastroschisis may include antibiotics to protect the exposed gastrointestinal contents and to help prevent ischemic injury to the abdominal contents. If pneumonia accompanies an esophageal atresia with tracheoesophageal fistula, aggressive antibiotic therapy may be instituted to clear the pneumonia and promote optimum surgical repair of the defect. The infant with a myelomeningocele requires antibiotic treatment to prevent meningitis.

Inotropic agents may be necessary to improve cardiac function and thus improve organ perfusion impaired by sepsis and stress. The most frequently used agents are dobutamine and dopamine. Dobutamine hydrochloride achieves organ perfusion by increasing cardiac output. Dopamine hydrochloride, used in low to moderate doses, causes vasodilation with resultant improvement in cardiac, renal, gastrointestinal, and cerebral blood flow. Use of dopamine

hydrochloride at high doses, however, causes vasoconstriction of renal and gastrointestinal vessels. This vasoconstriction could worsen the condition of a renal system affected by obstruction or poor flow status, as well as the gastrointestinal system already compromised by necrotizing enterocolitis, omphalocele, gastroschisis, or obstruction. **Emergency Alert: Doses of dobutamine hydrochloride and dopamine hydrochloride, therefore, must be carefully calculated and continually titrated to achieve the desired effect.** Furthermore, these medications are incompatible with many other drugs. For example, alkaline solutions (e.g., sodium bicarbonate, ampicillin, gentamicin, and furosemide) can inactivate dobutamine and dopamine. These inotropic agents are also irritating to vessels, and close monitoring of intravenous sites for infiltration is essential.

A buffering agent may be required to treat the acidosis that may accompany a diaphragmatic hernia, necrotizing enterocolitis, omphalocele, gastroschisis, or obstruction with resulting ischemic injury. Adequate ventilation and tissue perfusion must be established and maintained before medication is used to treat acidotic conditions.

Monitoring

Infants will require preoperative monitoring that continues during the operation into the postoperative period. At a minimum, cardiorespiratory monitoring is essential. The electrodes and leads should be placed with consideration of the operative area; this will enable the monitoring leads to be used during the surgery without the necessity of tissue damage from removal and re-siting. A pulse oximeter on an upper limb will enable the oxygen saturation levels to be monitored. The nurse needs to be mindful that some monitoring, such as transcutaneous oxygen, may be ineffective because of changes in skin perfusion during the procedure. The placement of a temperature probe can assist the anesthetist in monitoring the temperature during surgery. Amplitude electroencephalogram (aEEG) monitoring is recommended for neonates prior to surgery to aid in the postoperative course and as a way of determining cerebral insults that are possible during the anesthesia and surgery (Mehta, Hunt, Walker, & Badawi, 2016).

Intravascular Lines

Ideally, a central venous catheter (CVC) is placed to assist postoperatively for multiple drug infusions and parental nutrition (PN). It may be opportune for the CVC to be inserted during the operative procedure; this may be negotiated with the surgeon and anesthetist.

Quality and Safety: In addition, a peripheral arterial cannula is required for the continuing measurement of the acid–base balance during the operation and in the postoperative period. It is best if this is inserted before the infant is transferred to the OR. Precautions should be taken to ensure that all connections are Luer-Lok to avoid accidental disconnection when covered with surgical drapes. Emergency Alert: Caution needs to be taken if multiple drug infusions are required; incompatibilities and priority for access can be a challenge for complex conditions.

Nurse's Role

Adequate and thorough preparation of the infant can minimize stress during the process and help reduce the preparation and time of the surgery. Being prepared and anticipating the time and call for surgery can ensure that the infant is adequately prepared for transfer and surgery. If the nurse accompanies the infant to the OR, continued monitoring and a smooth handover can occur. In some institutions, the neonatal nurse can remain in the OR assisting the infant and helping with the monitoring of the oxygenation and temperature. This is, however, a contentious issue for some institutions and OR staff.

The prospective site of the surgery needs to be prepared through the use of an antiseptic wash prior to the transfer for surgery. In the case of a stoma formation, the stoma therapist will indicate on the infant's abdomen the preferred location for the stoma. This type of preparation can make the postoperative care easier and avoid undue stress for the infant from a leaking stoma bag due to poor location. The surgeon makes a mark to indicate the side (right or left) for the operation to avoid a potential mistake during the operation.

A Preoperative Checklist may be helpful in ensuring that all the relevant information is available (Box 25.1).

Box 25.1

PREOPERATIVE CHECKLIST

- Record infant's weight (both birth and current) and gestational age
- Determine that preoperative condition is stable and optimal
- Identify associated conditions such as heart or lung disease, renal abnormalities
- Review preoperative investigations
- Ensure that venous access has been established
- Ensure blood has been cross-matched and available
- Reassure the parents

DURING SURGERY

Anesthesia

The developing brain in neonates is susceptible to the possible neurotoxic effects of general anesthesia (Davidson & Sun, 2018). Other considerations that may contribute to neurodevelopmental outcomes include managing fluid, respiratory, cardiovascular, glucose, and pain responses to surgery. The timing of anesthesia needs to be considered and weighed in relation to the need for surgery and possible harmful effects, as the evidence in humans is yet to be determined.

The intraoperative period places the infant at risk of fluctuations in vital signs as well as stress. Many neonates will arrive at the OR already intubated and ventilated. The endotracheal tube needs to be secure to ensure that accidental extubation does not occur. This is the responsibility of the anesthetist, who may elect to re-intubate prior to the surgery.

The choice of anesthetic agent will depend on the type of operation, the defect, and the infant's status. Muscle relaxants are commonly used together with controlled ventilation and humidified gases for neonates. Inhalation anesthetic agents are commonly administered in 100% oxygen during the anesthesia, and the use of opioids can limit episodes of hypoxic pulmonary vasoconstriction. How infants are positioned during surgery can predispose them to hypoxia. For example, when positioned in the lateral decubitus position for thoracic surgery, infants are at significant risk of hypoxia due to their increased consumption of oxygen. Complications such as an elevated intrathoracic CO_2 pressure during thoracic surgery may lead to decreased cerebral oxygen saturation. The use of newer modes of monitoring such as cerebral oxygenation (near-infrared spectroscopy) and blood flow (cerebral Doppler) may be

warranted (Neunhoeffer et al., 2017). This type of information is useful when nurses are challenged to care for recovering infants in the postoperative period.

Anesthetic agents can cause respiratory depression, as can narcotic and sedative medications. The neonate has a limited capacity to tolerate prolonged anesthesia. Residual effects of anesthesia can delay recovery from the surgical procedure, as seen by the infant's diminished respiratory effort and apnea. For these reasons it remains unwise to extubate the infant in the immediate postoperative period. At least 24 hours of postoperative ventilation enables more control of the infant's condition and stability as well as enabling adequate postoperative pain management.

An alternate to general anesthesia is using regional anesthesia, which can be effective with less requirement for drugs; this may be beneficial in neonates with an immature physiology and metabolism. By reducing anesthetic drugs, a more stable hemodynamic response as well as faster recovery may contribute to a shortened length of stay (McCann & Soriano, 2014; Wadhwa, Hasija, & Saxena, 2017). However, close observation and assessment of pain is required for the management of postoperative pain.

Andropoulous et al. (2014) describe an association between perioperative anesthetic exposure, MRI brain injury, and neurodevelopmental outcome scores using the Bayley-III at the age of 12 months in neonates who underwent cardiac surgery. These researchers believe the recovery from brain injury can be influenced by the clinical environment, care, and length of stay in the ICU.

Stress Response

Early studies have shown that inadequate analgesia during surgery is associated with a large stress response that results in suboptimal postoperative recovery (Anand, Hansen, & Hickey, 1990). Despite this knowledge, neonates undergoing surgery continue to demonstrate a stress response, and different approaches to anesthesia and analgesia are being considered (Wolf, 2012). Surgical stress occurs as a result of an insult to the specific organ(s), tissue damage, and nociceptive stimulation presenting as an endocrine and metabolic response. The magnitude of the response is high in neonates due to the immature control of hormone secretion. The effects of the response manifest as hyperglycemia, lactic academia, tachycardia, hypertension, and hypothermia. These changes continue into the postoperative period for several hours and can obscure other clinical signs.

Thermoregulation

Concerns regarding temperature regulation continue during the intraoperative period. Although achieving a normal core temperature in the infant before surgery is always helpful, it is not always possible. Body temperature should be monitored throughout the procedure using either a skin or a rectal probe. A radiant warmer should be used during line placement, preparation, draping, and induction of anesthesia. A warming blanket under the infant can also be used to achieve constant temperature control. In addition, the room temperature should be increased to help compensate for the neonate's inability to stabilize temperature. Another mechanism for improving temperature control is humidification and warming of anesthetic gases. Slightly warming blood products, irrigation fluids, and intravenous fluids also assists in temperature maintenance. Surgical drapes should be replaced, if possible, when they become wet.

Another challenge in temperature maintenance is encountered during transport of the neonate to and from the OR. To ensure temperature stability, the infant should be covered with warmed linen during transport. During the operative procedure, the transfer bed should be warmed to allow for some warmth during transport postoperatively.

Fluid and Electrolyte Balance

The goal of intraoperative fluid management is to replace the fasting fluid deficit, maintenance and third space fluid losses, and blood loss to maintain homeostasis. Constant monitoring of fluid balance should continue throughout the surgical procedure. During the operative procedure, the fluid choice reflects the most dominant fluid loss. Early treatment of hypovolemia is essential. Intravenous fluid administration rates must be monitored to prevent fluid boluses, which could compromise fluid and electrolyte balance. Fluid loss from the surgical defect and blood loss during the operative procedure must be monitored and replaced. The metabolic response to surgery and the neuroendocrine stress response results in a rapid increase in antidiuretic hormone (ADH), which results in possible hyponatremia if the fluid sodium is not appropriate. If intraoperative free water administration is excessive, a postoperative reduction in plasma sodium ($\geq$4 mmol L) with a risk of clinically relevant postoperative hyponatremia is observed (Nkilly et al., 2014).

Monitoring

The trends of the infant's vital signs of heart rate, oxygenation, and gases are useful indicators for the anesthetist. Continuous monitoring during the operative phase can be useful in reviewing the infant's course during the surgery.

POSTOPERATIVE CARE

Oxygenation and Ventilation

Respiratory care in the postoperative period can present a great challenge to the caregiver. Intubation, anesthetic gases, and the stress of the procedure can traumatize the infant's respiratory tract. Depression of respiratory drive may be seen as a residual effect of anesthesia, and airway clearance may be difficult to maintain. These alterations in respiratory mechanics may lead to respiratory insufficiency and the need for prolonged mechanical support. Although specific respiratory needs may vary depending on the surgical procedure, a conservative approach to respiratory care is essential to maintain optimum oxygenation. Different ventilation modalities, such as high-frequency oscillation (HFO), have been found to be useful when commenced early in reducing the duration of ventilation required postoperatively (Bojan, Gioanni, Mauriat, & Pouard, 2012). An aggressive plan of weaning may cause recurring acidosis, hypoxia, or damage to the surgical repair. Following cardiac surgery, infants' slow weaning may be associated with low cardiac output and respiratory compromise.

Postoperative care of neonates includes maintaining ventilation and ensuring adequate analgesia. Small, premature, or low birth weight infants have lung function that is already compromised. The stress of severe infection and the surgical procedure itself, as well as the prematurity of the lungs, may necessitate prolonged ventilation with a slow weaning process. However, the majority of infants who undergo surgery for a congenital malformation have relatively normal lungs, and the ventilation can be quickly weaned while maintaining close observation on their work of breathing.

Pain Management

The assessment of the infant for postoperative pain is an important component of nursing care. Opioids remain the choice for pain management following major neonatal surgery. Morphine,

in particular, has proved effective and has widespread use despite its well-recognized limitation of a prolonged duration of action in neonates. Fentanyl is being used more often during neonatal surgery and for postoperative pain management, and the greater hemodynamic stability needs to be balanced against recognized disadvantages such as the early onset of tolerance (De Lima & Carmo, 2010).

Nurses need to have a good knowledge base for the physiologic responses, pharmacokinetics, and behavioral responses of the infant in pain. The use of a validated pain assessment tool and the reliability of the use of the tool between clinicians are important if postoperative pain is to be adequately managed. Most infants will have a narcotic infusion in the immediate postoperative period. The use of narcotics is encouraged; however, the assessment of their effect is important. Ceelie et al. (2012) found that despite having a protocol for postoperative pain management, it was poorly used, which can result in pain medications being underutilized. There remains a lack of information on the effectiveness of pain management strategies and outcomes of infants managed for pain with narcotics. The neonate's behavioral response and developmental capabilities are important components of the nurse's assessment. Research into the impact of the caregiving environment has revealed significant physiologic and behavioral responses to obviously painful and stressful procedures (Browne, 2011).

Fluid and Electrolyte Balance

A goal of postoperative care is to provide fluid and electrolyte balance without overhydration. Hypovolemia is a major cause of hypotension and must be resolved quickly to ensure adequate perfusion to all organ systems and to combat acidosis. However, extreme care must be taken in administering fluids because neonates are susceptible to third spacing and edema. Neonates are also very easily overloaded with excessive fluids.

Vital signs should be monitored frequently, as changes in heart rate or blood pressure could indicate shock or undetected fluid loss for which the body is trying to compensate. Assessment of temperature continues to be an important factor and must be considered when evaluating fluid needs. The serum electrolyte and glucose levels are evaluated immediately postoperatively and then intermittently until the infant's condition is stable. The frequency of laboratory evaluation is individualized to the neonate's condition. Sodium losses may continue through wound drainage as well as through gastric decompression. Thus, reevaluation of intravenous fluids, both maintenance and replacement, is required to achieve and maintain electrolyte balance. Glucose metabolism may be altered as a response to surgery. Serum glucose levels should be monitored regularly after surgery.

Replacement fluid therapy is designed to make up for abnormal fluid and electrolyte losses during therapy to reduce vomiting and for losses incurred through diarrhea, nasogastric tube drainage, stoma output, wound drainage, pleural fluid, and fistula losses. Because the constituents of these losses frequently are quite different from the composition of maintenance fluids, it may be hazardous to simply increase the volume of maintenance fluids in an attempt to compensate for these losses. In some cases, it is preferable to actually measure and analyze the electrolyte content of these losses and replace them milliequivalent for milliequivalent and milliliter for milliliter. Samples may be sent to the laboratory as needed for exact determination of the electrolyte content of these various body fluids.

Overzealous attempts to correct glucose or electrolyte problems can produce a rebound effect. The neonate may change from being hyperglycemic to being hypoglycemic without intervention over a period of minutes or hours. The neonate moves from a catabolic to an anabolic state fairly rapidly compared with an older child or adult. These phases may occur over a few days or weeks in the infant. Therefore, it is best to obtain baseline serum electrolyte and glucose levels. These values should be obtained every 2 to 4 hours, depending on how extreme the levels are. When intervention is needed, the sodium, potassium, or other electrolyte should be increased or decreased slowly and in small increments. These incremental changes should be followed by repeated measurement of serum levels, which must be closely monitored.

Nutrition

The nutritional needs of infants with altered function of the gastrointestinal tract present unique problems. Enteral feeds may be unable to be commenced, and nutrition is supplied with PN. The use of PN with increased protein is associated with beneficial outcomes, such as improved wound healing and shorter time to hospital discharge (Escobar & Caty, 2016). Neonates who undergo a stress response from abdominal surgery are able to achieve a positive protein balance with adequate support. When used, PN needs to be limited with the establishment of enteral feeds to avoid complications of PN-associated liver disease.

Feeding is usually initiated as soon as possible after surgery. This is largely controlled by the type of surgery performed and the responsiveness of the individual infant. Small trophic feeds of breast milk given every 3 to 4 hours can assist in the earlier feeding of many neonates who have undergone surgery. Infants who have undergone surgery on the gastrointestinal tract may take several days or indeed weeks before full enteral feeds are tolerated. A small stomach size with altered emptying ability, as is sometimes seen with a diaphragmatic hernia, gastroschisis, omphalocele, and bowel resection, may present paramount problems in providing proper nutrition when feedings are started. Use of continuous feedings may help with these problems. Feed tolerance is monitored with aspirations every 4 hours, with the larger volumes being returned to avoid electrolyte imbalance occurring. The routine administration of excess calories may not be warranted in critically ill surgical neonates as they do not have an increase in their resting energy expenditure. The energy is redirected from what is normally used for growth to fuel the stress response. Diligent nursing care with attention to the infant's thermal environment and supportive positioning and handling can support the infant until the infant returns to normal homeostasis following surgery.

It is imperative that the mother understands that breast milk is the first choice and that she is involved in decisions regarding feeding. When her infant returns from the surgery, her presence and an open dialogue can facilitate her ability to express and store her milk in readiness for breastfeeding as soon as possible.

Wound Care

The neonate's susceptibility to infection following surgery is due to immune suppression as a result of the trauma of surgery. This is due to changes in the neuroendocrine balance, inflammatory mediators, and both cellular and humoral components of the immune systems (Wolf, 2012). To prevent infection, nurses must provide careful handwashing and attention to wound care. Wound infections can occur during or after the surgical procedure, are related to the duration of the procedure, and can become a complicating factor. Infection occurs more often after "contaminated" surgeries, such as an intestinal perforation, compared with "clean" surgeries, such as ductal ligation. These wound infections may require treatment with antibiotics.

Nursing assessment of the site must be continual because these observations may provide the first indication of poor healing or

wound infection. The neonatal or surgical team (or both) should be made aware of any changes. If any suspicion of infection exists, blood cultures should be taken before treatment is started with broad-spectrum antibiotics that target anaerobes, aerobes, and gram-positive and gram-negative organisms. Consideration should be given to pain relief during potentially painful removal of surgical and wound dressings. The use of oral sucrose for pain relief is recommended if given 2 minutes prior to the procedure. The small volume given is not contraindicated when the infant is ordered nothing by gastrointestinal tract. New approaches to surgical incisions are being considered to give a more cosmetic effect for later in life. Comparison of different types of incisions has found no difference in terms of their postoperative outcome (Suri & Langer, 2011).

OUTCOMES

Outcomes of neonatal surgery can be considered both in the short term and in the long term. Short-term outcomes focus on issues such as recovery and establishment of feeds to enable discharge home.

Long-term consequences of neonatal surgery, if often related to the specific condition and gestational age of the neonate and early exposure to noxious or stressful stimuli such as surgery, may induce long-lasting pain behavior changes into adulthood (Escobar & Caty, 2016).

Research has shown that infants who underwent complex surgery in the newborn period to correct life-threatening birth defects performed significantly below population norms on a standardized test of infant development and were at risk of abnormal development (Laing, Walker, Ungerer, Badawi, & Spence, 2011). This finding is concerning. Laing et al. (2011) recommend that all infants undergoing major newborn surgery be routinely enrolled in systematic multidisciplinary developmental follow-up. This recommendation is supported by other specialist groups (Liddell, Walker, & Davis, 2011) that recommend long-term follow-up for all survivors of congenital diaphragmatic hernia surgery. This long-term follow-up care is critical to identify and proactively manage comorbidities.

Neurodevelopmental outcomes in school-age children were found to be reduced in children who underwent an arterial switch operation; however, there was no cognitive dysfunction. Cognitive and motor developmental delay was found in 23% of children who had surgery in the newborn period for noncardiac conditions (Stolwijk et al., 2016). Infant temperament following surgery for complex congenital heart disease was found to be a significant source of stress for the parents (Torowicz, Irving, Hanlon, Sumpter, & Medoff-Cooper, 2010), and predischarge guidance for the families is recommended. These outcomes need to be considered when following infants who have undergone neonatal surgery. Major neurosensory disability was found to be higher at 8 years of follow-up in extremely preterm infants who underwent surgery during their initial hospital admission (Hunt et al., 2018). These rates of disability have not changed over time and may indicate a need to examine the caregiving and management of surgical preterm infants in the NICU. It appears that the experience of surgery, neonatal intensive care, and hospitalization can be deleterious for sick infants and their families. Care needs to be taken to ensure that the stressors encountered are kept to a minimum, and nurses are in key positions to provide a quality focus to the care of these infants and families.

Socioeconomic and psychosocial factors are also important contributors to variability in longer term outcomes for infants and families and indicate a link between parent factors and child developmental outcomes following newborn surgery for birth defects (Laing et al., 2011). Further research is needed to identify how best to incorporate nursing practices that enable caregivers to simultaneously meet the medical and developmental needs of vulnerable infants and promote positive parent–child interactions in a surgical neonatal context. Evaluating the appropriateness of such care practices may require a multimodal approach and may also be developmentally directed, family-centered, and humane care judged by common sense (Laing, Spence, McMahon, Ungerer, & Badawi, 2012).

Data on many specific congenital malformations requiring neonatal surgery are now being collected through specific registries, both national and international. These registries enable a more population-based measurement of outcomes and provide an opportunity for earlier and newer treatments to be considered.

SUMMARY

This chapter highlights the special considerations for the neonate undergoing surgery and his or her family. These vulnerable infants require vigilance during their pre-, intra-, and postoperative course. The role of care coordination and fluid, electrolyte, and nutrition management are essential elements of this care. Follow-up programs enable the treatments to be evaluated and the effects of anesthetics to be monitored.

CASE STUDY

An infant born at 30 weeks' gestation who is now 2 weeks of age was transferred to a regional surgical center due to increasing abdominal distention and feed intolerance.

The transport team reported some instability prior to transport with unstable temperature and increasing respiratory effort requiring intubation for respiratory support during transfer.

Once in the surgical neonatal intensive care unit, the infant was stabilized. On initial assessment the temperature was 36.8°C, color pale with some webbing on chest, increased work of breathing above the ventilator rate of 40 breaths/minute, and a heart rate of 160 beats/minute. When attached to the monitor, the saturation was 98%.

An abdominal x-ray showed distended loops of small bowel with some pneumatosis. Fluid levels were seen on the lateral view. The neonatal team and surgical team consulted and agreed to plan exploratory surgery.

Prior to transfer to the OR, the neonatal nurse attended to the following:

- Warming the infant to a normal temperature of 37.5°C by placing in an incubator within the infant's neutral thermal range
- Administering pain relief with a morphine infusion following assessment through a pain score
- Positioning the infant in a supported flexed position to avoid undue strain in the distended abdomen
- Placing an 8 FR gastric tube to ensure the stomach is vented and avoiding risk of aspiration
- Assessing the respiratory support to maintain adequate acid–base balance, oxygenation, and perfusion
- Reassuring the parents and supporting them to hold their baby during transfer to the transport bed

In preparation for transfer to the OR, the following were checked and attended:

- A warmed transport cot was prepared with portable oxygen and air and the transport ventilator settings appropriate for the infant.
- Consent form signed by parents after explanation from surgeon.

- Infant's head and limbs wrapped in cotton webbing for added warmth ensuring abdomen is free for surgeon.
- IV cannula patent and secured and pump and fluid settings correct.
- All documentation correct and available for the staff in the OR.
- Identification bands placed on infant's limbs after checking information is correct.

During transfer from the SNIC to the OR, the nurse attended to the following:

- Closely observed the infant to signs of stress or deterioration
- Had the parents accompany their baby to the OR door with a chance to say good-bye
- Handed over to the staff in the OR ensuring they had a good understanding of the infant's history, gestational age, and need for warmth and fluid control
- Ensured the transfer bed was plugged in to maintain warmth for the postoperative transfer

This case demonstrates the need for a team approach and the importance of assessment and preparation of the infant for surgery. Attention to small details can ensure the transfer process is smooth with no delays or emergency situations.

CASE STUDY

During the operation, attention needs to be paid to fluid administration, warmth, and adequate pain relief during the procedure. This is the role of the anesthetist. However, as a neonatal nurse caring for the infant following surgery, it is important to be aware of the infant's management during the operation. Reviewing the intraoperative records can assist in gathering this information.

Critically review the following article in terms of different neonates who require surgery:

1. 30 weeks' gestation with necrotizing enterocolitis (NEC)
2. Infant who weighs 800 g requiring a patent ductus arteriosus (PDA) ligation
3. Term infant with cardiac abnormality
4. 36 weeks' gestation infant with a gastroschisis

EVIDENCE-BASED PRACTICE BOX

Measuring neurodevelopmental outcomes has become an important component in the continuum of neonatal surgery. There are many studies now examining the effects of anesthesia, drugs, and prolonged stay in the NICU. As more infants survive, the neurodevelopmental outcomes become a focus on care and future resources.

The anesthetic and the volatile drugs used can be harmful. Andropoulos et al. (2014) demonstrated an association between perioperative anesthetic exposure, MRI brain injury, and neurodevelopmental outcome scores using the Bayley-III at the age of 12 months. Larger anesthetic exposure and new postoperative brain injury on MRI were associated with lower neurodevelopmental scores. They state that the duration of ICU stay, with or without brain injury, was most strongly associated with poor neurocognitive outcome assessed with a 12-month Bayley-III.

The effects of neonatal surgery on preterm infants have also been studied. Filan et al. (2012) found that preterm infants exposed to surgery and anesthesia had greater white matter injury and smaller total brain volumes. They recommend that surgical exposure in the preterm infant should alert the clinician to an increased risk for adverse cognitive outcome. Hunt et al. (2018) found there was a greater neurosensory disability at 8 years of very preterm infants who underwent neonatal surgery.

Birth during the early term period of 37 to 38 weeks' gestation is associated with worse outcomes following neonatal cardiac surgery (Costello et al., 2014). Gaynor et al. (2015) found that neurodevelopmental outcomes after cardiac surgery in newborns are below population means and have not improved in recent years. Cognitive and motor developmental delay was found in 23% of patients with noncardiac conditions who required neonatal surgery (Stolwijk et al., 2016).

CHAPTER 26

Emerging Infections

Kathryn R. McLean and Tami Wallace

INTRODUCTION

Emerging infections are those infectious agents whose incidence has increased within the past two decades or have the potential to increase in the near future. It includes zoonotic pathogens that have crossed over from an animal population, organisms that develop resistance to antimicrobials, new mutations, seldom-occurring pathogens recognized through new detection methods, and re-emergence of organisms that had been controlled in the past but are making a comeback (Greenfield & Bronze, 2010; Stramer et al., 2009). Scientists estimate that more than three new human pathogen species have been discovered each year since 1980 (Morgan, Kirkbride, Hewitt, Said, & Walsh, 2009). While not all of these pathogens have entered the NICU, they all have the potential. A list of emerging infections is provided in Table 26.1.

As we discuss these pathogens, it becomes evident that this is very much a global problem. The Zika virus range expanded from first identification in Africa to scattered outbreaks in French Polynesia, to a pandemic involving citizens of 84 countries (McArthur, 2017; Rawal, Yadav, & Kumar, 2016). Methicillin-resistant *Staphylococcus aureus* (MRSA) has been reported in NICUs throughout the world (Chuang et al., 2004; Huang, Lien, Su, Chou, & Lin, 2011; Lepelletier et al., 2009; Nambiar, Herwaldt, & Singh, 2003; Regev-Yochay et al., 2005; Sakamoto, Yamada, Suzuki, Sugiura, & Tokuda, 2010; Seybold et al., 2008; Shirai et al., 2017; H. A. Silva et al., 2009). Air travel allows transmission between hosts on different continents in a matter of hours. It is possible to travel between most countries in less time than the incubation period for many infectious diseases (Castillo-Salgado, 2010). The expanding human population and loss of animal habitats bring closer proximity to wildlife, reservoirs of zoonotic pathogens that can emerge in humans (Brouqui, 2009; Wendelboe, Grafe, & Carabin, 2010). Climate changes can allow range expansion of arthropods and rodents, vectors of viruses such as the Zika virus and tick-borne protozoa such as *Babesia microti* (Gould, 2009; Rather, Lone, Bajpai, Paek, & Lim, 2017).

As we study emerging infections, we see a pattern of response consisting of four stages. This chapter describes these stages, using the Zika virus to illustrate the pattern. This pattern of response offers a framework to deal with future emerging infections.

It is important for the NICU team to understand how resistance develops and what steps can be taken to minimize the development of resistant organisms. Knowledge of chromosomal genetics and antimicrobial pharmacodynamics assists in this understanding. Infection control and antimicrobial stewardship are key elements to reduce the impact of resistance.

MATERNAL, FETAL, AND NEONATAL SUSCEPTIBILITY TO INFECTIOUS DISEASES

Outcomes for mothers and their infants are intertwined and interdependent. Pregnant women have increased susceptibility and increased severity of some types of infections during pregnancy. During pregnancy women are more susceptible to some infections such as listeriosis and HIV, but these disorders are not necessarily more severe during pregnancy. Other infections such as influenza and herpes simplex are no more likely to occur during pregnancy, but are more severe in pregnancy and may affect the newborn (Kourtis, Read, & Jamieson, 2014). Current medical science cannot yet fully explain all the reasons for the specific changes seen in pregnancy, but it is believed that a number of factors contribute to these alterations. Alterations in the immune system to allow tolerance of the fetal allograft, the effects of hormones on immune function, and the mechanical changes due to the enlarging fetus affect the pregnant woman's ability to fight infections (Kourtis et al., 2014). Infections in the mother can affect the fetus. Even when the fetus is protected from active infection, there may be teratogenic effects from maternal, placental, and fetal inflammatory cytokines (Kourtis et al., 2014).

The neonatal immune system is discussed more completely in Chapter 11, Immune System, but it is important to remember the limitations of the neonatal immune response when discussing emerging infections. The neonate has limitations in both the innate and the adaptive immune systems, making them particularly at risk for new and novel pathogens (Simon, Hollander, & McMichael, 2015). This intertwining of maternal and neonatal outcomes was evident in the 2009 pandemic with the H1N1 influenza virus. In the United States, it was recognized quite early that pregnant women were more likely than the general population to require hospitalization (Jamieson et al., 2009). Colleagues in the United Kingdom published data to demonstrate increased mortality and morbidity born to women infected with H1N1 (Pierce, Kurinczuk, Spark, Brocklehurst, & Knight, 2011). By mid-2011, there were enough data from multiple countries to publish a systematic review of literature with numbers of cases in pregnancy, additional risk factors, maternal outcomes, and neonatal outcomes (Mosby, Rasmussen, & Jamieson, 2011).

TABLE 26.1

EMERGING AND RE-EMERGING INFECTIONS IN NEONATES

Infection	Agent	Diagnosis	Spread	Consequences/ Treatment	Comments
Zika	Zika virus	Travel history + PCR or ELISA at the CDC-approved laboratories	Mother to fetus	Fetus: Brain defects in fetus, miscarriage and stillbirth No specific treatment	
Chagas	*Trypanosoma cruzi* parasite	Parasite on blood smear or PCR (antibody testing not helpful in newborn period)	Triatomine insect bite Or transfer from mother to fetus	Newborn: Most have mild or no signs May have low birthweight, prematurity, hepatosplenomegaly, anemia, thrombocytopenia Treatment: Nifurtimox and benznidazole	
Syphilis	*Treponema pallidum* bacterium, spirochete	RPR or VDRL, dark-field microscopic evaluation of any secretions, PCR (antibody testing may not be helpful in newborn period)	Mother to infant	Nonimmune hydrops, jaundice, hepatosplenomegaly, rhinitis, rash, pseudoparalysis of extremity, osseous lesions Treatment: Penicillin for 10 days	Reportable in all 50 states
Hepatitis C	HCV	Cannot be tested in newborn period, HCV RNA may be seen as early as 1–2 months	Mother to infant (5%–6% if mother is HIV negative and ~14% if mother is HIV positive; Alter et al., 1998) Not documented to be passed in breast milk	None in newborn period	Many exposed infants lost to follow-up Can develop chronic disease
CMV	CMV virus	PCR on saliva and urine	Mother to fetus, in breast milk, community contacts	Wide range of presentation from asymptomatic to fulminant viremia. Low birth weight, liver problems, microcephaly, seizures, hearing loss, vision loss, intellectual disability, lack of coordination Treatment: Ganciclovir or valganciclovir	May develop hearing loss even after passing newborn screen. Need long-term follow-up
Disease X	Unknown	The WHO has put potential disease on their priority list for monitoring A reminder that a new, potential disease-causing pathogen may quickly appear			

May present special risk specifically to NICU patients:
Multidrug-resistant bacteria
Resistant fungus
Diseases that are re-emerging due to lack of vaccination (e.g., measles)

HUMAN DRIVERS OF EMERGING INFECTIONS

Humans can and do influence many of the drivers of emerging infections. Globalization, changes in population density, climate change, antibiotic use, and intentional interventions all impact the types, location, and spread of these infections.

Many authors point to globalization as an important driver of emerging infections (Beigi, 2017; Rogalski, Gowler, Shaw, Hufbauer, & Duffy, 2016; Hopkins, 2007). Modern life with its increased global travel and trade facilitates the rapid spread of diseases. We are one day and one plane ride away from distant destinations. Our food and supply sources are international. People, supplies, and diseases can travel long distances in a short period of time. Movement of humans and disease vectors can expose naive hosts to novel infections. Local systems may not be prepared to recognize, treat, or prevent the spread of what are to them novel infections. The potential consequences are significant.

The effects of globalization were demonstrated in the 2014 Ebola outbreak. Ebola is a virus that probably originated in bats, but has now moved to humans. It can cause a hemorrhagic disease and is extremely deadly. In 2014, the Ebola virus quickly moved from an outbreak in a handful of African countries to a disease with repercussions for travel and healthcare around the world. An estimated 24 cases of Ebola were treated in Europe and the United States. Many of these cases were aid workers who traveled back to their home countries for treatment (Ashkenas et al., 2015), but others were travelers who unknowingly brought the disease with them. Transmission is by contact with infected secretions. At least one Ebola victim traveled from Liberia to Texas before becoming ill. Two nurses were infected in the process of caring for him. This infection in young women of childbearing age started a discussion about the possibility of Ebola in pregnancy, in the neonate, and in the NICU. This remained just a discussion as there were no documented cases in pregnancy outside of Africa. The cases moved from country to country within days, and each case was multinational news within hours thanks to modern communications. In a very short time, an outbreak in a small part of Africa became an international concern that required international collaboration and responses. Worldwide collaboration and knowledge sharing helped contain the outbreak.

Humans drive the location, evolution, and types of infections by multiple mechanisms. Modern life, technology, and medical care have multiple consequences that are far-reaching, unintended, and possibly unanticipated. Examples of proposed mechanisms for which there is empiric support are summarized in Table 26.2.

TABLE 26.2

HUMAN DRIVERS OF EMERGING INFECTIONS: MECHANISMS AND POTENTIAL EFFECTS

Proposed Mechanism	Potential Effects
Global travel and trade	• Rapid movement of people, pathogens • Movement of disease vectors (e.g., mosquitoes, rats)
Changes in population density	• Increased density creates potential for increased spread of infection (Rogalski et al., 2016)
Climate change	• Changes in vector density, diversity, and location (Rogalski et al., 2016) • Changes in human population density
Antibiotic use and abuse	• Antibiotic resistance • Changes to the human microbiome and host response
New vectors	• Blood transfusion (Flaherty, Moran, & Higgins, 2017) and organ transplantation as a vector
Intentional interventions	• Immunization • Decreasing vector populations (e.g., spraying for mosquitoes) (Rogalski et al., 2016)
Bioterrorism	• Potential deliberate spread of infection (American Academy of Pediatrics & the American College of Obstetricians and Gynecologists, 2017)

TRENDS IN EMERGING INFECTIONS

In 2007, the World Health Organization (WHO) first warned of the increasing number of emerging infections over time and of the more rapid spread of these infections. At the time, they cited a world that was increasingly mobile and interdependent as providing opportunities for the spread of infectious disease. The WHO called for global collaboration, pointing to the need for an increased capacity for rapid reporting, sharing, and improved response to assure health security (Hopkins, 2007). Many organizations such as the WHO, the United States Centers for Disease Control and Prevention (CDC), and other ministries of health have labored to create reporting structures and response systems. The WHO created the Emergency Response Framework to guide these processes (WHO, 2013). This framework has been expanded and updated over time. Thus, critical response teams at local and international levels have been created and have helped guide efforts in recent years. A recent example is the widespread and rapid response to the Zika virus and its potential fetal affects.

PATTERN OF RESPONSE TO EMERGING INFECTIONS

One approach to looking at emerging infections is to recognize a pattern of response. The pattern of response to emerging infections consists of four stages. The first stage, *Discovery*, begins with recognition of a new infectious agent. It is often precipitated by a global health crisis. Examples of such health crises include the hemorrhagic deaths associated with the Ebola outbreak in 2014 and the increased incidence of microcephaly following Zika virus infection noted in Brazil from 2015 to 2017. Surveillance programs and epidemiology studies provide evidence of emerging infections and their association with specific health crisis. The second stage, *Definition*, involves investigation into the causative agent: what are its properties, genetic make-up, methods of

transmission, and impact on victims. The third stage, *Defense*, involves the further development of tools to quickly identify the organism, prevention of new cases, and finding treatments to lessen the impact of the infection. The third stage is time-consuming as it often involves clinical trials of pharmaceuticals. There is often overlap between the second and third stage as new studies into the properties of the organism identify weaknesses that can be exploited with different therapies. The fourth stage, *De-escalation*, recognizes that the incidence of an emerging infection often wanes over time. The fourth stage can be a result of prevention, successful therapies, or part of the natural course of the emerging infection. HIV is an example of an infection which responded to pharmacological treatment, resulting in a decrease in new cases. In the natural course of an infection, the person who contracts the infection develops immunity and no longer acts as a host. H1N1 (swine flu) is an example of the natural decline; it is no longer an emerging infection as it peaked in 2009 to 2010 (Thorner, 2018). Arrival at the fourth stage does not eliminate the potential for re-emergence should a new population be exposed or resistance to pharmacologic treatment develop.

ZIKA VIRUS

The Zika virus was discovered in a rhesus monkey in the Zika forest of Uganda during a surveillance for yellow fever in 1947 (Passi, Sharma, Dutta, & Ahmed, 2017). In 1948, it was isolated from a mosquito. The first human infections were identified in 1952 in Uganda and Tanzania. Scattered mild infections occurred in Africa and Southeast Asia. The first outbreak occurred in 2007 on the island of Yap. Also, there was a major outbreak in 2013 in French Polynesia. During this outbreak, an increase in neurologic complications occurred and 73 cases of Guillain–Barré syndrome were identified (Eppes et al., 2017; McArthur, 2017). Beginning in 2015, a major outbreak was first noted in Brazil, eventually spreading throughout South and Central America and as far north as the states of Florida and Texas in the United States. Cases have been reported in 84 countries as of March 2017 (McArthur, 2017). An increase in microcephaly associated with mothers who developed a Zika infection prompted the WHO to announce a Public Health Emergency on February 8, 2016 (Oussayef et al., 2017). This recognition of Zika virus as a potential causative agent represents stage 1 (Discovery) of the Pattern of Response to Emerging Infections.

During stage 2 (Definition), surveillance and epidemiology studies and scientific investigation supported the causative nature between Zika virus infection in mothers and a congenital Zika syndrome (CZS). All infants with CZS tested positive for the Zika virus (Acosta-Reyes et al., 2017; Mattar et al., 2017; Reagan-Steiner et al., 2017). CZS involves neurologic, musculoskeletal, ocular, and possible cardiac deformities. Zika virus infection was associated with a 20-fold increase in microcephaly (Cragan et al., 2017; Marrs et al., 2016; A. Sharma & Lal, 2017). Those infants who developed severe microcephaly (with head circumference <3 standard deviations [SDs] below the mean) had a distinct craniofacial appearance with sloping forehead, overlapping cranial bones with partial collapse of the bones of the upper skull, and redundant scalp skin folds (Adebanjo et al., 2017; A. A. M. Silva et al., 2016; van der Linden, Filho et al., 2016;). Brain abnormalities detected by CT include microcephaly (head circumference <2 SDs below the mean), decreased brain volume with malformation of cortical development (such as lissencephaly and polymicrogyria), brain calcifications primarily at the cortical–white matter junction, ventriculomegaly, hypoplasia of the cerebellum, hypoplastic or absent corpus callosum, and hypoplasia of the ventral cord (Adebanjo et al., 2017; Petribu et al., 2017). Follow-up of infants without microcephaly at birth has shown occasions where head growth decelerated to the point of microcephaly months after birth (van der Linden, Pessoa, et al., 2016). Seizures occurred in over 50% of infants (A. A. M. Silva et al., 2016). Clinical findings may include hypertonia, irritability, dysphagia, dystonia, dyskinesia, hemiparesis, arthrogryposis (presence of multiple contractures associated with decreased fetal movement), or spastic quadriplegia (van der Linden, Filho, et al., 2016; van der Linden, Pessoa, et al., 2016; Pessoa et al., 2018). Ocular abnormalities include macular scarring with focal pigmentary retinal mottling, microphthalmia, coloboma, intraocular calcifications, optic nerve hypoplasia, and atrophy (Adebanjo et al., 2017; Ventura & Ventura, 2018). There is an association with sensorineural hearing loss (Leal, Muniz, Ferreira, et al., 2016; Leal, Muniz, Caldas Neto, van der Linden, & Ramos, 1016). DiCavalcanti et al. (2017) performed echocardiography on 103 infants with CZS and found that 13.5% had congenital heart disease. These findings included atrial septal and ventricular septal defects (DiCavalcanti et al., 2017). Fetal growth restriction or fetal loss can occur (Saiz et al., 2017; van der Eljk et al., 2016). In the United States and its territories, the prevalence of congenital birth defects associated with maternal Zika infection during pregnancy is approximately 5% (Shapiro-Mendoza et al., 2017). Malformations associated with CZS are summarized in Table 26.3.

Multiple studies confirmed the role of Zika virus infection in developmental brain abnormalities. In vitro experiments involving

TABLE 26.3

MALFORMATIONS ASSOCIATED WITH CONGENITAL ZIKA SYNDROME

System	Malformation
Neurologic	Microcephaly Hydrocephaly Lissencephaly Polymicrogyria Holoprosencephaly Ventriculomegaly Absent corpus callosum Intracerebral calcifications Pachygyria Agyria
Ocular	Optic nerve abnormalities Chorioretinal atrophy Maculopathies Vasculopathies
Musculoskeletal	Craniofacial abnormalities (sloped forehead) Clubfeet Arthrogryposis Craniosynostosis Hip dysplasia
Cardiovascular	Atrial septal defect Ventricular septal defect
Miscellaneous	Intrauterine growth restriction Anasarca Pulmonary hypoplasia

Zika virus infection of human neural progenitor cells showed a significant increase in mitosis abnormalities, increased frequency of aneuploidy involving chromosomes 12 and 17, marked reduction in cell proliferation, and increased autophagy and apoptosis (Souza et al., 2016). Animal and human brain cell organoid models supported the evidence that Zika virus can cross the placenta and induce brain abnormalities (Desai, Hartman, Jayarajan, Liu, & Gallicano, 2017; Janssens et al., 2018; Mittal et al., 2017; Nguyen et al., 2017; Nunes et al., 2016; Saiz et al., 2017). Surveillance studies have predicted the probability of microcephaly when a pregnant woman contracts a Zika virus infection as between 1.98% and 2.3% (Coelho & Crovella, 2017; Jaenisch et al., 2017).

The structure of the Zika virus was identified using cryoelectron microscopy (Faizan et al., 2016). It is a single-stranded, enveloped RNA virus composed of 10 proteins (three structural and seven nonstructural). Zika virus was identified as an arbovirus of the family *Flaviviridae*. Closely related viruses include dengue, West Nile, and yellow fever (A. Sharma & Lal, 2017). Two distinct lineages were identified: African and Asian. The current strain in the Americans is most closely related to the Asian lineage (Desai et al., 2017; McArthur, 2017).

Methods of transmission were identified. The primary mode of transmission is via infected mosquito bite. *Aedes aegypti*, *Aedes albopictus*, and multiple other mosquito species are known vectors (Petersen, Jamieson, Powers, & Honein, 2016; Rawal et al., 2016; A. Sharma & Lal, 2017). Sexual transmission has been documented, including unprotected male-to-female, female-to-male, and male-to-male. Zika virus has been detected in semen up to 188 days after the onset of symptoms (Saiz et al., 2017; A. Sharma & Lal, 2017). During the French Polynesian outbreak, Zika virus RNA was detected in 3% of asymptomatic blood donors (Musso et al., 2014). The first confirmed case of blood-transfusion-related Zika virus infection occurred in Brazil (A. Sharma & Lal, 2017). Vertical transmission between mother and fetus occurs. Zika RNA has been documented in amniotic fluid, placenta, and fetal brain tissue (Reagan-Steiner et al., 2017; Tschoeke, Oliveira, Leomil, Tanuri, & Thompson, 2017). Multiple studies involving animal models also demonstrated vertical transmission (Nguyen et al., 2017). Although Zika RNA and infectious viral particles have been detected in breast milk, no case of transmission related to breastfeeding has been documented (Cavalcanti et al., 2017; Colt et al., 2017; Sotelo et al., 2017).

Detection of Zika virus infection is complicated by multiple factors. Asymptomatic infection presents in up to 80% of those who tested positive for Zika immunoglobulin M (IgM) antibodies (Chua, Prat, Nuebling, Wood, & Moussy, 2017; A. Sharma & Lal, 2017). Even those with symptoms such as low-grade fever, maculopapular rash, arthralgia, headache, and conjunctivitis may fail to recognize and report the illness. Cross-reactivity between Zika, dengue, and chikungunya viruses confounds serum reverse transcription polymerase chain reaction (RT-PCR) testing. The optimal timing of tests is not known. Serum RT-PCR is positive for only a limited time during the first 3 to 7 days of symptoms (Adebanjo et al., 2017; Rabe et al., 2016; Rawal et al., 2016). Current definitive testing involves detection of IgM antibodies followed by a plaque reduction neutralization test ruling out dengue. This testing is labor-intensive and time-consuming, taking up to several weeks for final results (Adebanjo et al., 2017; Rabe et al., 2016; Shan et al., 2017). The results of IgM testing are not 100% indicative of a Zika infection during pregnancy: positive IgM results can reflect a pre-pregnancy exposure while negative IgM results can occur if testing occurred before the formation of antibodies (Adebanjo et al., 2017). The quest for a rapid, inexpensive test with adequate sensitivity and specificity continues.

The CDC recommendation for testing has evolved in response to expansion of the body of evidence and decline in prevalence creating increased risk for false-positive results. All pregnant women should receive screening questionnaires administered by a nurse or other healthcare provider to determine if there is a potential Zika infection risk due to travel by herself or her partner within a country with known Zika virus in the mosquito population. An updated map showing areas with a risk of Zika infection can be found at www.cdc.gov/zika/geo. The questionnaire also asks whether she or her partner has had any signs or symptoms of Zika infection. As of July 2017, the recommendation changed from testing all women who traveled to countries with known Zika virus infection to those who are symptomatic or have repeated exposure. Current recommendations may be found on the CDC website for Zika. The actual decision on whether to test is made based on discussion between the woman and her healthcare provider. The current recommendation on which test to provide can be found on www.cdc.gov/zika/hc-providers/testing-guidance.html (Adebanjo et al., 2017). In areas of active Zika infection, such as Puerto Rico in 2016, the recommendation may be for all pregnant women to be tested (D'Angelo et al., 2017).

The third stage of response to the Zika infection (Defense) is limited by a lack of effective treatments. The focus is on prevention with recommendations for mosquito control, prevention of mosquito bites, and limitation of travel by pregnant women to areas known to have Zika virus. Integrated vector management is used to describe steps for mosquito control. It includes elimination of breeding sites such as draining of swamps, elimination of free-standing water around homesites, insecticides, and use of *Wolbachia* bacteria and genetically modified male mosquitos to reduce reproduction (Rather, Kumar, Bajpai, Lim, & Park, 2017). Personal protection methods include use of insect repellants, wearing long sleeves and long pants, mosquito netting around beds, and screens on doors and windows. In January 2016, the CDC issued a travel notice advising pregnant women to avoid travel in areas of active Zika virus. The following precautions are recommended for the protection of the fetus from CZS: unintended pregnancies should be avoided, conception delayed by potentially exposed women for at least 8 months and potentially exposed men for at least 6 months, and abstinence or consistent condom use by those who live in/travel to those areas with active Zika virus (Peterson et al., 2016; Rather et al., 2017).

Development of a vaccine against the Zika virus is complicated by several factors. The population most at risk (pregnant women and their fetuses) necessitates strict adherence to safety protocols. There is a concern for the development of increased virulence of flavivirus infections due to antibody-dependent enhancement (ADE). ADE can occur with cross-reactivity to previous infections by a different closely related virus (dengue and chikungunya are endemic to the same areas as Zika). As of July 2017, at least 38 vaccines were in development with five advancing to phase 1 trials (Lagunas-Rangel, Viveros-Sandoval, & Reyes-Sandoval, 2017). Until a vaccine is developed, we will not reach stage 4 (De-escalation) in the Pattern of Response to Emerging Infections.

Until prevention is a viable option, we must be prepared to deal with the inevitable outcomes of CZS. Management of suspected Zika-exposed infants is described in Figure 26.1. Multidisciplinary specialists include any or all of the following: neurologists, ophthalmologists, infectious disease specialists, endocrinologists, geneticists, occupational therapists, audiology, orthopedics, and early intervention. Potential problems associated with CZS include developmental delays, seizures, impaired vision or hearing, dysphagia with associated feeding difficulties and growth restriction,

autoABR, automated auditory brainstem response screen; BMP, basic metabolic panel; CBC, complete blood count; CCHD, critical congenital heart disease; CDC, Centers for Disease Control and Prevention; CHD, congenital heart disease; LFTs, liver function tests; T_4, thyroxine; TSH, thyroid-stimulating hormone.

Sources: Adapted from Adebanjo, T., Godfred-Cato, S., Viens, L., Fischer, M., Staples, J. E., Kuhnert-Tallman, W., & Moore, C. A. (2017). Update: Interim guidance for the diagnosis, evaluation, and management of infants with possible congenital Zika virus infection—United States, October 2017. *Morbidity and Mortality Weekly Report, 66*(41), 1089–1099. doi:10.15585/mmwr.mm6641a1; Women and Infants Pediatric Zika Algorithm. (2017). Retrieved from http://cnesites/sites/clinicianresources/wih/Shared%20Documents/Zika%20Algorithm.pdf

contractures requiring orthopedic interventions, and recurrent respiratory infections if diaphragmatic paralysis occurs (rare; Adebanjo et al., 2017; Leal, Muniz, Caldas Neto, et al., 2016; Leal, Muniz, Ferreira, et al., 2016; Satterfield-Nash et al., 2017; van der Linden, Pessoa, et al., 2016). **Quality and Safety: Current CDC recommendations for infants with clinical findings consistent with CZS include head ultrasound, automated auditory brainstem response (ABR), and comprehensive ophthalmology examination by 1 month of age** (Adebanjo et al., 2017). Postnatal microcephaly or hydrocephalus can develop, requiring close monitoring of head circumference (A. A. M. Silva et al., 2016). Following an examination by a neurologist, a CT or MRI may be indicated, allowing better evaluation of the structures of the brain. The clinician should monitor feedings for any difficulty coordinating suck/swallow/breathing, coughing or choking during feedings, and/or prolonged feeding times (Adebanjo et al., 2017). Occupational therapists may be able to assist with feeding difficulties, but gastrostomy tube feedings could be indicated for extreme cases. Seizures were present in 50% of a group of 48 infants with CZS in Brazil (A. A. M. Silva et al., 2016). If seizures are present, the neurologist will guide use of antiepileptics. Pessoa et al. (2018) reported that 100% of infants with CZS had motor abnormalities similar to cerebral palsy, demonstrating both pyramidal and extrapyramidal motor abnormalities. **Quality and Safety: Early intervention referrals are indicated. Emergency Alert: Rare cases of diaphragm paralysis may necessitate ventilatory support.** If arthrogryposis is present, physical therapy or serial casting by an orthopedist may be indicated. Family support is necessary as parents deal with a handicapped child. A summary of potential problems requiring follow-up is presented in Table 26.4.

TABLE 26.4

POTENTIAL PROBLEMS ASSOCIATED WITH CONGENITAL ZIKA SYNDROME REQUIRING CLOSE FOLLOW-UP POST-DISCHARGE

Specialty	Problem
Neurology	Hydrocephalus Seizures Sleep apnea Irritability Hypertonia/spasticity
Developmental specialists/ occupational therapists/physical therapists/feeding specialists/ speech therapists	Developmental delays Dysphagia, swallowing dysfunction Feeding difficulties
Nutritionist/lactation consultants/occupational therapists	Poor growth
Pulmonology/ENT	Aspiration Diaphragmatic paralysis
Endocrinology	Hypothalamic or pituitary dysfunction Thyroid disorders
Cardiology	Congestive heart failure if significant ventricular septal defect or atrial septal defect
Ophthalmology	Visual impairment
Audiology/ENT	Auditory impairment
Orthopedic/physical therapy	Clubfeet Hypertonia/spasticity

ENT, ear nose throat.

ANTIMICROBIAL RESISTANCE

Microorganisms demonstrate remarkable adaptability in response to antimicrobials. Penicillin was first used to treat human infections in 1941. Penicillin-resistant *Staphylococcus aureus* presented in 1944 and became widespread by the 1950s (Rice, 2006; Tenover, 2006). Today 95% of *S. aureus* is resistant to penicillin due to penicillinase production (A. J. Shah, Mulla, & Revdiwala, 2012). Resistant strains of bacteria develop as new antimicrobials are introduced. The mechanisms of resistance vary with the antimicrobial actions of each antibiotic. Not only do the mechanisms vary, but the organisms have developed ingenious methods of transferring this resistance, making even existing susceptible organisms capable of developing resistance.

Natural or intrinsic resistance refers to the innate characteristics of an organism which interfere with the action of an antibiotic. Gram-negative bacterial wall structure, which includes an outer cell wall in addition to the peptidoglycan membrane layer and an intermediate space, can limit the uptake of a drug. This is an example of natural resistance. Acquired resistance occurs when a formerly susceptible organism becomes resistant (Mulvey & Simor, 2009). MRSA is an organism with acquired resistance.

Some bacteria have developed mechanisms to block the antibiotic binding necessary to act on bacteria. Beta-lactam antibiotics (such as the penicillins, cephalosporins, and carbapenems) inhibit bacterial cell wall synthesis, specifically with the synthesis of the peptidoglycan layer (Patel & Saiman, 2010). Interference requires the antibiotic bind to the cell wall at a target site called the penicillin-binding protein (PBP). Certain organisms have acquired genes encoding enzymes called beta-lactamases which hydrolyze the amide bond of the beta-lactam ring and deactivate the antibiotic. Other organisms have evolved altered PBP structure, prohibiting the binding of the antibiotic (Arias & Murray, 2019; Baley & Leonard, 2013; Patel & Saiman, 2010). Carbapenems bind at a different site, PBP2. *Klebsiella pneumoniae* may produce carbapenamases which hydrolyze carbapenems, interfering with binding at that site (Puopolo, 2017). Bacteria may have one or multiple genes encoding for these methods.

Certain antibiotics must enter the microorganism in order to attach to a ribosome. They interfere with protein synthesis. Aminoglycosides, macrolides, and chloramphenicol are examples of these antibiotics. Passage through gram-negative bacteria walls often occurs through "porin" channels. Some bacteria have evolved the ability to close these porin (down-regulation), blocking the entrance into the microorganism. Other bacteria have evolved efflux pumps with the ability to push the antibiotic out of the cell (Cotten, 2016; Soto, 2009; Tenover, 2006).

Other characteristics of microorganisms may influence the development of resistance. Certain bacteria develop biofilms. The microorganisms associate with and adhere to submerged surfaces (such as indwelling catheters). They become enclosed with a matrix, extracellular polymers composed primarily of polysaccharides, binding the cells to the submerged surface and to each other. This matrix prevents or impedes the diffusion of antimicrobials to the bacteria and protects the microorganisms from host defenses. In addition, oxygen and nutrient diffusion is impaired, decreasing growth of the organisms themselves. Antibiotics that act on growth can be impaired (Baley & Leonard, 2013; Cotten, 2016; Patel & Saiman, 2010).

GENETIC MECHANISMS OF RESISTANCE

Natural or intrinsic resistance is stable and conferred by genes encoded in the chromosomal DNA. It is shared by all members of the genus. Acquired resistance involves a change in genetic material, either by mutation or by exchange of genetic material. Bacteria have multiple methods to exchange genetic material. Genetic material, including genes encoding for resistance, may exist outside of the chromosome on plasmids. Exchange of genetic material between bacteria occurs through conjugation, transduction, and transformation (Arias & Murray, 2019; Cantley & Milstone, 2015; Cotten, 2016; Johnson, 2012; Mulvey & Simor, 2009).

Conjugation involves the transfer of plasmids through elongated proteinaceous structures called sex pili, extending from the donor to recipient. Both donor and recipient have a copy of the plasmid. Transfer can be inter-species, even between gram-negative and gram-positive organisms (Cantley & Milstone, 2015; Tenover, 2006; Vrtis, 2008).

Transduction involves exchange of genetic material facilitated by viruses called bacteriophages. The genes may be of plasmid or chromosome origin. Transduction is a relatively rare event (Tenover, 2006; Vrtis, 2008).

Transformation involves acquisition of genetic material from the environment. When cell lysis occurs, DNA is released. The

DNA binds to the cell surface of another bacterium. The bound DNA is taken up through the cell membrane and incorporated into its chromosome or a plasmid within the bacteria (Arias & Murray, 2019; Cantley & Milstone, 2015).

Transposition enhances the spread of resistance. Genes may be flanked by insertion sequences at either end, creating a transposon. These transposons can "jump" to different locations on the chromosome or plasmids. A gene that was formerly on a chromosome or non-transferable plasmid can jump to a plasmid that can be exchanged between bacteria. This is the mechanism by which characteristics that are intrinsic to only one species can be transferred to a different species (Arias & Murray, 2019; Johnson, 2012).

In some cases, the gene that confers resistance requires exposure to the antibiotic before the gene is activated. Bacteria with inducible resistance may initially test susceptibility to an antimicrobial. With exposure to the antimicrobial, the gene is activated and begins to produce enzymes such as beta-lactamases, inactivating the antimicrobial (Patel & Saiman, 2010). The patient's condition worsens as the protected bacteria proliferate. The provider draws a second culture, and susceptibility shows the organism is now resistant to the original antibiotic.

PHARMACODYNAMICS AND RESISTANCE

Activity is measured based on minimal inhibitory concentrations (MICs) expressed in micrograms per milliliter. MIC is the lowest concentration of an antimicrobial agent that results in inhibition of bacterial growth. Antimicrobials are classified as either time-dependent or concentration-dependent. Time-dependent antimicrobials rely on serum concentrations that remain above the MIC for 60% to 70% of the treatment duration. These include beta-lactams and macrolides. Concentration-dependent antimicrobials rely on plasma concentrations within an area under the curve formed by plotting the plasma concentration of the drug versus time. Concentration-dependent antimicrobials include aminoglycosides, quinolones, and azalides (Andrews, 2003). Peak and trough drug levels are monitored for concentration-dependent medications. Peak/MIC ratio is used to describe optimal bactericidal effect based on higher peak concentration and increased dosing (Shea & Jacobi, 2009). Under-dosing increases the probability of developing resistant organisms (Cotten, 2016).

The MIC susceptibility breakpoints for antibiotic agents have been established and published by the Clinical and Laboratory Standards Institute. Ranges exist for mildly resistant and highly resistant organisms (Shea & Jacobi, 2009). Culture and susceptibility reports interpret an isolate's activity based on these standards. One confounding variable is the possibility of heteroresistance. Heteroresistance presents when a single strain of bacteria has both susceptible cells (such as MIC $\leq$ 2 mcg/mL for vancomycin) and intermediate resistant cells (MIC $\leq$ 4–8 mcg/mL for vancomycin; Patel & Saiman, 2010). This results in the chosen antibiotic only being effective for some of the bacteria, resulting in prolonged repeat positive cultures and extended length of treatment until the antibiotic is changed.

SELECTIVE ANTIBIOTIC PRESSURE

Selective antibiotic pressure is the trend for dominant antimicrobial species to evolve in response to the antibiotics chosen for treatment. Exposure to antibiotics creates an environment that inhibits or kills susceptible organisms but leaves resistant organisms alive and reproducing. Over time, resistant organisms may become the dominant species, colonizing the host. Within individual hospitals and the community, the specific antimicrobial selection can influence the development and predominance of resistant strains (Doyle, Buising, Thursky, Worth, & Richards, 2011; Mulvey & Simor, 2009). Indiscriminate over-the-counter use of antibiotics in China and Egypt may have contributed to third-generation cephalosporin resistance in those countries (Huang, Zhuang, & Du, 2007; Mohsen et al., 2017). Antimicrobials have also been used as a livestock growth promoter. Researchers found vancomycin-resistant enterococci (VREs) in the gut flora of poultry and swine (DeLisle & Perl, 2003; Shuford & Patel, 2005). Consumption of livestock colonized by antimicrobial-resistant organisms promotes spread of these organisms to humans (Collignon, Powers, Chiller, Aidara-Kane, & Aarestrup, 2009). The impact of selective antibiotic pressure is a guiding principle for antimicrobial stewardship.

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS*

Neonates are exposed to and their skin subsequently colonized with *S. aureus* shortly after birth. Colonization can also occur in the nasopharynx and gastrointestinal tract. Eighty percent of infants are colonized by day 10 of life (Baley & Leonard, 2013; Bizzarro & Gallager, 2007). Of concern is the increasing prevalence of *S. aureus* which is resistant to third-generation cephalosporins and semi-synthetic penicillins such as methicillin. Premature and other compromised infants spend this early time period in NICUs where the selective pressure favors microorganisms with resistance. Outbreaks of MRSA infections were initially reported in the 1970s (Bizzarro & Gallagher, 2007). MRSA was first reported in an NICU in 1981 (Carey & Long, 2010; M. L. Gregory, Eichenwald, & Puopolo, 2009; Lessa et al., 2009; Sakamoto et al., 2010). MRSA outbreaks have now been reported throughout the world (Gregory et al., 2009; Huang et al., 2011; Jain, Agarwal, & Bansal, 2004; Kamath, Mallaya, & Shenoy, 2010; Lepelletier et al., 2009; Nambiar et al., 2003; Park, Seo, Lim, Woo, & Youn, 2007; Saiman et al., 2003; Seybold et al., 2008; Shirai et al., 2017; H. A. Silva et al., 2009). MRSA colonization rates vary by geographic location and institution, ranging from 1.3% to 50% (Azarian et al., 2016; Bizzarro & Gallagher, 2007; Carey, Della-Latta, et al., 2010; Carey, Duchon, Della-Latta, & Saiman, 2010; M. L. Gregory et al., 2009; Huang, Chou, Su, Lien, & Lin, 2006; Jain et al., 2004; Murillo, Cohen, & Kreiswirth, 2010; Nelson & Gallagher, 2012; Sarda et al., 2009; Seybold et al., 2008; Song et al., 2010). Infection rates following colonization range from 14.7% to 81% (Bizzarro & Gallagher, 2007; Carey, Duchon, et al., 2010; Gregory et al., 2009; Sarda et al., 2009; H. A. Silva et al., 2009; Song et al., 2010). From 1995 to 2004, the CDC National Nosocomial Infection Surveillance System (NNIS) reported that 23% of isolates causing infections in NICUs were methicillin-resistant (Lessa et al., 2009). The incidence of MRSA infection in the United States NICUs increased 300% from 1995 to 2004 (Blanchard, Quach, & Autmizquine, 2015; Cantley & Milstone, 2015; Lessa et al., 2009; Milstone, Song, Coffin, & Elward, 2010). Certain areas of the world such as Taiwan have such a high percentage (95%) as to be considered endemic (Huang et al., 2011).

Methicillin resistance is associated with specific genes: staphylococcal chromosome cassette (SCC) and *mecA*. The SCC gene complex and *mecA* gene confer resistance through changing the target site structure, creating (PBP)2A which has a low affinity for beta-lactam antibiotics (Blanchard et al., 2015; Carey & Long, 2010; Doyle et al., 2011; Lowy, 2019; Patel & Saiman, 2010).

MRSA infections are classified as either healthcare associated (HA-MRSA) or community acquired (CA-MRSA). Originally, HA-MRSA was the type more commonly seen in the NICU. Song et al.

(2010) reported 67% with HA-MRSA compared with 33% with CA-MRSA in their unit. CA-MRSA is gaining in prevalence (Baley & Leonard, 2013; Carey, Della-Latta, et al., 2010; M. L. Gregory et al., 2009). Pulse-field gel electrophoresis (PFGE) and polymerase chain reaction (PCR) allow identification of specific clones through molecular typing. Certain strains are associated with HA-MRSA. These strains differ in the type of SCC *mec* types: SCC *mecA* I to III. HA-MRSA strains include USA100, USA200, USA500 to USA800, and Rhine-Hessen (Healy, Hulten, Palazzi, Campbell, & Baker, 2004; Heinrich et al., 2011; Ramos et al., 2011; Seybold et al., 2008). Other strains are associated with CA-MRSA. These demonstrate SCC *mecA* IV to V. These include USA300 (majority), MW2, USA400, USA1000, and USA1100 (Carey, Della-Latta, et al., 2010; Carey, Duchon, et al., 2010; Healy et al., 2004; Nelson & Gallagher, 2012; Seybold et al., 2008). The two types of MRSA infections differ in their resistance to antibiotics with HA-MRSA more resistant than CA-MRSA. CA-MRSA is usually susceptible to more non-beta-lactam antibiotics such as trimethoprim-sulfamethoxazole, clindamycin, and quinolone agents (M. L. Gregory et al., 2009; Ramos et al., 2011; Yee-Guardino et al., 2008). CA-MRSA may present with higher virulence. Certain strains produce Panton-Valentine leukocidin (PVL) and enterotoxins. PVL in particular has been implicated in the production of cytotoxins that attack the cell membrane, causing necrosis and cell lysis. CA-MRSA can present with severe necrotizing pneumonia and furunculosis (Baley & Leonard, 2013; Carey & Long, 2010; Rice, 2006; Yee-Guardino et al., 2008). Surveillance of multiple units has shown an increase in incidence of CA-MRSA, with CA-MRSA acquired during birth while HA-MRSA is more likely to be acquired nosocomially (Azarian et al., 2016; Blanchard et al., 2015; Dolapo, Dhanireddy, & Talati, 2014; Nelson & Gallagher, 2012; Reich et al., 2016).

Routes of transmission are primarily horizontal with transfer from a colonized parent or healthcare worker, or transferred from a colonized patient through contaminated hands or equipment (Maraqa et al., 2011; Patel & Saiman, 2010). The anterior nares are a major site of MRSA colonization (Maraqa et al., 2011). Other sites of colonization include the umbilicus, groin, axillae, hands, ears, gastrointestinal tract, and sinuses (Heinrich et al., 2011; Maraqa et al., 2011). Although some disagreement exists, the majority of practitioners consider screening of nares or nasopharynx sufficient to identify carriers (Lepelletier et al., 2009; Maraqa et al., 2011). Detection is accomplished by either PCR or culture (Enomoto, Morioka, Morisawa, Yokoyama, & Matsuo, 2009; Francis et al., 2010). PCR has a turnaround time of hours as opposed to the 2 days required for culture (Francis et al., 2010). Francis et al. (2010) demonstrated that PCR had a sensitivity of 100% and specificity of 98%, recommending follow-up of positive results by culture. The necessity to culture all healthcare workers is controversial and usually confined to outbreaks (Grant, Charns, Rawot, & Benedetti, 2008). Transmission from healthcare workers is well documented (Burton, Edwards, Horan, Jernigan, & Fridkin, 2009; Heinrich et al., 2011; Seybold et al., 2008; Takei, Yokoyama, Katano, Tsukiji, & Ezaki, 2010). Transmission of MRSA from mother to infant has also been documented (Mongkolrattanothai, Mankin, Cranston, & Gray, 2010; Nelson & Gallagher, 2012). Horizontal transmission from siblings has also been implicated (Nelson & Gallagher, 2012). Hospitals report CA-MRSA vaginal colonization rate of 0.4% to 10.4% in pregnant woman (Carey & Long, 2010), indicating a potential for transmission at birth. A positive culture obtained shortly after birth occurred in 1.7% of infants in a German hospital and 1.9% in a New Jersey hospital, suggesting such a transmission (Murillo et al., 2010; Seybold et al., 2008). Cases of transmission of CA-MRSA from contaminated breast milk (Behari, Englund, Alcasid, Garcia-Houchins, & Weber, 2004) and from father to infant (Al-Tawfiq, 2006) have also been reported.

MRSA infections may present as bloodstream infections (positive blood culture), surgical site infections, cellulitis, pustulosis, pneumonia, conjunctivitis, or osteomyelitis. Meningitis, urinary tract infections, brain abscesses, and endocarditis are relatively rare (Carey & Long, 2010; Chuang et al., 2004; M. L. Gregory et al., 2009; Nelson & Gallagher, 2012; H. A. Silva et al., 2009). The NNIS survey of MRSA infections from 149 nurseries from 1995 to 2004 classified 31% as bloodstream infections, 18% pneumonia, 17% conjunctivitis, 14% skin and soft tissue, 4% surgical, and 10% other (Lessa et al., 2009). Skin infection outbreaks have been reported in multiple otherwise normal full-term nurseries (Carey & Long, 2010). As with any infection, death is a possible outcome (Chuang et al., 2004; Nelson & Gallagher, 2012). Symptoms remain the same as for any neonatal infection.

The majority of risk factors for MRSA infections also coincide with neonatal sepsis: extreme prematurity and low birth weight, indwelling central lines, prolonged hospitalization, endotracheal intubation, and previous exposure to antibiotics (Burton et al., 2009; Lessa et al., 2009; Maraqa et al., 2011; Nelson & Gallagher, 2012; Shirai et al., 2017). Parental nutrition and gavage feedings, nearly universal in premature infants, are also implicated (Nelson & Gallagher, 2012). The NNIS reports rates of 5.4 infections per 1,000 catheter days for infants 1,001 to 1,500 g and 9.1 per 1,000 catheter days for infants weighing less than 1,000 g (Perlman, Saiman, & Larson, 2007). Colonization with MRSA frequently precedes infection (M. L. Gregory et al., 2009; Maraqa et al., 2011; Milstone, Budd, et al., 2010). In a recent meta-analysis, Washam, Woltmann, Haberman, Haslam, & Staat (2017) found that the only consistent risk factors for colonization were a gestational age less than 32 weeks and a birth weight less than 1,500 g. Kaushik, Kest, Zauk, DeBari, and Lamacchia (2015) found that there was a 10-fold increase in risk of developing an infection if the infant was colonized. Meta-analysis by two different groups showed a relative risk of 24.2 to 37.75 as compared with non-colonized (Maraqa et al., 2011; Zervou, Zacharioudakis, Ziakas, & Mylonakis, 2014).

Quality and Safety: Vancomycin remains the gold standard of treatment. Standard dosing is dependent on postmenstrual age (gestational age plus postnatal age). Dosing interval decreases with increasing postmenstrual and postnatal age. Current online references are available for both dose and interval. Trough levels should be monitored during treatment. While a range of 7 to 15 mg/L usually results in a therapeutic MIC of 1 mg/L, some experts recommend trough levels of 15 to 20 mcg/mL when treating MRSA (Blanchard et al., 2015; Cantley & Patel, 2014; Truven Health Analytics, 2018). The practitioner adjusts dosing to maintain levels. Duration of treatment depends on the type of infection with most bacteremia requiring a 7- to 10-day course while osteomyelitis may require 6 to 8 weeks for treatment (Blanchard et al., 2015; Carey & Long, 2010). Infectious disease specialists may be consulted for guidance. In the event an infant is allergic to vancomycin or resistance develops, linezolid is an option. For fulminant cases gentamycin or rifampin may be added for synergy or better blood–brain barrier penetration (Blanchard et al., 2015; Carey & Long, 2010; Puopolo, 2017). Quinupristin-dalfopristin, linezolid, and daptomycin are also choices (Baley & Leonard, 2013). The monoclonal antibody tefibazumab has not been proven effective (Carey & Long, 2010). A Cochrane study meta-analysis showed no significant difference in the prevention of staphylococcal infections in very low birth weight infants when anti-staphylococcal immunoglobulins were administered (Nelson & Gallagher, 2012; Puopolo, 2017; P. S. Shah & Kaufman, 2009).

In addition to antibiotic coverage, additional measures are indicated to assure optimal outcomes. These measures include removal of indwelling catheters, drainage of any abscess, and documentation of sterilization of the bloodstream with follow-up blood cultures. The NICU team monitors the infant for any signs of osteomyelitis (Carey & Long, 2010).

Attempts to decolonize infants and care workers achieve varied results. Intranasal mupirocin for 5 days is one measure. Multiple courses of mupirocin may be required (Carey, Della-Latta, et al., 2010; Heinrich et al., 2011; Lepelletier et al., 2009). While chlorhexidine baths are often used in older patients (Doyle et al., 2011), concern over neurotoxicity and chemical burns limits its use in the neonatal population (Carey & Long, 2010; Saiman, 2016). Units that use hexachlorophene baths often limit its use to infants with a birth weight of 1,500 g or higher (Saiman, 2006) or more than 36 weeks gestation (Milstone, Budd, et al., 2010; Nelson, Bizzarro, Dembry, Baltimore, & Gallagher, 2014). The baths may have more of a role in decolonization of the healthcare worker. However, the REDUCE MRSA Trial (Randomized Evaluation of Decolonization vs. Universal Clearance to Eliminate Methicillin-Resistant *Staphylococcus aureus*) found Universal Clearance to have a 37% reduction in rates of MRSA-positive cultures and 44% reduction of MRSA-positive blood cultures. The Universal Clearance protocol consisted of 5 days of daily 3% chlorhexidine baths and twice daily nasal mupirocin (Climo et al., 2013; Nelson et al., 2014). At present, a survey of the U.S. NICUs showed that only 37% followed a decolonization protocol (Pierce, Lessler, Popoola, & Milstone, 2017). Chlorhexidine- and mupirocin-resistance has been developed in some strains of MRSA (Reich et al., 2016). Despite attempts to decolonize, many infants remain colonized at the time of discharge (Francis et al., 2010; Lepelletier et al., 2009; Reich et al., 2016). Contact isolation is usually maintained until a minimum of two consecutive cultures are obtained (Francis et al., 2010).

MRSA outbreaks can be particularly stubborn and require strict adherence to infection control methods and additional surveillance and isolation. In 2006, the Chicago Department of Public Health issued a consensus statement on control of MRSA in NICUs. These measures include strict adherence to hand hygiene with the availability of waterless, alcohol-based hand-hygiene products at bedside. **Quality and Safety: Hospital infection control professionals should provide education and direct observation to ensure adherence.** Nasopharyngeal surveillance cultures should be done on admission and then weekly. All positive cultures require contact precautions with gowns and gloves for all care and masks for suctioning. For nursing assignments, admissions can be cohorted in one group until cultures are available, infants with positive cultures in another group, and infants with negative cultures in a third group. Mupirocin has been used to decolonize MRSA-positive infants and healthcare workers. However, a recent decolonization program at Johns Hopkins showed no difference in the rate of positive MRSA infections pre- and post-intervention (Popoola et al., 2016). Culture of healthcare workers and the environment may be indicated. Molecular analysis such as PFGE should be performed to analyze the relationship between strains and identify potential reservoirs and areas of infection control breakdown (Gerber et al., 2006). Extreme outbreaks with high persistence may require closure of the unit to new admissions until the organism is eradicated. Restriction of transfer of colonized patients prevents further contamination of outlying hospitals. Song et al. (2010) documented a stepwise approach using many of the Chicago consensus recommendations which took over 4 years to eradicate an MRSA outbreak in their nursery. In a Taiwan NICU where MRSA is endemic, it took 7 years (Huang et al., 2011).

The financial burden of MRSA can be tremendous. M. L. Gregory et al. (2009) reported screening costs alone during a 7-year period were 1.5 million dollars at their hospital. Infections are associated with prolonged length of stay, increasing the cost of hospitalization.

EXTENDED SPECTRUM BETA-LACTAMASE (ESBL) PRODUCING ORGANISMS

ESBL-producing organisms were first discovered in 1983 in Germany (Huang et al., 2007). Gram-negative microorganisms that produce ESBLs include *Escherichia coli*, *Enterobacter cloacae*, *K. pneumoniae*, *Klebsiella oxytoca*, *Pseudomonas*, *Salmonella enterica*, and *Serratia marcescens* (Blaschke et al., 2009; Crivaro et al., 2007; O'Connor et al., 2017; Pessoa-Silva et al., 2002; D. Sharma et al., 2016; Stapleton et al., 2016). Colonization rates of ESBL-producing organisms range from 5% to 53.8%, varying by geographic location and individual institutions (Murki, Jonnala, Mohammed, & Reddy, 2010; Ofek-Shlomai et al., 2011; Pessoa-Silva et al., 2003; Shakil, Ali, Akram, Ali, & Khan, 2010; Tsai et al., 2016). Outbreaks have been reported worldwide (Abdel-Hady, Hawas, El-Daker, & El-Kady, 2008; Bagattini et al., 2006; Conte et al., 2005; Gundes et al., 2005; Huang et al., 2007; Iregbu & Anwaal, 2007; Kristóf et al., 2007; López-Cerero et al., 2008; Mesa et al., 2006; O'Connor et al., 2017; Otman, Cavassin, Perugini, & Vidotto, 2002; Stapleton et al., 2016). Jain, Roy, Gupta, Kumar, and Agarwal (2003) reported ESBL in 86.6% of *Klebsiella* species, 73.4% of *Enterobacter* species, and 63.6% of *E. coli* strains causing infections in their nursery in India. The NNIS reported similar rates of ESBL resistance: 81.8% of *Klebsiella* species, 73.1% of *E. coli*, and 60% of *Enterobacter* species (Kamath et al., 2010). ESBL resistance has spread to *Neisseria gonorrhoeae* (Tapsall, 2009).

As previously described, beta-lactamase enzymes deactivate beta-lactam antibiotics through hydrolyzing the amide bond of the beta-lactam ring (Abdul-Hady et al., 2008; Huang et al., 2007; Mulvey & Simor, 2009; Shea & Jacobi, 2009). These enzymes extend resistance beyond penicillin to the extended-spectrum cephalosporins (ceftazidime, cefotaxime, ceftriaxone, etc.) and aztreonam (Abdel-Hady et al., 2008). Beta-lactamase enzymes make two of the four most common empirically prescribed antibiotics ineffective: ampicillin and cephalosporins. Inadequate empirical treatment is associated with higher mortality (Abdel-Hady et al., 2008; Maragakis, 2010; Shea & Jacobi, 2009).

Most ESBLs are encoded on genes located on plasmids, promoting the transfer of resistance between bacteria of the same and other species (Crivaro et al., 2007). Identified genes associated with ESBL include *SHV*, *TEM*, *CTX-M*, and *OXA* (Abdel-Hady et al., 2008; Blaschke et al., 2009; Kristóf et al., 2007; O'Connor et al., 2017; Tsai et al., 2016). Crivaro et al. (2007) demonstrated the same plasmid in both *S. marcescens* and *K. pneumoniae* during the investigation of ESBL in their NICU, indicating probable conjugal transfer of the plasmid between the two species. Other gram-negative bacilli may have chromosomal mutations which produce the gene *AmpC*, causing overproduction of beta-lactamase enzymes and making them resistant to even the beta-lactamase–beta-lactamase-inhibitor combination drugs (Kanj & Kanafani, 2011; Mulvey & Simor, 2009).

ESBL transmission can be either horizontal or vertical. Seale and Millar conducted a systematic review and found four documented cases of perinatal vertical transmission as of 2014. The reported prevalence of ESBL-producing *E. coli* in pregnant women ranges from 5% to 20% (Seale & Millar, 2014). The majority of neonatal

cases are transmitted horizontally. Horizontal transfer from contaminated patients through healthcare workers has been documented through PFGE analysis (Abdel-Hady et al., 2008; Boszczowski et al., 2005; Otman et al., 2002). Artificial fingernails on healthcare workers have been implicated in adult outbreaks (Boszczowski et al., 2005). Measures to control outbreaks are similar to those previously described for MRSA: strict hand hygiene, contact isolation, and cohorting of patients. Clinical improvement and sterilization of the bloodstream by antibiotics do not necessarily protect the gastrointestinal tract from colonization (Gundes et al., 2005). Screening for colonization is by stool or rectal culture (N. Singh et al., 2002). In contrast with MRSA, there is no reliable process for decolonization of carriers (Seale & Millar, 2014).

Risk factors for infection with ESBL-producing organisms include lower gestational age, low birth weight, and longer length of stay. Previous exposure to third-generation cephalosporins has been implicated in all studies. Mixed results were found for endotracheal intubation duration (Jain et al., 2003; Kristóf et al., 2007; Ofek-Shlomai et al., 2011; Pessoa-Silva et al., 2003; Shakil et al., 2010). In contrast with MRSA, only one of the studies found the presence of a central line to be a risk factor (Pessoa-Silva et al., 2003). Colonization frequently precedes infection (Crivaro et al., 2007). Infections with ESBL-producing bacteria are associated with increased costs, prolonged length of stay, and higher mortality rates (Abdel-Hady et al., 2008; Gundes et al., 2005; Iregbu & Anwaal, 2007; Scheans, 2010).

Treatment is guided by susceptibility to antibiotics. Many of the ESBL-producing organisms are less susceptible to beta-lactam–beta-lactamase inhibitor combinations due to higher production of ESBLs (Huang et al., 2007). Carbapenems are often first-line agents used to treat ESBL-producing organisms (Kanj & Kanafani, 2011). Synergy with gentamycin allows the beta-lactam antibiotic to be therapeutic in some cases of low resistance (Arias, Contreras, & Murray, 2010).

VANCOMYCIN-RESISTANT ENTEROCOCCUS

VRE was first reported in 1986 in Europe (DeLisle & Perl, 2003). By 2004, VRE strains accounted for 28.5% of enterococci (Bizzarro & Gallagher, 2007). VRE strains have been found in *Enterococcus faecium* and *Enterococcus faecalis* (Rice, 2006).

Enterococci have intrinsic resistance to many antimicrobials. They have long been resistant to beta-lactam antibiotics as they produce low-affinity PBP5, interfering with the binding of the antibiotic to the cell wall. They can also bypass the block of folic acid synthesis by extracting folinic acid derivatives directly from their environment, interfering with trimethoprim-sulfamethoxazole. Aminoglycosides have difficulty crossing the cell wall unless paired with beta-lactams for synergy. Enterococci also produce enzymes that modify the ribosomes, decreasing the binding and bactericidal activity. Macrolides cannot stop protein synthesis because of a modified ribosomal target (Arias & Murray, 2019; DeLisle & Perl, 2003; Tenover, 2006). Concern develops when acquired resistance occurs to one of the few antibiotics that was previously successful: vancomycin.

Vancomycin resistance is attributed to multiple gene clusters (*vanA* to *vanZ*), with *vanA* and *vanB* most significant (Arias & Murray, 2019). These clusters are associated with transposons that can move from chromosome to plasmids and transfer readily between bacteria. Glycopeptides normally interfere with cell wall synthesis by binding to the D-alanyl-D-alanine terminus of a pentapeptide cell wall precursor. Resistance is conferred by substituting D-ala-D-lactate depsipeptide instead of the D-alanyl-D-alanine, interfering with vancomycin binding and allowing cell wall synthesis to continue (Arias & Murray, 2019; DeLisle & Perl, 2003; Mulvey & Simor, 2009).

Transmission of VRE is horizontal with transfer from colonized patients. VRE generally colonizes the gastrointestinal tract. Screening involves stool, rectal, or perirectal cultures. Patient-to-patient transfer can occur through contamination of healthcare workers' hands. The hospital environment provides many potential fomites, with survival of VRE up to 5 weeks (DeLisle & Perl, 2003; Mulvey & Simor, 2009; N. Singh & Valsangkar, 2016). Known cases require contact isolation until three stools obtained 1 week apart remain negative (DeLisle & Perl, 2003). Risk factors for infection include prior antimicrobial therapy with vancomycin or broad-spectrum cephalosporins, prolonged hospitalization, and invasive procedures (Akturk et al., 2016; Louie, 2011; Mulvey & Simor, 2009).

Treatment of VRE is challenging and often involves a combination of agents. Microbial susceptibilities should guide treatment. Bacteriostatic agents such as chloramphenicol may need to be used (Bizzarro & Gallagher, 2007; DeLisle & Perl, 2003). Limited data suggest that linezolid may be effective in some neonates (Bizzarro & Gallagher, 2007). Linezolid is an oxazolidinone antibiotic that interferes with ribosomal protein synthesis (Arias et al., 2010). Multiple blood cultures are recommended to confirm sterilization of the bloodstream (DeLisle & Perl, 2003). VRE is associated with higher mortality (Bizzarro & Gallagher, 2007). Methods to control outbreaks are similar to those described for MRSA: strict hand hygiene, screening, isolation, cohorting of patients and nurses, and environmental decontamination (DeLisle & Perl, 2003).

MULTIDRUG-RESISTANT ORGANISMS

Multidrug-resistant organisms (MDROs) are gram-negative bacteria which are resistant to more than two classes of antimicrobials. These organisms are typically resistant to penicillins, cephalosporins, fluoroquinolones, and aminoglycosides. Some have developed resistance to carbapenems, making treatment options difficult (Mohsen et al., 2017; Mulvey & Simor, 2009; Puopolo, 2017). MDROs include some strains of *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, *E. coli*, *E. cloacae*, *K. pneumoniae*, *K. oxytoca*, *Staphylococcus capitis*, and *S. marcescens* (Butin, Martins-Simões, Rasigade, Picaud, & Laurent, 2017; Mammina et al., 2007; Mohsen et al., 2017; Mulvey & Simor, 2009; Shea & Jacobi, 2009; Simões et al., 2016). These organisms often have multiple mechanisms for resistance. Energy-dependent efflux pumps located on the cytoplasmic membrane are encoded on the *MexB* gene. Regulation of outer membrane porin is encoded on the *OprM* gene. A protein joins these genes and is designated MexA. These combine to form the gene complexes *MexAB-OprM*, *MexXY-OprM*, *MexCD-OprJ*, and *MexEF-OprN* (Tenover, 2006). Efflux systems work against multiple classes of antimicrobials by lowering the concentration within the cell to a subtherapeutic level. Many already produce beta-lactamases, causing resistance to penicillins and cephalosporins (Mammina et al., 2007). A carbapenem-resistant gene, *VIM11*, has been identified (Mammina et al., 2007). Carbapenemase production occurs in some species of *E. coli* and *K. pneumoniae* (Cantley & Milstone, 2015; Kanj & Kanafani, 2011). Simões et al. (2016) found a *S. capitis* strain that carries a gene (*nsr*) which confers resistance to nisin, a bacteriocin secreted by an organism in the gut microbiota.

The usual reservoir of MDROs is the gastrointestinal tract. Screening is via stool culture. The proportion of colonized MDROs varies by geographic location and individual NICUs, ranging from 12% to 55.2% in nurseries with surveillance systems geared to

detect these organisms (Giuffrè et al., 2016; Mammina et al., 2007; A. J. Shah et al., 2012; Tsai et al., 2014). Colonization is a risk factor for infection (Giuffrè et al., 2016). Breast milk proved protective in one study. Transfer is horizontal from patient-to-patient via contaminated healthcare workers' hands or the environment. Identified risk factors for infection include early gestational age, low birth weight, use of invasive devices, and longer duration of NICU stay (Giuffrè et al., 2016; Mammina et al., 2007).

MDROs have caused conjunctivitis, pneumonia, bloodstream infections, and death (Scheans, 2010). Treatment of MDROs should be guided by susceptibilities and may involve a combination of antimicrobials that are normally considered bacteriostatic instead of bactericidal. Clinicians may be forced to use antimicrobials that have few studies of the pharmacodynamics in neonates. Partnership between neonatologists, clinical pharmacists, and infectious disease specialists may present the best management. Outbreaks are managed through a combination of effective hand hygiene, isolation, cohorting of patients and nurses, and environmental decontamination (Giuffrè et al., 2016; Maragakis, 2010).

Babesia

Babesia is an example of a pathogen with an animal vector, which has been recognized by new detection methods as causing human infection (Stramer et al., 2009). Like Lyme disease, it is tick-borne and found primarily in certain geographic locations. *B. microti*, the most common species, is an intraerythrocytic protozoa which is detected by finding characteristic ring forms within the blood cell on blood smears (Aderinboye & Syed, 2010; Fox et al., 2006; Herwaldt et al., 2011; Raju, Salazar, Leopold, & Krause, 2007; Snow, 2009). It can also be detected by PCR or serologic immunofluorescent antibody testing (Aderinboye & Syed, 2010; Fox et al., 2006; Graham, Stockley, & Goldman, 2011; Simonsen, Harwell, & Lainwala, 2011). In 2008, the Food and Drug Administration (FDA) identified *B. microti* as the most frequent transfusion-transmitted microbial pathogen in the United States (Levin & Krause, 2016).

Most cases of human babesiosis are associated with deer tick bites. Babesiosis is most common in five Northeastern states: Connecticut, Massachusetts, Rhode Island, New York, and New Jersey. It has also been found in two Midwestern states, Minnesota and Wisconsin. It is primarily associated with the species *B. microti* (FDA, 2018; Hoffman, 2018). Other areas of the country such as the Pacific Northwest (Washington and California) are associated with a different species, *B. duncani* (Herwaldt et al., 2011). In contrast, the majority of neonatal infections are the result of blood transfusions from asymptomatic donors (Fox et al., 2006; Herwaldt et al., 2011). The first documented neonatal case occurred in 1982 (Raju et al., 2007). As of October 2011 there have been 18 neonatal cases (Herwaldt et al., 2011). Seven infants in a NICU acquired babesiosis from transfusions from two infected donors (Simonsen et al., 2011). There have been two reported congenital infections transmitted from a mother with babesiosis (Aderinboye & Syed, 2010; Fox et al., 2006). There are two reported cases of infants acquiring the infection post-discharge, with ticks removed from their bodies 2 weeks prior to the development of symptoms (Fox et al., 2006).

Babesiosis in neonates presents with jaundice, hepatosplenomegaly, hemolytic anemia, occasional thrombocytopenia, and occasional conjugated hyperbilirubinemia (Aderinboye & Syed, 2010; Fox et al., 2006). Unlike adult cases, fever is only reported in some cases (Aderinboye & Syed, 2010). Treatment includes the combination of clindamycin and quinine or the combination of azithromycin and atovaquone. Response is usually rapid with reduction or clearing of parasites within a few days. Treatment is continued for 7 to 14 days (Aderinboye & Syed, 2010; Fox et al., 2006; Raju et al., 2007; Simonsen et al., 2011). Packed red blood cell transfusions may be required for anemia. In severe cases an exchange transfusion may prove beneficial (Aderinboye & Syed, 2010; Fox et al., 2006; Simonsen et al., 2011). Cardiac monitoring will identify any arrhythmias, a potential adverse reaction associated with quinine (Raju et al., 2007). Hearing screening should follow treatment with quinine as hearing loss and tinnitus are potential adverse reactions reported in adults (Snow, 2009).

In March 2018, the FDA approved the first screening test for *Babesia*. The FDA plans to release guidelines for testing later in the year (FDA, 2018; Hoffman, 2018). Prior to this, blood banks relied on screening of donors for babesiosis by questionnaire only, with only known cases excluded, and a question about exposure to tick bites not routinely included (Germain & Goldman, 2002). Asymptomatic donors with babesiosis remain undetected. The true extent of neonatal *Babesia* exposure may be higher with asymptomatic infants undiagnosed. In addition, leukoreduction and irradiation are not effective against *Babesia* (Simonsen et al., 2011). Until the blood supply is routinely screened, transfusion blood products for infants may be screened for babesiosis similar to our screening for cytomegalovirus (Hoffman, 2018).

MEASLES

Measles is an example of a disease that is re-emerging. Prevention is managed through a series of two vaccinations: the first at 12 to 15 months and the second at 5 to 6 years. Parents may elect to decline immunization, and their child may be protected by herd immunity. A paper from Italy documents seven cases of measles in infants: four were less than 3 months and three were less than 12 months. Four of the mothers had no immunization and contracted measles themselves, while the other cases involved siblings with the disease (Bozzola et al., 2011). Of concern with infants is the case-fatality rates are increased in children younger than 5 years and in the immune-compromised (The Committee on Infectious Diseases American Academy of Pediatrics, 2015b, p. 535). Infants who are exposed to measles will require respiratory isolation. There is no specific antiviral therapy (The Committee on Infectious Diseases American Academy of Pediatrics, 2015b, p. 536).

COMBATING EMERGING INFECTIONS

The war against emerging infections begins with infection control. Many of the infection control methods such as isolation, cohorting patients, and surveillance are described in the "Methicillin-resistant *Staphylococcus aureus*" section. The goal of infection control is to reduce and control reservoirs. Hand hygiene remains an important action to protect the patients (Cantley & Milstone, 2015; Higgins, Baker, & Raju, 2010; N. Singh & Valsangkar, 2016). The use of alcohol-based gel disinfectants at the bedside improves compliance (Saiman, 2006; Sakamoto et al., 2010; N. Singh & Valsangkar, 2016). Steps to minimize overcrowding and understaffing also assist. The American Academy of Pediatrics recommends a minimum of 150 square feet for each critically ill infant (Cantley & Milstone, 2015). Many NICUs have switched to a private room layout. Understaffing was the most frequent predisposing factor reported in a meta-analysis of 75 outbreaks of ESBL (Stapleton et al., 2016).

Care bundles are a group of evidence-based actions that when implemented together have been successful in reducing infections. Central Line-Associated Blood Stream Infections

(CLABSI) and Ventilator-Associated Pneumonia (VAP) are examples of care bundles (Doyle et al., 2011; Toth, Chambers, & Davis, 2010). A typical CLABSI bundle includes hand hygiene, use of full barrier precautions during line insertion, effective skin antisepsis at the insertion site, minimizing catheter entry and disinfecting hub with alcohol when entry is required, use of closed medication systems, daily fluid and tubing changes using sterile technique, infection surveillance, and removal of catheter when appropriate (Doyle et al., 2011; Garland et al., 2008; Saiman, 2006; N. Singh & Valsangkar, 2016). Removal of unnecessary catheters in particular is important as catheter duration is a risk of CLABSI. Sengupta, Lehmann, Diener-West, Perl, and Milstone (2010) reported that incidence of CLABSI increased by 14% per day during the first 18 days, decreased by 20% during day 19 through 35, then increased by 33% per day after 35 days. A survey of NICUs reporting CLABSI data to the National Healthcare Safety Network in 2009 showed that the majority followed a CLABSI bundle of some type (Hocevar et al., 2014). Hawes and Lee (2018) reported a decline in the incidence of CLABSI from 4.4 to 1.5 per 1,000 line days following implementation of a CLABSI bundle in their institution. VAP bundles have been implemented in some NICUs. A VAP bundle in the NICU might include hand hygiene, the use of in-line suction devices, limitation of saline administration, providing oral care with sterile water, planned extubation when readiness is achieved, and surveillance (N. Singh & Valsangkar, 2016).

Neonatal care providers continuously seek strategies to reduce the likelihood of colonization by antibiotic-resistant organisms. The use of probiotics is one strategy under investigation. The theory behind probiotics is viable nonpathogenic bacteria, such as *Lactobacillus acidophilus* or *Bifidobacterium infantis*, fed enterally to compete with potential pathogen-producing antibiotic-resistant organisms. Results of studies are mixed, with optimal dosing, organism type, and effectiveness to be established (Patel & Saiman, 2010; Saiman, 2006). The use of breast milk is protective, with decreased incidence of necrotizing enterocolitis and other infections documented. Breast milk contains 23 to 130 different oligosaccharides, a substance utilized by bifidobacteria. Lactoferrin in breast milk has anti-inflammatory, antimicrobial, and immunomodulatory properties (Higgins et al., 2010).

One strategy to reduce infections is the development of vaccines. This strategy effectively reduced the incidence of *Haemophilus influenza* serotype b disease by 99% after it was introduced in 1990. Less than one case per 100,000 children under 5 years old contract this disease after the introduction of the immunization program (CDC, 2008). Vaccine development is a goal in the fight against HIV. Infants remain at risk worldwide from perinatal transfer and through breastfeeding. A vaccine would be a lower cost alternative to detection and treatment of the disease. Research is in early stages, with safety and efficacy yet to be established.

The symptoms of sepsis are nonspecific in neonates, resulting in empiric treatment prior to obtaining a negative blood culture. Improved detection methods may help distinguish those episodes that are most likely sepsis-related from those that are related to other causes. Adjunctive tests such as C-reactive protein, procalcitonin, or interleukin-8 may help to distinguish cases of sepsis (Cantley & Patel, 2014; Higgins et al., 2010; Patel et al., 2009; N. Singh & Valsangkar, 2016; Zingg et al., 2011). Early detection also allows streamlining of antibiotics to those most likely to treat the microorganism. PCR tests are under investigation for some microorganisms such as group B *Streptococcus*, *E. coli*, *Candida albicans*, and MRSA (Enomoto, Morioka, Morisawa, Yokoyama, & Matsuo, 2009; Francis et al., 2010).

ANTIMICROBIAL STEWARDSHIP

Antimicrobial stewardship is the cornerstone in the battle against antimicrobial resistance. It is defined as "the optimal selection, dose, and duration of an antimicrobial that results in the best clinical outcome for the treatment or prevention of infection, with minimal toxicity to the patient, and minimal impact on subsequent resistance" (Lipsett, 2008; Louie, 2011). The goal of such a program is to preserve the effectiveness of prescribed antimicrobials by reducing resistance. Additional benefits include a reduction in costs, fewer antibiotic-related adverse events, and shorter hospital length of stay (Di Pentima & Chan, 2010; Louie, 2011; Newland & Hersh, 2010). Core strategies of antimicrobial stewardship include monitoring antimicrobial prescription and infectious agents, providing practitioners with feedback on this monitoring, and restricted use of certain antimicrobials to protect their effectiveness. Additional strategies include education, development of guidelines and policies, use of tools such as computerized order entry or automatic stop orders, dose optimization, cycling of antibiotics, and de-escalation of therapy (K. E. Gregory, 2016; Newland & Hersh, 2010). A multidisciplinary team is a key component for many antimicrobial stewardship programs. Membership can include pharmacists, infectious disease specialists, neonatologists, nurses, hospital epidemiologists, and bioinformatics specialists (Cantley & Patel, 2014; K. E. Gregory, 2016; Patel & Saiman, 2010; N. Singh & Valsangkar, 2016). Programs can be highly structured with formulary restriction, preauthorization requirements, and computerized order templates (Lipsett, 2008; Louie, 2011). Medical providers prefer programs that offer guidance over those which restrict prescriptive privileges (Patel, Rosen, Zaoutis, Prasad, & Saiman, 2010).

Principles of appropriate antimicrobial usage include prescribing only when clinically indicated, basing empiric antimicrobial selection on local flora and antimicrobial resistance patterns, adjusting antimicrobials according to susceptibilities obtained and within as narrow of coverage as to be effective, assuring dose and timing provide therapeutic levels for the required duration, and stopping the drugs as soon as appropriate (Hart, 2011; McPherson, Liviskie, Zeller, Nelson, & Newland, 2018). It is estimated that antibiotic use is unnecessary or inappropriate in 50% of treatment episodes (Fishman, 2006). Patients and families can pressurize practitioners to prescribe antimicrobials when they are not needed. Past practice in pediatrics included prescribing antibiotics for respiratory illnesses which were most likely viral and not affected by the antibiotics (Hart, 2011). This resulted in microorganisms exposed to many antimicrobials in their environment, contributing to the selective pressure favoring resistant organisms. **Emergency Alert: Inappropriate or excessive use of antibiotics has been linked with the development of MDROs, necrotizing enterocolitis, late-onset sepsis, or death** (Cantley & Patel, 2014; K. E. Gregory, 2016). Infectious disease committees for hospitals, states' departments of health, and various surveillance systems tabulate statistics on infectious agents and their antimicrobial resistance patterns. This information can guide choice of empiric antibiotics. While early-onset infections are initially treated with ampicillin and gentamycin, late-onset infections' empiric choice reflect broad-spectrum coverage of those microorganisms most likely to cause infection. In the past, this empiric choice often involved a cephalosporin, contributing to the selective pressure for ESBL-producing microorganisms. Once culture and sensitivity results are obtained, adjust antimicrobial coverage to monotherapy with a narrower activity if possible (Fishman, 2006; N. Singh & Valsangkar, 2016). Infection with multiple microorganisms may require multiple antibiotics (Vrtis, 2008). Failure to adjust to an

appropriate antimicrobial can contribute to increased morbidity and mortality (Cantley & Patel, 2014). Monitoring of drug levels and compliance with recommended dose and frequency based on gestational and postconceptual age promotes maintenance of levels above the MIC. Subtherapeutic levels will target susceptible microorganisms while allowing resistant agents to proliferate. Suspected infections are generally screened by blood culture and covered by empiric antibiotics. Practitioners should stop antibiotics if cultures fail to turn positive in 48 hours, limiting unnecessary environmental exposure. Duration of antimicrobial coverage is governed by the type of infection and proof of sterilization of the infected site. Any protracted exposure beyond that necessary to treat the infection contributes to the selective pressure for resistance.

In an era of rising resistance and limited development of new classes of antimicrobials, it is essential to protect the effectiveness of the current antimicrobials. **Quality and Safety: Restricted use of certain antimicrobials is a strategy to reduce resistance.** Vancomycin is the most commonly restricted drug as it is associated with the development of VRE (Cotten, 2016; Hammer, Lardieri, & Morgan, 2016; Louie, 2011). Several studies (Chiu et al., 2011; K. E. Gregory, 2016; McPherson et al., 2018) showed no increase in morbidity or mortality when vancomycin use was restricted to specific indications and no longer used for general empiric therapy. A vancomycin restriction policy at a Delaware children's hospital reduced the incidence of VRE (Di Pentima & Chan, 2010). Its effectiveness in treating infections caused by ESBL-producing microorganisms is another reason to protect it. The Committee on Infectious Diseases of the American Academy of Pediatrics (2015a, p. 875) recommends vancomycin use be limited to cases of MRSA. Other antimicrobials that may be restricted include carbapenems, linezolid, and fourth-generation cephalosporins. The substitution of beta-lactam–beta-lactamase inhibitors for cephalosporins resulted in decreased prevalence of ESBL-producing pathogens in a nursery in Korea (Lee et al., 2007). Restriction of cephalosporins in a nursery in India led to a 22% reduction in ESBL-producing gram-negative bacteria (Murki et al., 2010). Restrictions may come in the form of guidelines, preauthorization, or post-prescription review (Louie, 2011). Antibiotic cycling is another strategy. This cycling is a scheduled rotation of two or more antibiotic classes with similar range of activity over a specific time period, eventually returning to the original antibiotic class. Time periods vary from 1 to 4 months. The theory behind cycling is to reduce the selective pressure by limiting the exposure time to a particular antibiotic class. Evidence has not supported this strategy (Patel & Saiman, 2010; Puopolo, 2017).

Optimizing antimicrobial therapy involves tailoring dosing and method of antimicrobial administration to take advantage of the drug's pharmacodynamics. In the neonatal field, this is an area of evolution requiring current knowledge of recommendations. The use of yearly updated references such as Red Book or Micromedex Pediatric and Neofax Standard, both online resources, can assist in maintaining current knowledge. Clinical pharmacists who attend rounds with the care team are also resources. Potential alternate dosing regimens include continuous infusion or prolonged intermittent infusion. These alternate dosing methods can be effective for time-dependent antimicrobials, increasing the total time above the MIC (Shea & Jacobi, 2009). Inhaled antibiotic administration offers the potential for local action with minimal systemic adverse effects. Intermittent aerosolized administration of antibiotics has been used in older patients with *P. aeruginosa* pneumonia, particularly in patients with cystic fibrosis (Kanj & Kanafani, 2011). Antimicrobial stewardship promotes appropriate antimicrobial prescription through recommendations on antibiotic choice to narrow down the therapy and eliminate redundancy, monitoring effectiveness and providing reminders when antibiotics should be stopped (The Committee on Infectious Diseases American Academy of Pediatrics, 2015a).

Monitoring is another essential component of antibiotic stewardship. Days of therapy (DOTs) adjusted for 1,000 patient-days of hospitalization is a measurement of antibiotic utilization often used as a benchmark between NICUs (Cantley & Patel, 2014; K. E. Gregory, 2016). DOTs are often utilized to evaluate the effectiveness of broad-spectrum antibiotic reduction programs. Monitoring of infectious agents allows use of a NICU-specific antibiogram-guiding empiric antibiotic therapy. Monitoring of individual cultures allows reduction of duration of antibiotic use when cultures are negative and adjustment of appropriate antibiotic use when sensitivities are available (Cantley & Patel, 2014).

SUMMARY

Use of a conceptual framework, Pattern of Response to Emerging Infections, makes understanding emerging infections easier. It gives us an idea of where we stand in regard to the fight against specific pathogens. The conceptual framework can be applied to future outbreaks.

Sepsis and the steps to reduce it are a part of the NICU life. When acuity increases and the census rises, a heavy workload makes it easy to forget compliance with those mechanisms that protect our patients. Hand hygiene, isolation precautions, and surveillance are a necessary burden. Antimicrobial stewardship offers many benefits, including reduction of antimicrobial resistance. We may not be able to eliminate resistant organisms, but we can limit their spread and slow down their development.

Thirty-five years ago, the emerging infectious disease was HIV, an evolved zoonotic pathogen. Fifteen years ago, the emerging diseases focused on antimicrobial-resistant microorganisms. Today's emerging infection, Zika virus, is a different zoonotic pathogen. Tomorrow's emerging pathogens will be equally challenging. Development of new diagnostic tests and antimicrobial agents remain important and will involve research within and outside of the NICU.

EVIDENCE-BASED PRACTICE BOX

The practices used to control the spread of infectious diseases within a hospital setting have been evaluated for strength of evidence by the Hospital Infection Control Practice Advisory Committee of the Centers for Disease Control and Prevention and the Chicago-area Neonatal MRSA Working Group (Newman, 2016). The quality of evidence is rated I, II, or III. The highest quality, I, has one or more randomized trials with clinical outcomes supporting the evidence. Quality II is supported by one or more well-designed, non-randomized, or observational cohort studies with long-term clinical evidence. Quality III evidence is supported by expert opinion. Recommendations are rated A (strong evidence), B (moderate evidence), or C (optional based on existing evidence). Categories combine quality and strength of evidence (Table 26.5).

(*continued*)

EVIDENCE-BASED PRACTICE BOX (*continued*)

TABLE 26.5

EVIDENCE-BASED INFECTION CONTROL PRACTICES

Category	Infection Control Practice
IA	Hand hygiene (including periodic monitoring)
IA	Isolation of culture-positive patients
IA	Environmental support (bedside alcohol-based cleanser, adequate room/space for isolation, isolation supplies, environmental cleaning practices)
IA	Administrative support (organize data and reporting, adequate staffing)
IB	Contact isolation precautions
IB	Surveillance—scheduled screening for colonization
IB	Consider strain identification (molecular analysis)
IB	Infectious disease consultation
IB	For epidemics, consider halting admissions to unit until current patients are discharged
IC	Decolonization (previously categorized as IB, but mixed results as far as effectiveness and feasibility in neonates warrant a change in category)
II	Cohort patients (dedicated staff to care for colonized patients)
II	Education/training for all healthcare providers
II	Administrative and fiscal support
II	Communication system within hospital, community, nation, and global when indicated (reporting system). Report cases as per state regulations
II	Data collection (monitoring) and analysis—angiobiograms, trend recognition

Source: Adapted from Table 2 "Centers for Disease Control and Prevention/HICPAC MRSA Management" and Table 3 "Recommendations for Surveillance, Isolation, Cohorting, and Communication" in Newman, K. M. (2016). Surveillance and isolation of methicillin-resistant *Staphylococcus aureus* colonization in the neonatal intensive care unit. *Advances in Neonatal Care, 16*(4), 301, 303, 304. doi:10.1097/ANC.0000000000000312

CASE STUDY

Identification of the Problem. Baby Q is a 3,100 g 40-week gestation female infant whose mother resided in a country with known Zika virus-infected mosquitoes. She had a head circumference in the 3rd to 10th percentile but otherwise presented with a normal examination. She initially passed a routine hearing screen (otoacoustic emission), but per protocol for Zika-exposure was tested using an automated ABR screen which did not pass on the left ear.

Assessment: History and Physical Examination. The mother received the majority of her prenatal care in the Dominican Republic, then New Jersey during the last trimester. She transferred care to a practice in Rhode Island 2 weeks prior to delivery with incomplete obstetric records. She was a 20-year-old G3 P1 Hispanic woman. She reported a benign medical history. There was a verbal report of a negative Zika test, but no physical copy of the labwork. Her prenatal labwork included blood type A positive, antibody screen negative, rapid plasma reagin unknown (test sent on admission—non-reactive), rubella unknown (test sent—negative),

hepatitis B and C negative, HIV negative, and group B *Streptococcus* positive. She denied toxic habits. Her urine toxicology screen came back negative. Mother presented in labor with intact membranes and was delivered by repeat cesarean section. Membranes were ruptured artificially at delivery—fluid was clear. At delivery, infant was vigorous and required no resuscitation. APGAR scores were 8 at 1 minute and 9 at 5 minutes.

On admission, the infant's weight was 3,100 g (10th–25th percentile), length was 51 cm (25th–50th percentile), and head circumference was 33 cm (3rd–10th percentile). Vital signs were within normal limits. She was alert, active, with normal tone. She did not have obvious microcephaly or an abnormally shaped head. Her fontanels were open, soft, and flat. Sutures were mobile. Her eyes were in alignment with ears and normally shaped. Her nares were patent and palate intact. The neck was supple and without abnormal masses. Her clavicles were intact and without crepitus. The chest was symmetrical, breath sounds were clear and equal, and there were no retractions. She had a grade II/VI systolic murmur auscultated at the left sternal border which was resolved in 24 hours. Her femoral and peripheral pulses were 2+ equal. The abdomen was soft, non-tender, and without abnormal mass or organomegaly. She had normal female genitalia and a patent anus. Her hip examination was normal, and she had normal upper and lower extremities. There were normal grasp and suck and a symmetrical Moro response.

During her hospitalization, the infant was breastfeeding well, voiding, and stooling. She remained in the normal newborn nursery. She received hepatitis B vaccine. The infant passed the critical congenital heart disease screen. Discharge occurred on the fourth day of life.

■ Differential Diagnosis

- Hearing deficit of unknown origin
- Mechanical functions limiting passage of hearing screen (such as canal blockage with vernix, equipment failure)
- Zika virus infection with hearing loss

■ Diagnostic Tests

- Urine PCR for Zika
- Serum Zika IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA)
- Serum Zika RNA
- Urine toxicology screen (sent for lack of maternal obstetric records)
- Newborn metabolic screen

Working Diagnosis. The urine PCR was positive for Zika. The serum Zika MAC-ELISA IgM was negative. However, Zika RNA was detected using the rRT-PCR Triaplex PCR assay. The working diagnosis was CZS as a possible cause of hearing deficit.

Development of Management Plan. Diagnosis of CZS required a multidisciplinary approach. A referral was made to audiology for a diagnostic brainstem auditory evoked response (BAER), with plans to involve an ear nose throat (ENT) specialist for potential hearing aids or cochlear implants if needed. A neurologist was consulted, and an MRI was ordered. A cardiologist was consulted, and an echocardiogram was ordered. The team requested a consult with an ophthalmologist, who performed an eye examination. A referral was made to early intervention. The private pediatrician was informed of all findings and recommended follow-up.

Implementation and Evaluation of Effectiveness. The MRI revealed normal anatomy with no evidence of microcephaly or abnormal development. The eye examination was normal. The echocardiogram showed normal anatomy and cardiac function. The pediatrician monitored for possible future development of microcephaly. By 3 months, the infant developed feeding difficulties, dusky episodes with feeding, noisy breathing, and stridor. A swallow study demonstrated dysphagia with coughing episodes triggered. The ENT specialist re-evaluated and found that the infant had laryngomalacia. Prevacid and Zantac were ordered for gastroesophageal reflux. Sleep apnea was also documented. Despite the feeding difficulties, at 14 months she weighed 11.3 kg (91st percentile), had a length of 83 cm (98th percentile), and had a head circumference of 45.6 cm (52nd percentile). This case demonstrated the subtle changes that can occur with CZS and need for ongoing monitoring and evaluation.

QUALITY ASSESSMENT AND QUALITY IMPROVEMENT ACTIVITY BOX

Situational Awareness of Emerging Infections in the Perinatal Population

Preparing for emerging infections:

In 2017, the American Academy of Pediatrics Committee on the Fetus and Newborn published a clinical report on disaster preparedness in the NICU (Barfield, Krug, AAP Committee on Fetus and Newborn, & AAP Disaster Preparedness Advisory Council, 2017). This report addressed possible natural and industrial disasters, including pandemic infectious disease and the possibility of a bioterrorist event. Pregnant women and infants are seen as particularly vulnerable to infectious outbreak or attack. This is due to alterations in immune function and lack of information in these populations. Some biologic agents (plague, smallpox, radioactive agents) target dividing cells, making infants particularly at risk (Barfield et al., 2017). Both this clinical report and the *Guidelines of Perinatal Care*, Eighth Edition (Kilpatrick, Papile, & Macones, 2017) provide a list of suggested online and continuously updated resources to be used in case of an infectious event that should be referenced in planning.

Each NICU, hospital, community, state, and region should develop a program for awareness of local infections and a plan for responses. While many hospitals have disaster plans that include memoranda of understanding for the care and transfer of adults, not all address pediatric patients (Barfield et al., 2017). This could have significant consequences in the event of a pandemic or bioterrorism event. Disaster plans should be local, collaborative, and require regular review and education. Table 26.6 includes a list of potential quality metrics and activities for use in disaster planning.

(*continued*)

QUALITY ASSESSMENT AND QUALITY IMPROVEMENT ACTIVITY BOX (*continued*)

TABLE 26.6

POTENTIAL QUALITY METRICS AND ACTIVITIES RELATED TO EMERGING INFECTIONS

Awareness and evaluation of risk	• Does maternal history taking include history of recent travel? • Does maternal history taking and care include screening for signs of infection? • Is there a mechanism for sharing maternal infectious risks with neonatal providers? • Does the NICU have a program for periodic review of local pathogens? • Is the unit compliant with CDC infection prevention guidelines such as handwashing audits? • Does the unit perform audits of isolation technique? Drills? • Are nursing and medical staff aware of local, national, and international guidelines and resources available to guide the evaluation, treatment, and prevention of spread of infectious disease?
Planning	• Does the institution/unit have a plan for emergency preparedness that includes an infectious pathogen plan? • Does the plan include care of the mother–infant dyad and for the provision of maternal breast milk whenever possible? • Is there budget to support supplies needed for emergency planning? • Is simulation available and used to prepare for emergency planning and isolation technique? • Does planning include collaboration with local and regional facilities in the event of large-scale evacuation?

CHAPTER 27

Newborn or Infant Transplant Patient

Kathleen P. Juco-Purdy

INTRODUCTION

Transplantation is not a common procedure in the neonatal period. The ability to perform various transplants has risen as technology has improved and knowledge of the physical processes has increased. Solid organ transplants such as liver, kidney, and heart are the most usual procedures. Use of stem cells is an exciting prospect for treating many limiting and sometimes fatal congenital diseases, but this therapy is surrounded by controversy regarding the ethics of its use. The ethics of transplantation in general is muddled when a child's life is at stake. However, it is not always in the infant's best interest to do these procedures.

Transplantation has become a reliable solution to infants suffering from end-stage organ disease. The ability to perform transplants has risen in the last decade due to policy changes, improved surgical techniques, improved donor allocation system, and development in the preservation of organs. Based on the National Data Report of the Organ Procurement and Transplantation Network (OPTN, 2019a), the number of transplanted organs in infants less than 1 year of age is 8,415. These are transplants performed in the United States from January 1, 1988 to April 30, 2019. In patients less than 1 year of age, the organs most often transplanted are the liver, heart, and intestine, with 4,758, 2,928, and 311 cases, respectively (OPTN, 2019a).

The success and outcome of the transplantation is a concerted effort from multiple disciplines and processes. It involves the early detection, accurate diagnosis and management of care, pretransplant evaluation and management, listing and finding the right donor, and intraoperative and posttransplant management. In this chapter, common types of transplants are discussed. Procurement of organs and cells is addressed. The procedure descriptions are meant to provide an overview. Key points to remember when working with infants and families undergoing transplants are the following:

- Infants are the most vulnerable transplant candidates. Great care and attention from multiple healthcare providers will determine the outcome of the transplant.
- Transplant nurses play an important role in solid organ transplantation.
- ABO blood type verification or ABO verification is for patient safety and it is strictly regulated.
- ABO incompatible transplants are proven to have good results in neonates or infant transplant recipients.
- Neonatal organ donation is becoming a viable solution to donor organ shortage.

LIVER TRANSPLANTATION IN INFANTS AND CHILDREN

Liver transplantation in recent years has become a viable solution to many destructive liver diseases. In infants and small children, especially those weighing less than 15 lb, a liver from a larger donor is "trimmed" to fit the small recipient. This has reduced the wait for an ideal matching donor. The technique is applied in living-related liver transplants when a segment of liver from a relative is removed and transplanted into the recipient. By using reduced-size and related donors, mortality has been reduced to as little as 4% in some transplant centers. Increase in survival has been coupled by reduced stay and a greater number of transplants being done for infants and children.

According to the OPTN and Scientific Registry of Transplant Recipients (SRTR) Annual Data Report 2010, the median number of months waiting for a liver-alone transplant for all blood types in pediatric recipients was 2.6 in 2009 (U.S. Department of Health & Human Services, 2017). The median waiting time for patients less than 1 year of age, listed from 2011 to 2014, is 119 days, whereas the median waiting time for patients 1 to 5 years of age, listed from 2011 to 2014, is 113 days (OPTN, 2018). Pretransplant mortality declined for patients wait-listed for a liver-alone transplant from 14.4 deaths per 100 wait-list years in 1998 to 8.2 in 2008. Patients on the waiting list aged younger than 6 years have the highest death rate, but this improved from 23.2 deaths per 100 wait-list years in 1998 to 14.9 in 2008. The number of deceased donor liver transplants has remained steady, while the number of living donor transplants decreased from a peak of 120 in 2000 to 51 in 2009. The rate of pediatric liver transplant has increased since 2002 to the current rate of 83.1 transplants per 100 patient-years on the waiting list. Patients aged 1 to 5 years are the most common recipients. Whites accounted for more than half of recipients. The most common etiology of liver disease was cholestatic disease. Among children and adolescents who underwent transplant in 2007 to 2009, 58% were on the waiting list for 60 days or less. Fifteen percent of patients were Status 1A at transplant, and 29% had a

model for end-stage liver disease (MELD)/pediatric end-stage liver disease (PELD) score of 30 or higher. Sixty-four percent of patients received a whole liver. Among living donor liver transplants, 72% were from related donors in 2009. Only a small number of transplants were from donation after cardiac death (DCD) donors.

According to the SRTR and OPTN 2016 Annual Report published in 2018 (Kim et al., 2018; OPTN & SRTR, 2018), patients less than 1 year of age remain the third most transplanted patients in the pediatric age group for liver transplantation. In 2016, there were over 700 new pediatric candidates added to the wait-list with the highest number in ages 1 to 5 years and 11 years and older (OPTN & SRTR, 2018). The median waiting time for patients less than 1 year of age, listed from 2011 to 2014, is 119 days, while the median waiting time for patients 1 to 5 years of age, listed during the same time period, is 113 days according to the OPTN Competing Risk Median Waiting Time to Decrease Donor Transplant for Registrations Listed: 2003 to 2014 based on OPTN data as of May 10, 2019 (OPTN, 2019a).

INDICATIONS FOR LIVER TRANSPLANTATION

According to Bucuvalas and Feng (2014), the data from the Studies of Pediatric Liver Transplantation (SPLIT) Registry shows that "biliary atresia is the most common underlying condition for liver transplantation, accounting for approximately 37% of the cases. Acute liver failure, retransplantation, and primary liver tumors including hepatoblastoma account for 13.5%, 10%, and 9% of transplants, respectively. Approximately 21.5% of the pediatric liver transplants are performed for inherited gene defects that can be categorized into (1) disorders of cholestasis (4.5%), (2) disorders of metabolism refractory to medical therapy, without cirrhosis (6%), and (3) disorders of metabolism that lead to structural liver injury (11%). The remaining cases comprise a heterogenous group of chronic conditions including cryptogenic cirrhosis, autoimmune hepatitis, sclerosing cholangitis, and mitochondrial hepatopathy. Disease recurrence is rare, occurring only in patients with autoimmune disease and in a subset of recipients with inherited disorders of cholestasis (Jara et al., 2009). As a result, liver disease distribution differs distinctly between children and adults as the latter is dominated by hepatitis C cirrhosis, alcoholic and nonalcoholic steatohepatitis, and hepatocellular carcinoma (Bucuvalas & Feng, 2014, p. 1390).

Etiology

"Acute liver failure is a severe hepatic dysfunction occurring within 8 weeks of onset of illness, with no known underlying chronic liver disease in patients from birth through 17 years of age with a liver-based coagulopathy (not corrected with vitamin K) with an INR ≥1.5 or PT ≥15 seconds in patients with encephalopathy or an INR ≥2.0 or PT ≥20 seconds in patients without encephalopathy" (Berquist et al., 2014, p. 5).

In neonates, acute liver failure (ALF) is a rare but often fatal event. Infants and younger children do not display the main symptom of ALF, hepatic encephalopathy, as do adults and older children. It is hard to diagnose and prove. Causes of ALF include congenital malformations, metabolic liver disease, hepatotoxins, idiopathic liver failure, malignant and benign neoplasms of the liver, infections, ischemic injury, congenital vascular or heart anomalies, and drugs.

Recognition of liver disease in a newborn is difficult because biochemical findings, such as hyperbilirubinemia and coagulopathy, may be due to various physiologic and pathophysiologic processes:

1. Hepatic encephalopathy is difficult to identify in any infant and almost impossible to distinguish from other metabolic encephalopathies in an ill neonate, especially if the infant requires ventilation support.
2. Because infants are so young, all neonatal liver failure tends to be labeled as "acute," which is consistent with the adult definition of a duration of less than 8 weeks. However, some infants clearly have liver failure from end-stage liver disease with cirrhosis due to liver damage that occurred during gestation (Jackson & Roberts, 2001). See Table 27.1 for examples.

Biliary Atresia

A progressive inflammatory process beginning shortly after birth is the hallmark of biliary atresia. Extrahepatic biliary atresia is the most common form. Biliary atresia occurs in 1 in 15,000 live births. The cause of the disease is unknown, but about 10% of the cases have other associated congenital defects of heart, blood vessels, intestine, and/or spleen involvement.

The Kasai procedure or Roux-en-Y hepatoportojejunostomy is the treatment for biliary atresia. Of newborns under 3 months of age undergoing this procedure, 80% will have reestablishment of their bile flow. The 20% remaining infants will not be helped by the procedure. A liver transplant is their only other treatment option (Esquivel, 2005).

Errors of Metabolism

Inherited errors of metabolism contribute greatly to liver failure and must be diagnosed promptly in the neonatal period. Galactosemia, hereditary fructose intolerance, and tyrosinemia are the most common metabolic diseases. Newborn screening by tandem mass spectrometry in many states tests for many metabolic diseases. These infants are being identified at a much earlier age than in previous years and treated when possible. An associated metabolic disease with acute liver disease is neonatal hemochromatosis

TABLE 27.1

CONDITIONS IN-UTERO POTENTIALLY LEADING TO LIVER DAMAGE

Tyrosinemia	*Fumarylacetoacetate hydrolase* deficiency	Autosomal recessive	OLT for fulminant neonatal form or OLT at about 2 years to avoid hepatocellular carcinoma
Urea cycle defects	*Ornithine transcarbamylase* deficiency *Carbamoyl phosphate synthetase* deficiency *Argininosuccinate synthetase* deficiency	X-linked dominant Autosomal recessive Autosomal recessive	OLT may be needed in the neonatal period to prevent irreversible CNS damage Variants may present in later childhood

CNS, central nervous system; OTP, orthotopic liver transplantation.

(NH). It is the most common cause of liver failure in infancy, linked with massive intrahepatic and extrahepatic iron disposition sparing the reticuloendothelial system (Dhawan & Mieli-Vergani, 2005). Despite chelation therapy, many severely affected infants will require transplantation.

"Biliary atresia is the number one indication of liver transplants in infants. However, primary transplantation without portoenterostomy is not recommended in patients with biliary atresia unless the diagnosis is made at an age greater than 120 days and a liver biopsy shows advanced cirrhosis" (Tiao, 2014, p. 1306).

"The pathogenesis of biliary atresia remains obscure despite numerous etiologic theories and investigations. It has been suggested that the disease is caused by (a) a failure of recanalization, (b) genetic factors, (c) defective morphogenesis, (d) ischemia/vascular lesions, (e) viruses, or (f) toxins. Currently, the most intriguing theory is that biliary atresia is the end result of 1 or more of these insults that then cause the biliary epithelium to become 'upregulated' to express the antigen on the cell surface" (Jones & Karrer, 2014, p. 710).

According to the Liver Kaplan-Meier Graft Survival Rates for Transplants Performed: 2008 to 2015 (OPTN, 2019a), recipients diagnosed with biliary atresia have a 737 functioning/alive graft 1-year post transplant, with a survival rate of 91.3% and a 89.2%, 93.1%, 95% confidence interval.

The indications for liver transplantation for children with metabolic liver disease according to the OPTN are alpha-1 antitrypsin deficiency A-1-A, Wilson's disease, hemochromatosis-hemosiderosis; metabolic disease: other specify, tyrosinemia, primary oxalosis/oxaluria-hyper, glycogen storage disease type IV (GSD-IV), glycogen storage disease type I (GSD-I), hyperlipidemia-II-homozygous Hy (OPTN, n.d.).

"The decision to perform liver transplant in patients diagnosed with metabolic disease causing structural liver damage is based on the PELD score, medical urgency and the survival benefit. In patients without structural damage, the aim is to prevent damage to extra hepatic organ(s) occurring consequent to the gene defect" (Bucuvalas & Feng, 2014, p. 1391).

CONTRAINDICATIONS FOR LIVER TRANSPLANTATION

There are many contraindications or reasons why transplantation should not be performed: (1) positive test for AIDS or HIV, (2) cancer outside the liver, (3) infection outside the liver, (4) technical infeasibility, and (5) other medical problems such as heart disease, lung failure, or epilepsy that would interfere with the success of the transplant (Esquivel, 2005).

"The contraindications to transplant include: (1) Primary unresectable extrahepatic malignancy, (2) progressive terminal nonhepatic disease, (3) uncontrolled systemic sepsis, and (4) irreversible neurologic injury. Relative contraindications to transplantation that must be individually evaluated include: (1) serology positive for HIV, (2) advanced or partially treated systemic infections, and (3) severe psychosocial abnormalities" (Tiao, 2014, p. 1308).

TRANSPLANT SELECTION

The advent of partial liver transplant and the use of living liver donors has eased transplant selection. Not all patients can receive a transplant. A liver function test based on the hepatic conversion of lidocaine to monoethylglycinexylidide (MEGX) can give prognostic information. This test has been used because of its rapid turnaround for real-time assessment of hepatic function in transplantation. The MEGX test is a useful tool that can improve the decision-making process with respect to the selection of transplant candidates. Patients with a MEGX 15- or 30-minute test value less than 10 mcg/L have a particularly poor 1-year survival rate. Serial monitoring of liver graft recipients early after transplantation with the MEGX test may initially alert the clinician to a major change in liver function; if used with other tests, such as serum hyaluronic acid concentrations, it may become more discriminatory. In critically ill patients, several studies have shown that an initially rapid decrease in MEGX test values is associated with an enhanced risk for the development of multiple organ dysfunction syndromes and a poor outcome. Further, this decrease appears to be associated with an enhanced systemic inflammatory response (Oellerich & Armstrong, 2001).

"Each liver transplant candidate is assigned a score that reflects the probability of death within a 3-month period as determined by the Model for End-Stage Liver Disease (MELD) scoring system or the Pediatric End Stage Liver Disease (PELD) scoring system. Liver candidates can also be assigned a priority status if the candidate meets the requirements for that status" (OPTN, 2019, p. 147).

"Liver candidates less than 18 years old at the time of registration may be assigned *any* of the following:

- Pediatric status 1A
- Pediatric status 1B
- Calculated MELD or PELD score
- Exception MELD or PELD score
- Inactive status" (OPTN, 2019, p. 147).

A pediatric Status 1A is assigned if the candidate meets the criteria defined by OPTN Policy 9.1.A. A candidate must be less than 18 years old and have one of the following conditions: (1) Fulminant liver failure without pre-existing liver disease, defined as the onset of hepatic encephalopathy within 56 days of the first signs and symptoms of liver disease, (2) Primary non-function of a transplanted liver within 7 days of transplant, (3) Hepatic artery thrombosis (HAT), and (4) Acute decompensated Wilson's disease" (see OPTN Policies for complete data; OPTN, 2019b).

Patients who do not meet the criteria for pediatric Status 1A or whose MELD/PELD score does not coincide with the severe condition presented but meets the criteria specified by OPTN Policy 9.3.C are eligible for MELD or PELD score exceptions. The Specific Standardized MELD/PELD exceptions are (1) cholangiocarcinoma, (2) cystic fibrosis, (3) familial amyloid polyneuropathy (FAP), (4) hepatic artery thrombosis (HAT), (5) hepatocellular carcinoma (HCC), (6) hepatopulmonary syndrome (HPS), (7) metabolic disease, (8) portopulmonary hypertension, and (9) primary hyperoxaluria (OPTN, 2019b, Table 9.2; see Policy 9.3.C for complete data.)

For purposes of Status 1A/1B definition and classification, candidates listed at less than 18 years of age who remain on or have returned to the waiting list on or after reaching age 18 may be considered Status 1A/1B and shall qualify for other pediatric classifications under the following criteria. There are five allowable diagnostic groups: (i) fulminant liver failure; (ii) primary nonfunction; (iii) hepatic artery thrombosis; (iv) acute decompensated Wilson's disease; and (v) chronic liver disease. Candidates meeting criteria (i), (ii), (iii), or (iv) may be listed as a Status 1A; those meeting criteria (v) may be listed as a Status 1B.

ESTIMATION SCALES OF LIVER ALLOCATION

The MELD and PELD are numerical scales that are currently used for liver allocation. The MELD and PELD scores are based on a patient's risk of dying while waiting for a liver transplant and are

based on objective and verifiable medical data. United Network for Organ Sharing (UNOS, 2005) uses the PELD for patients who are under 12 years old. The PELD score is calculated using the following:

Albumin (g/dL)
Bilirubin (mg/dL)
International normalized ratio (INR)
Growth failure (based on gender, height and weight ratio)
Age at listing

PRETRANSPLANT MANAGEMENT

The care of infants and children before transplantation is significant in the outcome of the transplant. "In order for a pediatric candidate to be medically and psychosocially optimized at the time of transplantation, the transplant team must develop processes to (1) address patient and family education; (2) maximize access to suitable organ, living or deceased; (3) optimize nutritional status; (4) prevent infection; and (5) prevent and/or treat complications of portal hypertension" (Bucuvalas & Feng, 2014, p. 1392).

Quality and Safety: Management of infants and children before the transplant is paramount for success. So-called spiffing up to improve the clinical status of the patient before surgery could include normalizing electrolyte imbalances, improving nutrition, decreasing ascites and edema, improving diuresis, and giving blood transfusions if indicated. Infants and children who have severe renal insufficiency are placed on continuous venovenous hemofiltration (CVVH) or continuous venovenous hemodialysis (CVVHD) and brought to the operating room with the CVVH machine.

Nutritional Support

The nutritional status of infants and children prior to and after transplantation is significant in the success of the transplant. According to Bucuvalas and Feng (2014), children who are able to achieve an optimal nutritional status have lesser complications post transplant (Bucuvalas & Feng, 2014, p. 1392). Nutrition is best achieved enterally. Effective enteral administration is not always possible with patients with liver failure because of impaired absorption. Total parenteral nutrition (TPN) may be needed to support hepatocellular function and improve altered metabolism and absorption. A thorough assessment of nutritional status can be difficult because of metabolic disturbances. The balanced dietary approach moderated to replenishment of substrates and calories as needed helps prevent complications. Protein is needed to maintain lean body mass and preserve organ function (Pomposelli & Burns, 2002).

Based on the data from the SPLIT Registry, 40% of transplant candidates less than 2 years old are more than 2 standard deviations below norms for growth at time of transplant (Buculavas & Feng, 2014, p. 1392).

PRETRANSPLANT EVALUATION

During the pretransplant evaluation, the recipient's immunizations should be updated. Since the recipient's response to vaccinations may be suboptimal, it is recommended that vaccination should be given as soon as possible (Kline, 2014).

Recommended vaccinations:

1. Inactivated polio virus
2. Tetanus-diphtheria toxoid
3. Influenza (yearly)
4. Pneumococcal
5. Varicella (if nonimmune)
6. Hepatitis B
7. Hepatitis A (if nonimmune)
8. Haemophilus influenzae type b (pediatric candidates)
9. Measles–mumps–rubella (pediatric candidates)
10. Meningococcal vaccine (particularly for patients entering college within the next 1–2 years; Hockenberry-Eaton, 1998, p. 137)

"Pediatric candidates . . . must wait at least 4 weeks between administration of live vaccines and transplant procedure for *all* adult and pediatric candidates" (Dumas-Hicks, Fitzmorris, Cassidy, & Canales, 2017, p. 132).

PREPARING THE PATIENT FOR THE OPERATING ROOM (OR)

Infants and small children transplant candidates are either already admitted in the intensive care unit or in surgical–medical units for evaluation and workup. Transplant centers or hospitals have their own pretransplant protocols. The checklist may include but is not limited to the following:

a. Laboratory panels
b. Transfusion orders
c. Diagnostic imaging
d. Biopsy
e. Preoperative orders such as nothing by mouth, preoperative bath, and chlorhexidine gluconate (CHG) wipes, as well as induction of immunosuppressive agents
f. Consent and updated history and physical

Most transplant recipients are admitted in the ICU, but in some cases patients are at home waiting or in a nearby housing facility. For patients who are already admitted, the hospital pretransplant protocol or checklist is initiated. The checklist would include but is not limited to the following:

a. Laboratory panels
b. Transfusion orders
c. Immunosuppressant drugs and antibiotics are ordered to go to OR
d. Patient is kept NPO
e. Verification of consent and updated history and physical
f. Preoperative bath given and CHG wipe prior to transport to the OR

For outpatients, the transplant coordinator contacts the family when a donor organ becomes available. The patient is then brought to the hospital, and on admission, the inpatient pretransplant checklist is initiated.

Nursing Care in the Operating Room

The circulating transplant nurse has a unique role in the OR. The nurse provides education to families and transplant patients in the preoperative setting and provides direct care to the patient intraoperatively.

Responsibilities of the Circulating Transplant Nurse:

- Provide safe and effective environment
- Assist anesthesia team
- Ensure compliance with UNOS and OPTN regulations, that is, ABO verification
- Track organ ischemia time
- Appropriate tissue and extra vessel handling and storage

Infants and small children require specific care in the OR. One of the many roles of the nurse is to keep the patient thermodynamically stable by maintaining optimum room temperature. Because

the surgery involves a rather wide abdominal incision, the patient will be exposed to extreme temperatures for the entirety of the procedure. A typical liver transplant surgery can last for 10 to 12 hours. Thus, it is imperative that the nurse provides measures to prevent heat loss. One of the many ways to keep infants warm in the OR is to wrap the infant's limbs or extremities in cotton padding and plastic drape. Place a warming device and absorbent padding under the patient and use a radiant heat lamp if possible. Monitor the patient's temperature and provide warm irrigating solutions in the sterile field.

The nurse also helps the anesthesia team by checking blood products and making sure that they are available at all times. Time is crucial in the delivery of blood products to infants and small children in the OR.

Another important role of the nurse is initiating the ABO verification of the intended recipient and donor. The ABO verification of donor organs and intended recipients during the pretransplant and transplant phase has received meticulous and rigorous attention from UNOS, Organ Procurement and Transplantation Network Board, and Center for Medicare and Medicaid Services (CMS) in the last several years. Because organ transplantation is a highly regulated program, the implementation and compliance of ABO verification has a major impact on the existence of said program.

The UNOS/OPTN Board had implemented the following modification to the policies and requirements for ABO verification on June 23, 2016:

- Policy 5.7 Organ Check-in states that the transplant hospital must complete an organ check-in any time an organ is recovered outside the facility where the transplant will take place. The organ check-in must be completed upon arrival at the transplant hospital prior to opening the organ's external transport container.
- Policy 5.8 Pretransplant Verification is the verification of the donor and recipient using source documents as required by OPTN.
- Policy 5.8.A Pretransplant Verification Prior to Organ Receipt states that if the recipient's surgery will begin prior to organ receipt in the OR, the transplant hospital must conduct a pretransplant verification that meets all the current OPTN requirements.
- Policy 5.8.B Pretransplant Verification Upon Organ Receipt states that the transplant hospital must conduct a second verification at the time of organ receipt in the OR, prior to anastomosis and must meet all the current OPTN requirements (OPTN, 2016).

TYPES OF LIVER TRANSPLANTS

"The transplant procedure is carried out through a bilateral subcostal with midline extension incision. Meticulous ligation of portosystemic collaterals and vascularized adhesions is necessary to avoid slow but relentless hemorrhage. Dissection of the hepatic hilum, with provision for division of the hepatic artery and portal vein above their bifurcation, allows maximal recipient vessel length. The bile duct, when present, is divided high in the hilum to preserve the length and vasculature of the distal duct in case it is needed for later reconstruction. Preservation of the Roux-en-Y in biliary atresia patients who have undergone portoenterostomy simplifies biliary reconstruction. . . . In children with serious vascular instability who cannot tolerate caval occlusion or in patients undergoing transplantation using a left lateral segment, 'piggy-back' implantation is required. In this procedure, the recipient vena cava is left intact, and partial caval occlusion allows end-to-side implantation of a donor hepatic vein patch" (Tiao, 2014, p. 1310).

The orthotopic approach requires replacing the recipient liver with the donor liver. After the donor liver is removed, preserved, and packed for transport, it must be transplanted into the recipient within 12 to 18 hours. The surgery begins by removing the diseased liver from the four main blood vessels and other structures that hold it in place in the abdomen. After the recipient's liver is removed, the new healthy donor liver is then connected and blood flow is restored. The final connection is made to the bile duct, a small tube that carries bile made in the liver to the intestines.

Heterotopic Liver Transplantation

In heterotopic liver transplantation, the recipient's liver is left in place and a donor liver is sewn into an ectopic site (UNOS, 2005). The advantage to this transplant is that the patient retains the original liver with the donor liver helping. It is not as common as other types of liver transplantation in recent years.

Reduced-Size Liver Transplantation

In reduced-size liver transplantation, allografts of donor liver are divided into eight pieces, each supplied by a different set of blood vessels. Two of these pieces have been enough to save a patient in liver failure, especially if the patient is a child. It is therefore possible to transplant one liver into at least two patients. Liver tissue grows to accommodate its job so long as there is initially enough of the organ to use. Patients have survived with only 15% to 20% of their original liver, provided the 15% to 20% was healthy (Boudi, 2019).

"When left lateral segment reduced-size grafts are used, the left hepatic vein orifice is anastomosed directly to the anterolateral surface of the infradiaphragmatic IVC (inferior vena cava). The left lateral segment allograft is later fixed when necessary to the undersurface of the diaphragm to prevent torsion and venous obstruction of this anastomosis. Fixation is unnecessary with right/left lobe grafts or with a whole organ" (Tiao, 2014, p. 1310).

Living Donor Transplantation

Living donor liver transplantation (LDLT) is a procedure in which a healthy, living person donates a portion of his or her liver to another person. The feasibility of LDLT was first demonstrated in the United States in 1989. The recipient was a child, who received a segment of his mother's liver. In the pediatric experience, survival of the recipient child and function of the transplanted liver (graft) at 1 year is about 90%. The transplanted liver grows to almost full size within 6 to 8 weeks and begins to function fully.

Based on the OPTN National Data, the number of living donor liver transplants performed in pediatric transplant recipients aged less than 1 yr is 4770 and 6518 for ages 1 to 5 years old., from January 1,1988 to May 31,2019 (OPTN, 2019a; see OPTN National Data for complete data). "In most pediatric cases, the left lateral segment donated from an adult is used as a graft. In situ dissection of the left lateral segment, preserving the donor vascular integrity until the parenchymal division is completed, is undertaken" (Tiao, 2014, p. 1310).

Auxiliary Liver Transplantation

There are three levels of cells in the hepatic lineage that respond to injury: the mature hepatocyte, the ductular "bipolar" progenitor cell, and a putative periductular stem cell. Hepatocytes are numerous and respond rapidly to liver cell loss by one or two cell cycles.

The ductular progenitor cells are less numerous, may proliferate for more cycles than hepatocytes, and are generally considered "bipolar," that is, they can give rise to biliary cells or hepatocytes. Periductular stem cells, although rare in the liver, can proliferate for a long time. Extrahepatic (bone marrow) origin of the periductular stem cells is supported by recent data showing that hepatocytes may express genetic markers of donor hematopoietic cells after bone marrow transplantation.

These different regenerative cells with variations in potential for proliferation and differentiation may provide different sources of cells for liver transplantation: hepatocytes for treatment of acute liver damage, liver progenitor cell lines for liver-directed gene therapy, and bone marrow-derived cells for chronic long-term liver replacement. A limiting factor in the success of liver cell transplantation is the condition of the hepatic microenvironment in which the cells must proliferate and set up housekeeping.

Few liver stem cell transplantations have taken place. Cases of mold and other infections have been associated with liver stem cell transplantations. Further evaluation is warranted before such transplantation is accepted as a therapy in end-stage liver disease.

PORTAL HYPERTENSION

Portal hypertension is abnormally high blood pressure in the portal vein, the primary vein that brings blood from the intestine to the liver. When this vein clots or when the liver develops scar tissue from disease and compresses the vein, the blood pressure in the vein goes up and portal hypertension develops. **Emergency Alert: In most patients, portal hypertension develops regardless of primary disease process with progressive cirrhosis.**

The liver normally filters blood from the abdominal organs. Portal hypertension can prohibit the liver from doing its job by causing the growth of collaterals that connect blood flow from the intestine to the general circulation, bypassing the liver. When this occurs, substances that are normally removed by the liver pass into general circulation. If not treated, portal hypertension can be progressive and cause serious complications. Pharmacologic management with medications such as vasopressin and octreotide has been used for acute portal hypertension. Complications of portal hypertension can include esophageal varices complicated by hemorrhage and hypersplenism. Treatment with endoscopic sclerotherapy has emerged as an effective treatment for bleeding esophageal varices. Sclerotherapy is the ideal, safe, and effective treatment for bleeding esophageal varices; it prevented bleeding in 88.1% of patients after variceal eradication (Zargar et al., 2004). Though rarely used, the Sengstaken–Blakemore tube can achieve direct balloon tamponade of bleeding varices or transthoracic ligation of the bleeding.

Splenectomy is used for older children when hypersplenism and splenic sequestration of blood components is noted (leukopenia, thrombocytopenia, or anemia). In neonates and small children, splenectomy is rarely done as fatal sepsis is a major complication; functional disorders, such as ascites and thrombocytopenia, should be treated with a more conservative approach.

INFECTION

Infants and children are compromised, as their immune system is still developing. End-stage liver disease further decreases their ability to fight off any infections. They are especially vulnerable to infections normally seen during childhood such as colds, flu, and other childhood diseases (e.g., meningitis, otitis media, and pneumonia). Nosocomial exposure in the hospital from invasive procedures (liver biopsy, intravenous [IV] lines) and handling by the healthcare team further jeopardize the patient for infections. Standard precautions must be followed. According to the indications from the Centers for Disease Control and Prevention (CDC), infection can be decreased by as much as half with attention to handwashing, draping for procedures, rubbing IV hubs with alcohol at least 30 seconds before using them, use of disinfectant before invasive events, and discontinuance of lines on a timely basis. Antibiotics are used when indicated by culture and sensitivity.

Vaccinations should be given to infants and children on a routine, scheduled basis when possible. Other immunizations advised before transplantation include hepatitis B, hepatitis A, and influenza for older children. Respiratory syncytial virus (RSV) is the most common cause of bronchiolitis and pneumonia among infants and children under 1 year of age. RSV is highly infectious and almost all babies get it before the age of 2. Palivizumab (Synagis; MedImmune, Gaithersburg, MD) is given for neonates at risk for RSV before transplant on a monthly basis.

POSTTRANSPLANT MANAGEMENT

Posttransplant management would include care given to any postoperative patient. Blood gases, laboratory reports, fluid balance, urinary output (1–2 mL/kg), and IV access are as usual watched closely. Drainage from the liver transplant is closely observed. Dark, black, bloody discharge can mean that the circulation to the transplant is not working and the liver may be dead.

Prophylactic antibiotics are given before, during, and after surgery. Antifungal and anti–herpes virus prophylaxis is also given.

Immunosuppressive Management

Immunosuppressive management usually starts with prednisone in infants and children. The calcineurin inhibitors, cyclosporine and tacrolimus, are also used; they have distinct advantages and drawbacks. It is important to tailor their use to the patient's tolerance. In some patients, the need to ameliorate the adverse effects of tacrolimus may necessitate a switch to cyclosporine-based therapy and vice versa. Some centers use azathioprine as part of an initial cyclosporine immunotherapy program. It is usually discontinued early in the posttransplant period.

Rejection is treated with steroid pulses, steroid recycling, or the monoclonal anti–T cell antibody muromonab-CD3 (Orthoclone OKT3). **Quality and Safety: Daily monitoring of immunosuppressive medications is necessary for proper dose adjustment in infants and children.** Rescue therapy with a cyclosporine microemulsion (Neoral, Novartis Pharmaceuticals Corporation, East Hanover, NJ)–based regimen for transplant patients intolerant of tacrolimus has been evaluated to assess the best method of switching and determining the initial and maintenance doses in children. Transplant centers are evaluating this therapy at present.

Drugs used for immunosuppression have been implicated in causing numerous long-term side effects including nephrotoxicity, glucose intolerance, and hyperlipidemia. Calcineurin inhibitors are known to cause nephrotoxicity, which is of concern in pediatric liver transplant recipients. Almost all patients will require antihypertensive therapy. Posttransplant malignancies are among the most important complications in organ transplantation.

"Rather than using induction to augment overall immunosuppression and reduce rates of acute rejection, induction immunosuppression is now used to facilitate minimization or even complete avoidance of corticosteroids and/or reduction of exposure to calcineurin inhibitors while maintaining stable rates of acute rejection, graft, and patient survival. Currently, induction is administered to

31% of pediatric liver transplant recipients. The dominant choice for induction has been anti-interleukin-2 (IL-2) receptor antibodies, over antithymocyte globulin (Di Filippo, 2005). Historically, two IL-2 receptor antibodies have been available, basiliximab and daclizumab, but the latter is no longer available. In general, the IL-2 receptor antibodies have had an excellent safety profile with no increase in hemodynamic, metabolic, nephrologic, neurologic, infectious or malignant adverse events including post-transplant lymphoproliferative disease" (Bucuvalas & Feng, 2014, p. 1395).

POSTOPERATIVE COMPLICATIONS

Most complications after liver transplantation are heralded by an increase in hepatocellular enzymes, often associated with malaise, fever, leukocytosis, and jaundice. The clinical picture defines hepatic allograft dysfunction, but it does not separate allograft rejection from other allograft complications such as primary nonfunction, bile duct abnormalities, hepatic artery thrombosis, or allograft infection. The use of real-time and Doppler ultrasonography to assess hepatic vasculature and the use of CT and MRI are often necessary. Allograft biopsy is definite when the cause of the graft abnormality is rejection; it can strongly support the diagnosis of viral infection or cholangitis when the characteristic histologic markers and microscopic appearance are seen. Definitive diagnosis of the cause of the allograft dysfunction should precede immunologic manipulation (OPTN, 2012).

POSTTRANSPLANT MANAGEMENT OF COMPLICATIONS

Most patients are taken to the pediatric intensive care unit (PICU), intubated, and monitored for the following:

1. Hypothermia—common in infants due to prolonged exposure of the abdominal viscera during surgery; careful monitoring of patient's body temperature is needed to prevent dysrhythmias, clotting abnormalities, impaired renal function, and delayed wound healing.
2. Hemorrhage—increased blood in Jackson-Pratt drains, increased abdominal girth, oozing from suture line, and change in cardiovascular status will require blood products such as fresh frozen plasma (FFP), platelets, and cryoprecipitate.
3. Fluid and electrolyte imbalance—decreased urine output less than 1 mL/kg/hour may indicate early graft dysfunction or nephrotoxicity; electrolytes monitoring is required every 6 hours.
4. Neurologic status—encephalopathy/ hepatic coma may indicate bad liver; "getting the shakes"—may indicate elevated levels of Prograf.
5. Gastrointestinal status—watch for abdominal distention, rigid or painful abdomen; stool color and consistency.
6. HAT—most common postoperative complication; watch for sudden spike in temperature, abdominal pain with increased liver function tests (LFTs), change in mental status, and biliary leaks.
7. Portal vein thrombosis—presents with variceal bleeding or a slowly enlarging liver or spleen and low platelet count.
8. Biliary leaks—leading cause of morbidity and mortality in children; a change in the color of fluid in the Jackson-Pratt drains noted in the immediate postoperative period; will need surgical intervention.
9. Rejection—early signs include low-grade fever, increased liver enzymes and bilirubin, pain over graft, irritability, and ascites.

"In infants and small children, the challenge is to anastomose very small recipient blood vessels to donor graft. Because of the anatomical features of recipient and donor, the risk for surgical complications in infants and small children is relatively high. The common immediate post-op transplant complications are vascular and biliary complications. The vascular complications involves the main vessels of anastomoses, specifically hepatic artery thrombosis, portal vein stenosis or obstruction and venous outflow obstruction (Bucuvalas & Feng, 2014, p. 1394).

HEART TRANSPLANT

"The first pediatric heart transplant was performed by Kantrowitz and colleagues at the Maimonides Medical Center in Brooklyn, New York on December 6, 1967. Three days prior to the first transplant, Christiaan Barnard performed the first cardiac allotransplantation in South Africa.

Donor organs for infants and small children are still very limited thus increasing time on waiting list. Because of this shortage, the use of ABO incompatible transplants has recently been advocated by the Toronto group for neonatal and infant candidates, since antibodies to the major blood group antigens are not produced until later in infancy" (Webber, 2014, p. 1407). West (2011) concluded in her report that "ABOi (ABO incompatible) heart transplantation has shown to be safe early in childhood and allows improved access to donor organs. ABO-related AMR has been reported only rarely; long-term outcomes are comparable with ABOc (ABO compatible) transplantation. Limits of suitability based on age or other indicators of maturity are still undetermined" (p. 553).

The OPTN Network Heart Allocation Classifications and Ranking Policy includes Eligibility for Intended Blood Group Incompatible Offers for Deceased Donor Hearts (OPTN, 2019b, Policy 6.6.B).

"The candidate will be eligible for intended blood group incompatible heart offers if the candidate meets at least *one* of the following conditions:

1. Candidate is less than one year old at the time of the match run, and meets *both* of the following:
    1. Is registered as status 1A or 1B.
    2. Has reported isohemagglutinin titer information for A or B blood type antigens to the OPTN contractor within the last 30 days.
2. Candidate is at least one year old at the time of the match run, and meets all of the following:
    1. Is registered prior to turning two years old.
    2. Is registered as status 1A or 1B.
    3. Has reported to the OPTN Contractor isohemagglutinin titers less than or equal to 1:16 for A or B blood type antigens from a blood sample collected within the last 30 days. The candidate must not have received treatments that may have reduced isohemagglutinin titers to 1:16 or less within 30 days of when this blood sample was collected" (OPTN, 2019b, p. 110).

Based on the 2016 OPTN/SRTR Annual Data Report (Colvin et al., 2018), 624 new pediatric candidates were added to the heart transplant waiting list, with few at inactive status. At year-end 2016, 367 candidates listed before their 18th birthdays were awaiting heart transplant, 69.8% active. Over the past decade, the number of candidates listed as inactive status decreased from 178 in 2006 to 111 in 2016. The largest pediatric age group on the waiting list in 2016 was 11 to 17 years (34.2%), followed by ages younger than 1 year (27.7%), 1 to 5 years (23.4%), and 6 to 10 years (14.7%). According to the OPTN National Data, there

were 2,928 heart transplants performed in the United States on patients less than 1 year of age from January 1, 1988 to April 30, 2019 (OPTN, 2019a).

With the advent of new surgical techniques, younger and smaller patients are having heart transplants. The availability of organs is limited for small children. Many centers try to wait until the child is larger to accommodate a larger heart. Developmental studies have shown that young infants and children are at risk for growth failure, developmental delays, and serious neurologic sequelae.

INDICATIONS FOR HEART TRANSPLANT

Heart transplantation in infants and small children is usually the only way or the last resort to save a patient's life. The primary indications for heart transplant are dilated cardiomyopathy and complex congenital heart defects. Diagnoses leading to transplantation are age dependent, with congenital heart defects accounting for over half of transplants in the infant age group, and cardiomyopathy accounting for almost two-thirds among adolescents (Webber, 2014, p. 1407).

The Common Causes of Heart Failure

The common causes of heart failure in the newborn period are

a. Fetal–maternal transfusion
b. Myocarditis
c. Cardiomyopathy
d. Anemia of Rh sensitization
e. Fetal and postnatal arrhythmias
    i. Congenital complete heart block
    ii. Supraventricular arrhythmia
f. Birth asphyxia
g. Sepsis
h. Hypoglycemia
i. Hypocalcemia
j. Severe anemia
k. Congenital structural heart defects

The common causes of heart failure during infancy are

a. Structural defects
b. Cardiomyopathy
c. Myocarditis
d. Arrhythmias
e. Renal failure
f. Systemic hypertension
g. Hypothyroidism
h. Adrenal insufficiency

(Seattle Children's Hospital, 2015).

Bridge to Transplant

Heart failure due to congenital defects and organ deterioration affects the entire body. Many patients waiting for a heart transplant are so debilitated that they may not be able to tolerate the surgery. To assist the body and improve the patients' physical status, several modalities are used to help the patient gain strength while awaiting transplant—hence a "bridge to transplant." Devices commonly used for bridge to transplant are the left ventricular–assist device (LVAD), extracorporeal membrane oxygenation (ECMO), and, on a limited basis, the Berlin Heart.

Left Ventricular–Assist Device

The LVAD is an implantable mechanical device to pump blood through the body. It takes over the work of the failing heart. Bridge-to-transplant facilities that have an aggressive approach to implantable LVAD placement may substantially improve the survival rate of patients with postcardiotomy heart failure (Garbade, Bittner, Barten, & Mohr, 2011).

Extracorporeal Membrane Oxygenation

ECMO currently comes in two varieties: venoarterial (VA) and venovenous (VV). VA ECMO takes deoxygenated blood from a central vein or the right atrium, pumps it past the oxygenator, and then returns the oxygenated blood, under pressure, to the arterial side of the circulation (typically, to the aorta). This form of ECMO partially supports the cardiac output as the flow through the ECMO circuit is in addition to the normal cardiac output.

VV ECMO takes blood from a large vein and returns oxygenated blood back to a large vein. VV ECMO does not support the circulation. VA ECMO helps support the cardiac output and delivers higher levels of oxygenation support than does VV ECMO. VA ECMO carries a higher risk of systemic emboli than does VV ECMO. The normalization of left heart filling pressures alleviates pulmonary edema and improves the child's physical status.

Berlin Heart

The Berlin Heart (Berlin Company, Berlin, Germany) has been used for infants and small children who can utilize neither LVAD nor ECMO. Named after the company in Berlin, Germany, that manufactures it, the Berlin Heart is a ventricular-assist device that works by helping the right ventricle of the heart pump blood to the lungs and the left ventricle to pump blood to the rest of the body. The bulk of the Berlin Heart is located outside of the body, with only the pumps connected to the heart emerging from the body. The device is run by a laptop. The Berlin Heart comes in various sizes for a range of patients and is the only mechanical heart small enough to be used in very young children.

Great consideration is taken when determining the right-size donor for an infant or small child recipient. For orthotopic heart transplant, the most common technique is the bicaval anastomosis. "The heart is implanted in a more anatomical position avoiding enlarged atria. A separate end-to-end anastomoses of the caval veins are performed. And a bicaval anastomosis of donor and recipient inferior vena cava (IVC) and superior vena cava (SVC) is performed. The bicaval technique has been further refined by the addition of a bipulmonary vein technique whereby common cuffs of the pulmonary veins are left in place" (Lerret & Stendahl, 2017, p. 741).

PHYSIOLOGY OF THE TRANSPLANTED HEART

The physiology of the transplanted heart is distinctive. Both the recipient and donor atria are present, but function separately, resulting in decreased atrial input. The transplanted heart does not experience angina because of denervation. Low cardiac output can result, as the transplanted heart has no innervation pacing the heartbeat.

Postoperative Management

Care of the heart transplant patient is similar to that for any other cardiac surgery. Good perfusion with adequate gas exchange and hemodynamic stability are goals after transplantation. Normal perfusion is evidenced by normalized blood gases, adequate urinary output, and adequate blood pressure.

Emergency Alert: A major complication from surgery is hemorrhage. This can be due to anticoagulation therapy secondary to end-stage heart disease, reoperation (prior cardiac surgery), and cardiopulmonary bypass during surgery, or clotting related to hepatic congestion secondary to severe right heart failure. The donor heart is smaller than the diseased heart it replaced. This results in the pericardial space acting as a reservoir for blood, resulting in cardiac tamponade. Frequent milking of the chest tubes helps decrease the blood volume in the pericardial space and maintains the patency of the chest tubes.

"Some of the early complications after heart transplant in children include low cardiac output, systemic hypertension, pulmonary hypertension and post-operative tachy- and brady-arrhythmias.

Infections are a leading cause of death and morbidity in the first year following pediatric heart transplantation. Most severe infections occur during the initial hospitalization" (Webber, 2014, pp. 1412–1413). Meticulous care of IV, central lines, arterial lines, dressings, drains, and catheters is observed in the intensive care units to prevent infections.

RENAL TRANSPLANTATION IN INFANTS AND CHILDREN

Renal transplantation in infants and children has been the most successful of all types of transplants. Recent advances in the techniques of dialysis and the management of end-stage renal disease (ESRD) in neonates have allowed many patients with complex urologic or hereditary abnormalities to reach the age and size at which transplantation is possible. These advances have permitted the implementation of renal transplantation, along with dialysis, as a complementary treatment in the care of infants with irreversible renal dysfunction.

Etiology

Acute renal failure in infants is most often the consequence of hemodynamic instability, hypoxia, or malperfusion, resulting in acute tubular necrosis. Most of these infants either recover sufficient function for normal long-term survival or die of multisystem failure. Chronic renal failure is uncommon in infants. Congenital nephrosis, dysplasia/hypoplasia, and other anatomic abnormalities associated with complex urogenital malformations are the common causes of ESRD in infants.

In children younger than 5 years of age with glomerulonephritis, 46% have a congenital cause for ESRD. Lupus nephritis and recurrent pyelonephritis, which are more common in older patients, are uncommon causes of ESRD in the infant. Hereditary causes of renal failure are important to identify in planning the appropriate overall treatment strategy; evaluation of other family members and provision of genetic counseling, when needed, must also be considered. Appropriate identification of the cause of the ESRD also allows assessment of the potential for recurrence within a transplant allograft and consideration of living related–donor transplantation.

"Infants with ESKD (end-stage kidney disease) during the first year of life may suffer neurologic abnormalities. These include alterations in mental function, neurocognitive delay, microcephaly, and involuntary motor phenomena, such as myoclonus, cerebellar ataxia, tremors, seizures, and hypotonia. The pathogenesis is unclear, although aluminum toxicity, uremia, prematurity, hypertensive crises, and dialysis-related seizures have been incriminated" (Chambers, Pearl, & Ettenger, 2017, p. 468).

According to the OPTN National Data, the number of kidney transplants performed in the United States on children less than 1 year of age from January 1, 1988 to April 30, 2019 is 116. The number of children aged 1 to 5 years is impressively higher at 4,552 compared to the younger recipients (OPTN, 2019a).

Based on the 2016 OPTN/SRTR annual report, 917 pediatric candidates were added to the kidney transplant waiting list, 522 (57%) as inactive. The number of prevalent pediatric candidates (listed at age less than 18 years and on the list on December 31 of the given year) has been steadily increasing and reached 1,494 on December 31, 2016. The most common reason for inactive status among newly listed candidates in 2016 was incomplete workup (52.1%), followed by living donor candidate status (16.8%), and too well to need transplant (11.6%). Over the past decade, the age of pediatric candidates on the list at year-end shifted, with an increase in those aged 1 to 5 years (14.9%–24.6%) and a decrease in those aged 11 to 17 years (66.3%–54.3%). Proportions of candidates with congenital anomalies of the kidney and urinary tract (CAKUT) as primary cause of disease increased from 27.8% in 2006 to 37.3% in 2016, and proportions with glomerulonephritis decreased from 12.3% to 7.1%. Most candidates (65.7%) had a calculated panel reactive antibodies (cPRA) of less than 1% (Hart et al., 2018).

"The most common primary diagnosis remain aplastic, hypoplastic, or dysplastic kidney and obstructive uropathy, each present in about 15% of patients. FSGS (focal segmental glomerulosclerosis) is the third most common (12%) and continues to be the most prevalent acquired renal disease" (Chambers et al., 2017, p. 453).

Pretransplant Management

Pretransplant tests are done to evaluate the patient's physical status and also to identify potential problems. The tests help determine whether transplantation is truly the best option and will increase the likelihood of success. Transplant feasibility consists of histocompatibility laboratory tests of tissue typing, panel reactive antibody, cross-match testing, and blood typing.

Dialysis is often used to keep the child stable until a donor is available or the child reaches at least 10 kg (Chambers et al., 2017). "At some centers, transplantation has been successful in children who weighed less than 10 kg and who were younger than 6 months" (Chambers et al., 2017, p. 455).

Kidney Transplant Surgery

Kidney transplantation in very small recipients can be very challenging due to the size of the recipient versus the size of the donor kidney. The size of the graft can impact anastomosis time, ischemia time, and may eventually cause early graft dysfunction. In infants or small children, the placement of the donor graft is done intra-abdominally. The aorta and inferior vena cava are among the vessels most commonly used, as they are larger with higher blood (Chambers et al., 2017).

Dialysis

Dialysis is indicated in infants as in older children if complications of medical management of ESRD occur, namely, hyperkalemia, volume overload, acidosis, intractable hypertension, or uremic symptoms, such as vomiting. Dialysis can be accomplished by hemodialysis or peritoneal dialysis. Dialysis centers can take older children until a transplant is available. In neonates and small children, peritoneal dialysis is frequently utilized because (1) it avoids the multiple transfusions associated with hemodialysis; (2) it allows smoother gradual correction of electrolyte abnormalities, preventing cerebral disequilibrium syndrome in small infants; and (3) it is easier to perform. For long-term peritoneal dialysis, parents are taught how to care for the infant. This allows the parent to take the child home and be a family. The infant is given time to

grow and normalize as much as possible. Glucose and electrolytes can be enhanced via peritoneal dialysis to enhance nutrition.

Nutritional Support

Nutritional support is a primary concern for the renal patient. Growth retardation is a major problem. The cause of this growth disturbance is multifactorial and includes both protein and calorie insufficiency, renal osteodystrophy, aluminum toxicity, acidosis, impaired somatomedin activity, and insulin resistance. A registered dietitian will need to constantly monitor the nutritional needs of the infant and child. The most intense period of growth occurs during the first 2 years of life. Head circumference is the key to monitoring growth, as it follows overall body development. When a child experiences uremia, feeding and nutritional support may be difficult. To promote optimal nutrition, use of enteral feeding tubes is sometimes necessary, especially if dialysis is being used (Chambers et al., 2017).

INTESTINAL TRANSPLANT

According to the OPTN National Data, the number of intestinal transplants performed in the United States on patients less than 1 year of age from the year 1990 to 2019 is 311. The number of patients 1 to 5 years of age is 874 from the year 1990 to 2019 (OPTN, 2019a).

Since 1985, data compiled by the international Intestinal Transplant Registry show that 55 intestinal transplant programs have performed 601 transplants, of which 402 were in children. Although not many infants and children have had intestinal transplants, the numbers are growing.

Intestinal transplantation is an acceptable treatment for patients with intestinal failure according to Centers for Medicare and Medicaid Services (CMS; Reyes, 2014). One-year survival rates are nearly 90% (OPTN, 2019a). For pediatric intestine recipients, 1- and 5-year survival rates are 86.2% and 75.4%, respectively (Smith et al., 2019; U.S. Department of Health & Human Services, 2017).

Intestinal Transplant Considerations

"Intestinal failure (IF) is now defined as the inability of the functional intestinal mass to provide adequate nutrition and hydration to maintain normal growth and development, and to support life. IF (intestinal failure) can occur exclusive of intestinal length" (Mangus & Subbarao, 2013, p. 162).

Patients with poor intestinal function who cannot be maintained on TPN via IV routes are potential candidates for transplantation. In some patients, most of the bowel has been surgically removed to treat the disease, or it became diseased. This produces the short-gut syndrome, which is the most common cause of intestinal failure. For some infants and children, the entire intestine is present, but it is unable to absorb enough fluids and nutrients. Transplantation is a potentially lifesaving option for patients with intestinal failure who cannot tolerate TPN. Because patients' survival rates are better after isolated bowel transplants, this is the preferred type of transplant. Combined intestinal–liver transplants or cluster transplants are options for patients who have developed liver failure on TPN or for patients who have large, local tumors that can only be removed by removing several organs.

Diseases leading to intestinal transplantation include the following:

- Short-gut syndrome caused by volvulus, gastroschisis, trauma, necrotizing enterocolitis (NEC), ischemia, Crohn's disease
- Poor absorption caused by microvillus inclusion, secretory diarrhea, autoimmune enteritis
- Poor motility caused by pseudo-obstruction, aganglionosis (Hirschprung's disease), visceral neuropathy
- Tumor or cancer such as desmoid tumor, familial polyposis (Gardner's disease)
- Congenital intestinal atresia
- Poor intestinal absorption
- Autoimmune disorders
- Brush-border element assembly problems
- Microvillus inclusion disease
- Severe disorders of motility resulting from intestinal pseudo-obstruction (congenital or acquired)
- Gardner's disease (intestinal polyposis)
- Serious complications of TPN therapy
- Thrombosis (blockage due to a blood clot) of two or more major central veins (subclavian, jugular, femoral)
- Repeated episodes of line sepsis or line infections
- The decision to proceed with intestinal transplantation is made only after careful evaluation determines that surgery is the child's most promising treatment option.

Donor Options

Most intestinal grafts come from cadaver donors—people who have been declared dead in a hospital while attached to a ventilator (artificial breathing machine). Consent is given by the next of kin for organ removal and transplant. Occasionally, a portion of the bowel is taken from a living donor—a relative such as a parent or sibling.

The graft used depends on the patient's condition, including the viability of the remaining bowel (Reyes, 2014). For the patient experiencing problems with the liver and intestine, determination of the course of treatment including the surgical procedure such as simultaneous hepatic and intestinal replacement depends on the physical condition of the patient. If portal hypertension is severe, or there are coagulopathy problems, jaundice, and cholestasis then simultaneous transplants may be necessary (Reyes, 2014).

Intestinal Transplant Evaluation

Small intestine transplant evaluation is similar to liver transplant evaluation. It is important that the child has a good history of central-line placement, IV access, upper gastrointestinal studies, number of gastrointestinal resections, and length of bowel to ensure that transplantation is the best medical option.

Studies done for evaluation include the following:

- Blood tests
- Chemistry panel
- Liver panel
- Hematology group
- Coagulation studies
- Blood typing and antibody screen
- Infectious diseases: hepatitis B, hepatitis C, HIV, cytomegalovirus, Epstein–Barr virus
- Imaging studies and other tests
- Ultrasound of the liver in combined intestinal–liver transplants
- CT scan
- MRI to map abdominal vasculature
- Endoscopy (esophagogastroduodenoscopy, EGD)
- Mobility studies
- Colonoscopy
- Liver biopsy for combined liver–intestinal patients to determine whether TPN damage is reversible
- Psychosocial and developmental evaluations
- Social worker
- Child development expert evaluation

If the child is a candidate for intestinal transplantation, his or her name is added to the transplant waiting list for an isolated intestinal transplant or for a combined liver and intestinal transplant based on the severity of organ damage and dysfunction. Transplant waiting lists are maintained by the UNOS (OPTN, 2012).

Postoperative Management

After the procedure, patients are placed on immunosuppressive drugs to prevent rejection of the transplanted organ. The doctors perform biopsies (take tissue samples of the intestine) at various intervals to check for signs of rejection. Rejection may be managed by adding immunosuppressive drugs or increasing dosages. Patients who have received intestinal transplants remain on immunosuppressive drugs indefinitely. Since patients on immunosuppressive drugs are vulnerable to infections by bacteria and viruses, they are monitored for signs and symptoms of infection. Particular attention is paid to wound care issues and fluid management. A multidisciplinary team performs a nutritional assessment to determine the child's caloric needs.

Reyes (2014) states that "endoscopic surveillance of the graft with biopsy remains the gold standard of intestine graft evaluation; this is performed weekly for the first 3 to 4 weeks, then at gradually decreasing frequencies depending on clinical need" (p. 1320).

Enteral feedings are started as soon as possible gradually weaning off TPN (Reyes, 2014). Oral aversion is common. So feeding may be a challenge in this population.

Intestinal Transplantation Survival

Improved antirejection drugs, refined surgical procedures, and a greater understanding of immunology have contributed to successful intestinal transplants. Short-term survival is now comparable to lung transplantation results. Most of the patients in the international Intestinal Transplant Registry have been followed for a brief time; it will take several years to obtain reliable data on long-term results (Intestinal Transplant Registry, 2005).

Until a few years ago, cyclosporine was used most often to prevent organ rejection. Tacrolimus (Prograf, Astellas Pharma US, Deerfield, IL) has been given to most intestinal transplant patients over the past 4 years. As of June 1995, 49% of all intestinal patients had died, usually from sepsis (42%) or multiple organ system failure (30%). Four patients (5%) died of rejection. Of the surviving patients, 78% had stopped TPN and had resumed a normal, oral diet.

To become the standard treatment for intestinal failure, transplantation must offer better survival, better quality of life, and lower costs than TPN. Considerable progress has been made toward these goals, but further refinements are needed before bowel transplantation becomes a routine surgical procedure.

Despite improved immunosuppression, the intestine offers more rejection than other organs.

Rejection of the intestine is also difficult to diagnose, as there are no biochemical (blood) tests to indicate rejection. To prevent intestinal rejection, patients require higher doses of immunosuppression than with other types of transplantation. Now, because of new, more specific antirejection medications, the success of intestinal transplant has improved dramatically (Intestinal Transplant Registry, 2005).

ORGAN PROCUREMENT

Organ procurement is facilitated by the UNOS, a nonprofit, scientific, and educational organization that administers the nation's only OPTN and was established by the U.S. Congress in 1984. Functions of OPTN include the following:

- Collects and manages data about every transplant event occurring in the United States
- Facilitates organ matching and placement process using UNOS-developed data technology and the UNOS Organ Center
- Brings together medical professionals, transplant recipients, and donor families to develop organ transplantation policy

UNOS was awarded the initial OPTN contract on September 30, 1986. UNOS is the only organization to ever manage the OPTN and has continued to administer the contract for more than 16 years and four successive contract renewals (OPTN, 2012).

Waiting List

The OPTN maintains the only national patient waiting list and features the most comprehensive data available in any single field of medicine (OPTN). UNetSM is the web-based electronic utility used by the contractor to conduct the business of OPTN. UNetSM comprises the Match System, all software, applications, and security architecture needed for the collection, modification, validation, reporting, management, and redundancy of data associated with the tasks and activities of the OPTN. The Organ Procurement Organization, having identified a potential organ donor, assumes responsibility for donor management and organ allocation. The Match System is the computerized algorithm used to prioritize candidates waiting for organs. It eliminates potential recipients whose size or ABO type is incompatible with that of a donor, and then ranks those remaining potential recipients according to the ranking system (OPTN, 2012).

The waiting list is the computerized list of candidates waiting to be matched with specific donor organs in hopes of receiving transplants. Candidates are registered on the waiting list by member transplant centers. The candidate's transplant program is responsible for ensuring the accuracy of candidate ABO blood group system data on the waiting list. Each transplant program implements and operates procedures for online verification of a candidate's ABO data on the waiting list against the source documents by an individual. The transplant program maintains records documenting separate verification of the source documents against the entered ABO data. Upon entry of the candidate's wait-list data, the candidate will be added to the wait-list but will not be listed as an active candidate until separate verification of the candidate's ABO data has taken place (OPTN policy 3. 2019).

All transplant candidate interactions will be required to be completed through UNetSM by transplant programs. The Organ Center will facilitate candidate listings and modifications in the event of computer and/or Internet failure. When the Organ Center facilitates a candidate's listing or modification due to computer and/or Internet failure, the transplant center will be required to submit a statement explaining the event.

Each transplant candidate must be ABO typed on two separate occasions prior to listing. Two separate occasions are defined as two samples, taken at different times, sent to the same or different laboratories. Transplant candidates are listed on UNetSM with the candidate's actual blood type (OPTN, 2012).

PEDIATRIC CRITICAL PATHWAY

After brain death has been declared, and consent granted for organ donation, pediatric specialists and organ procurement professionals should work together to care for the organ donor and family members. The UNOS (2005; Table 27.2) describes optimal care for the pediatric organ donor and maps the process to improve the outcome for successful organ transplantation.

TABLE 27.2

CRITICAL PATHWAY FOR DONATION AFTER CARDIAC DEATH

Collaborative Practice	Phase I Identification and Referral	Phase II Preliminary Evaluation	Phase III Family Discussion and Consent	Phase IV Comprehensive Evaluation and Donor Management	Phase V Withdrawal of Support/ Pronouncement of Death/Organ Recovery
The following health care professionals may be involved in the Donation After Cardiac Death (DCD) donation process: Check all that apply: ❍ Physician (MD) ❍ Critical Care RN ❍ Nurse Supervisor ❍ Medical Examiner/ Coroner ❍ Respiratory Therapy (RT) ❍ Laboratory ❍ Pharmacy ❍ Radiology ❍ Anesthesiology ❍ OR/Surgery Staff ❍ Clergy ❍ Social Worker ❍ Organ Procurement Coordinator (OPC) ❍ Organ Procurement Organization (OPO)	Prior to withdrawing life support, contact local OPO for any patient who fulfills the following criteria: ❍ Devastating neurologic injury and/or other organ failure requiring mechanical ventilatory or circulatory support ❍ Family and/or care giving team initiate conversation about withdrawal of support Following referral, additional evaluation is done collaboratively to determine if death is likely to occur within 1 hour (or within a specified timeframe as determined by care giving team and OPO) following withdrawal of support Patient conditions might include the following: ❍ **Ventilator dependent for respiratory insufficiency:** apneic or severe hypopneic; tachypnea ≥ 30 breaths/ min after DC ventilator ❍ **Dependent on**	Physician ❍ Supportive of withdrawal of care and has communicated grave prognosis to family ❍ Review DCD procedure with OPC ❍ Will be involved in withdrawal/ pronouncement ❍ Will designate a person to be involved with withdrawal and/or pronouncement Family ❍ Has received grave prognosis ❍ Understands prognosis ❍ In conjunction with care giving team, decide to withdraw support Patient ❍ Age _____ ❍ Weight _____ ❍ Height _____ ❍ ABO _____ ❍ Medical Hx _____ ❍ Surgical Hx _____ ❍ Social Hx _____ ❍ Death likely < 1 hour following withdrawal (determined collaboratively by	❍ Support services offered to family ❍ OPC/hospital staff approach family about donation options ❍ Legal next-of-kin (NOK) fully informed of donation options and recovery procedures ❍ Legal NOK grants consent for DCD following withdrawal of support ❍ Family offered opportunity to be present during withdrawal of support ❍ OPC obtains _____ Witnessed consent from legal NOK for DCD _____ Signed consent Time _____ Date _____ _____ Detailed med/soc history Notification of donation ❍ Hospital supervisor ❍ ME/coroner notified _____ ME/coroner and releases for donation _____ ME/coroner has restrictions	❍ MD, in collaboration with OPO, implements management guidelines ❍ Establish location and time of withdrawal of support ❍ Review plan for withdrawal to include: – Pronouncing MD (should be in attendance for duration of withdrawal of support, determination of death, and may not be a member of the transplant team) – Comfort care – Extubation and discontinuation of ventilator support – Establish plan for continued supportive care if pt survives > 1 hour or predetermined time interval after withdrawal of support ❍ Notify OR/Anesthesia _____ Review patient's clinical course, withdrawal plan, and potential organ recovery	❍ Withdrawal occurs in _____OR _____ICU _____Other_____ ❍ Family present for withdrawal of support _____ Yes _____ No ❍ OR/room prepared and equipment set up ❍ Transplant team in the OR (not in attendance during withdrawal) ❍ Care giving team present ❍ Administration of preapproved medication (e.g., heparin/Regitine) ❍ **Withdrawal of support according to hospital/MD practice guidelines** **Time** _____ **Date** _____ ❍ **Vital signs are monitored and recorded every minute (see attached sheet)** ❍ **Pt pronounced dead and appropriate documentation completed**

STEM CELL TRANSPLANTATION

Human umbilical cord blood (CB) in recent years has become a source of hematopoietic progenitor cells. These so-called stem cells are used to treat a variety of diseases such as malignancies, hemoglobinopathies, immunodeficiencies, and inborn errors of metabolism.

Umbilical CB was used until recently to assess infants' health status. Otherwise, CB was discarded with all the other biologic tissues of birth: placenta, amniotic fluid, birth sac, and umbilical cord. These biologic tissues have been shown to be useful medically for other purposes. For example, it was found that a specific lung lipid isolated from amniotic fluid could ascertain the lung maturity of the fetus in the last trimester of pregnancy: the lecithin/sphingomyelin ratio.

Physiology

Umbilical CB is extremely rich in stem cells. Stem cells differ from other kinds of cells in the body. Regardless of their source, they have three general properties:

1. They are capable of dividing and renewing themselves for long periods.
2. The cells are unspecialized.
3. They give rise to specialized cells.

There is controversy regarding where stem cells and progenitor cells originate in the yolk sac or aorta-gonad-mesonephros region/intraembryonic splanchnopleural region. Cells move through the fetal liver and then the fetal circulation, where the numbers are high at birth.

In October 1988, the first CB transfusion was performed for a patient with Fanconi anemia: a sibling donor contributed the HLA-matched cells. Since then, several diseases have been treated with stem cells. In a number of genetic, hematologic, and oncologic disorders, infusion of CB can be a potentially lifesaving procedure. Allogenic (related or unrelated) or autologous (self) bone marrow is the usual source of hematopoietic progenitor cells. One child in 2,700 might eventually benefit from an autologous stem cell transplant. Bone marrow is not always readily available. Umbilical CB can be a viable alternative for certain conditions (Table 27.3).

Collection of Cord Blood

CB can be collected from the placenta in situ during the third stage of labor or immediately after delivery of the placenta. About 50% to 70% of donated units are ineligible for storage, mainly because of low volume. Each unit should contain more than 40 mL of CB for a child weighing up to 30 kg. Maximal storage time is unknown, but, under stable conditions, the cells are likely to remain viable for decades.

CB is collected according to directions from the particular bank. In general, the samples are obtained from normal full-term deliveries under orders from the healthcare provider (physician, midwife, or nurse practitioner). Once labor has been established, the nurse will label the tubes, place them in a plastic zip-closure bag, and return them to the kit's Styrofoam box per instructions. The Styrofoam box will then be labeled with time, date, name, and initials of collector. The tops of the heparin vials are cleansed with alcohol and 5 mL is drawn. The heparin is injected into 60-mL syringes. Each syringe is labeled.

After the infant's birth, CB is collected within 10 minutes. It is drawn from the umbilical vein with as much blood as possible. The syringes are inverted back and forth for 1 to 2 minutes to mix the blood and heparin well. The syringes are capped and put into the provided plastic bag. Then they are packaged into the Styrofoam box with the provided absorbent pad. Blood should remain at room temperature to ensure viability of stem cells. CB is not refrigerated. It is usually the families' responsibility to ship the blood in a timely manner to the CB bank.

TABLE 27.3

CONDITIONS FOR WHICH UMBILICAL CORD BLOOD CAN BE A VIABLE ALTERNATIVE

Disease	Indication	Blood Cell Transplantation
Leukemia, lymphomas	Engraftment of healthy cells	Effective
Bone and soft tissue sarcomas, Wilms' tumor, brain tumors	Very rarely indicated	Effectiveness unproven
Hematologic diseases	The new donor cells will produce normal white cells, red cells, and platelets	Effective
Immunodeficiency diseases	Engraftment of healthy allogenic cells	Effective
Hemoglobinopathies	The new donor cells will produce normal white cells, red cells, and platelets	Effective
Metabolic storage disorders	Donor cell will eventually produce the deficient enzyme	Controversial; may be effective in select patients
Genetic conditions	Cells from umbilical cord blood can be isolated, transduced, and engrafted to produce mature hematopoietic and lymphoid cells for at least several years	Effective in select diseases

Cord Blood Banks

Private banks such as the Cord Blood Registry in San Bruno, California, offer collection kits to families. Private banks are companies that are accredited by the American Association of Blood Banks (AABB). Typical fees range from $1,000 to $1,500 for registration and collection. Storage is charged $100 a year, but there are no additional fees for retrieving the cells for use. The costs are borne by the families.

Public cord banks accept collections only from affiliated hospitals. Units stored in them are available for any patient in need who

is medically eligible for transplantation therapy. In the unlikely event that the donor or a member of his family develops an indication for a stem cell transplant, the stored cells could be traced and used. Public CB banks charge no fees for donation, but may charge $15,000 or more if the blood is actually used. The number of public banks is limited.

The American Academy of Pediatrics (Shearer et al., 2017) recommends that institutions or organizations (private or public) involved in CB banking should consider the following recommendations:

- Recruitment practices should be developed with an awareness of the possible emotional vulnerability of pregnant women and their families and friends. Efforts should be made to minimize the effect of this vulnerability on recruitment decisions.
- Accurate information about the potential benefits and limitations of allogenic and autologous CB banking and transplantation should be provided.
- A policy should be developed regarding disclosing to the parents any abnormal findings in the harvested blood.
- Specific permission for maintaining demographic medical information should be obtained, and the potential risks of breaches of confidentiality disclosed.
- Written permission should be obtained during prenatal care, and before the onset of labor. The practice of collecting blood first and obtaining permission afterward is considered unethical and should be discouraged.
- Consultation with the institutional review board or hospital ethics committee about recruitment strategies and the wording of consent forms is recommended.
- CB collection should not be done in complicated deliveries, and the CB stem collection program should not alter routine practice for the timing of umbilical cord clamping.
- Because of the investigational status of CB banking and the high risk for its potential abuse, the regulatory agencies (e.g., U.S. Food and Drug Administration, Federal Trade Commission, state equivalent of these federal agencies) are encouraged to have an active role in providing oversight for the safety and welfare of the population (Ikuta, 2008; Shearer et al., 2017).

Cord Blood Transfusion in Neonate

There are two types of cord stem cell transfusions: frozen and fresh. Each type of transfusion is discussed in regard to considerations, side effects, and nursing care needed for the neonate.

Frozen stem cells are used in autologous (collected from the patient) CB transplants. A preservative, dimethyl sulfoxide (DMSO) is added to the cells just prior to cryopreservation. It acts to coat the cells and prevent their lysis during the process of freezing and thawing. DMSO is infused to the patient with the transfusion of the cells. The garlic-like odor of DMSO is very distinctive and unpleasant. DMSO is excreted primarily through the respiratory system. DMSO is smelled and tasted as soon as it is infused, which can result in the baby having nausea and vomiting. Other side effects commonly seen are bradycardia and shortness of breath. Volume overload can occur as each bag of cells contains 50 to 100 mL. Hypertension may require medication with antihypertensives and diuretics. Giving the transfusion over a 2 to 4–hour time period and in two different sessions may help lessen side effects. A significant reaction to DMSO may occur even without volume overload. The transfusion is thawed to break the ice crystals, so it is advised to keep the infant's environment as thermally neutral as possible with the use of a radiant warmer, isolette, or warm blankets. Monitor the temperature frequently. Stem cells should not be warmed as they may be damaged. After the transfusion, red urine may be seen as some of the cells will be excreted in the urine. Red urine will diminish over time. Hydration should be provided following infusion.

Fresh stem cells are given for allogenic transplants (related or unrelated) within 48 hours of collection. **Emergency Alert: Side effects may include hemolytic transfusion reactions, volume overload, pulmonary microemboli, and infection (as the transfusion is neither irradiated nor filtered).**

Assess the family's understanding of CB transfusion prior to the procedure and provide information and/or education. **Quality and Safety: For either transfusion type, careful monitoring of intake and output, oxygenation saturation, heart and respiratory rates, and blood pressures is warranted.** Vital signs are taken before, during, and after the infusion. Interventions are based on the type of transfusion used (Table 27.4).

TABLE 27.4

POSSIBLE COMPLICATION SEQUENCE FOR CORD BLOOD TRANSFUSION

Immediate	Delayed (First Month)	Late Effects (After First Month)
Nausea/ vomiting	Bone marrow suppression	Immunosuppression
Diarrhea	Mucositis	Chronic graft-versus-host disease
Red urine	Hemorrhagic cystitis	Cataracts
Parotitis	Anorexia	Endocrine dysfunction
Hypertension	Capillary leak syndrome	Pulmonary restrictive disease
Volume overload	Veno-occlusive disease	Genetic disease recurrence
Apnea/ bradycardia	Graft failure	Secondary malignancies
Tachypnea	Graft-versus-host disease	Bacterial infections
Respiratory distress	Acute renal failure	Cytomegalovirus infection
	Bacterial infection	Varicella zoster infection
	Viral infections (herpes simplex, cytomegalovirus)	Latent viral infections
	Fungal infection	*Pneumocystis carinii* pneumonia

Sources: Adapted from Baggott, C., Kelly, K., Fochtman, D., & Foley, G. (Eds.). (2002). *Nursing care of children and adolescents with cancer* (3rd ed.). Philadelphia, PA: Saunders; Hockenberry-Eaton, M. J. (Ed.). (1998). *Essentials of pediatric oncology nursing: A core curriculum.* Glenview, IL: Association of Pediatric Oncology Nurses.

TABLE 27.5

ADVANTAGES AND DISADVANTAGES OF CORD BLOOD TRANSFUSION

Advantages	Disadvantages
1. Easily obtained from cord at delivery of child. Not a good source of progenitor cells.	1. Can only be obtained at delivery if it is matched perfectly. Procedure for obtaining cord blood must be followed exactly. At times, not enough is collected or cannot be collected due to difficult delivery.
2. Can use unmatched cord blood from donors.	2. Need adequate volume of cord blood.
3. Decreased graft-versus-host disease with use of cord blood.	3. Slower engraftment of cells and delayed rebuilding of immune system, depending on hospital criteria for discharge, could mean greater length of stay.
4. Infection risk from blood-borne viruses lessened.	4. At risk longer from infection due to delayed rebuilding of immune system.

Umbilical CB transfusions offer hope to families of infants with various diseases requiring hematopoietic progenitor cells. It is not a common procedure as yet. In neonatal units affiliated with CB banks, study of benefits versus ineffectiveness is occurring. It is still an uncommon procedure that can have far-reaching consequences. Thorough education of the family is required to deal with potential complications associated with stem cell infusion. Neonatal nurses need to be aware of the immediate, delayed, and late effects to give prompt intervention and treatment as needed. Advantages and disadvantages of CB transfusion are listed in Table 27.5.

SUMMARY

In the past decade, transplantation has become more common but is more the exception than the rule. Transplants with solid organs were the mainstay, but stem cell transplants are beginning to be explored. Transplants are a tertiary treatment that is not irreversible. It is the last, best option for many patients. The next few years will change indications for transplant, with earlier treatments and procedures.

CASE STUDY

■ **Identification of Problem.** Late preterm twin female infants born vaginally; presented with lethargy, poor feeding, and weight loss at 3 days of age.

■ **Assessment: History and Physical Examination.** Twin female late preterm infants were delivered vaginally to a 28-year-old G2 P2 woman after an uncomplicated pregnancy. Infants were 36 weeks' postmenstrual age with twin A's birth weight of 2.8 kg and twin B's birth weight of 2.7 kg. Twin A had Apgars of 9^1 9^5 and twin B had Apgars of 8^1 9^5. Admission to the NICU. Both infants had a gross normal physical examination upon admission. As late preterm infants, they had temperature instability requiring warming in isolettes. They are poor nipplers who require gavage feeds.

■ **Second Day of Life.** Newborn screens were sent on the second day of life. Screens are sent overnight for spectronomy.

■ **Differential Diagnosis**
1. Late preterm twins
2. Hypothermia
3. Feeding difficulties

■ **Diagnostic Tests.** Newborn screens

■ **Working Diagnosis.** Late preterm twins

■ **Third Day of Life.** These twins were born in a state that has expanded newborn screens. Expanded newborn screening results by spectronomy revealed a rare genetic disorder of methylmalonic acidemia (MMA). In most states, these twins would have died before a diagnosis of MMA would have been made.

■ **Outcome.** The twins are late preterm infants whose appropriate acting masked their metabolic disorder. Both twins were diagnosed with MMA because of expanded newborn screening, which saved their lives. They were put on a low-protein diet and medications until they were big enough for a liver transplant. Liver transplants were done at 15 months of age. Transplants were done early in life to ward against the toxic effects to the brain, kidney, and other organs. They remain on low-protein diets and medications. By having liver transplants, their chances at a long life have improved greatly.

EVIDENCE-BASED PRACTICE BOX

Expanded Newborn Screening

Universal newborn screening is the practice of screening every newborn for genetic testing. Through early identification and treatment, newborn screening improves care. Primary intervention provides an opportunity for reduction in infant morbidity and mortality.

Expanded newborn screening using tandem mass spectrometry (MS/MS) can detect many genetic diseases. Every year, approximately 4 million infants are screened. Of these screened infants, 12,500 are diagnosed with one of the 29 core conditions of the uniform screening panel (Howell et al., 2012). Hearing loss, primary congenital hypothyroidism, cystic fibrosis, sickle cell disease, and medium-chain acyl-CoA dehydrogenase deficiency are the most common genetic entities detected in the United States. A group of experts was assembled in 2006 by the American College of Medical Genetics under the sponsorship of the Health Resources and Services Administration. These experts standardized tests of the expanded newborn screening for the United States. The new expanded screening panel is composed of 29 core conditions. Within the panel are 20 inborn errors of metabolism, three hemoglobinopathies, and six other conditions (Howell et al., 2012).

Many of the diseases of the expanded newborn screen in the past were not diagnosed until after the child was very ill or died. Diagnosing disease early from the newborn screen can result in treatment before mortality or morbidity occurs. In the case of the twin infants with MMA, they had liver transplants to prevent the devastating effects of the disease. Therrell, Buechner, Lloyd-Puryear, van Dyck, and Mann (2008) noted that several studies provide data for the cost-effectiveness of testing. Each infant with detectable disease leads to primary intervention, which leads to cost savings.

False-positive tests have been explored regarding parental stress and anxiety. It was hypothesized that the false-positive tests would cause undue emotional distress in parents and families. Several studies have addressed the false-positive tests and emotional distress of parents/families and concluded that benefits outweighed the distress (Sun, Lam, & Wong, 2012).

The expanded newborn screen has limitations of not enough experts trained to care for neonates affected by complex rare conditions, laboratory capabilities, and possible false-positive results. Long-term follow-up of test results could answer these limitations. While the expanded newborn screen has helped many infants to be diagnosed and cared for earlier, there is still the question of which ones. Consumers need to be educated and empowered to make informed decisions regarding the tests.

CHAPTER 28

Extremely Low Birth Weight (ELBW) Infant

Abhay Lodha, Jenna L. Dobry, and Shahirose S. Premji

INTRODUCTION

Recent advances in neonatal intensive care unit (NICU) technology and research in this area have improved the survival of extremely preterm infants. The extremely low birth weight (ELBW) infant, one who is born weighing less than 1,000 g, is a frequent resident of most modern NICUs. The survival rate for ELBW infants has improved (Doyle et al., 2011; Kilbride, 2004) as a result of advances in technology, organization of perinatal care (Rozé & Bréart, 2004), and obstetrical interventions (e.g., antenatal corticosteroid use; Kilbride, 2004). Survival rates to hospital discharge range from 26.5% to 87.8% (Guillen et al., 2011); the variations may be explained by strategies used to report rates (i.e., denominator bias) or differences in available resources, particularly in developing countries (Ballot, Chirwa, & Cooper, 2010). Greater survival, however, has not always been associated with increased quality-adjusted survival (Kilbride, 2004). The rate of survival of periviable infants (22–24 weeks' gestation) has improved from 30% to 36% between 2000 and 2011 in a large cohort from 11 centers affiliated with the National Institute of Child Health and Human Development (NICHD) network (Younge et al., 2017). We must strive for better neonatal outcomes of extremely premature infants and propose evidence-based strategies to improve the quality of perinatal, neonatal, and post discharge care with the goal to improve the long-term neurodevelopmental outcomes of ELBW infants (Rozé & Bréart, 2004). This chapter reviews the challenges facing an ELBW infant and its family.

EVIDENCE-BASED NEONATAL NURSING CARE

Over the past 45 years, it has become clear that preterm infants are a heterogeneous population who require very specialized treatment depending on their birth weight (Silverman, 1992). All preterm infants were viewed as "low birth weight or small infants," and their care usually reflected a variation on general pediatric care. The definition of low birth weight (LBW) now includes both ELBW and very low birth weight (VLBW); an infant who is born weighing less than 1,500 g. Whatever the reasons for the ELBW status, these neonates require highly specialized care if they are to survive and thrive. In the 1950s and 1960s, healthcare professionals realized that neonates, especially those who were sick and premature, required care based on an understanding of the pathophysiology of their diseases and identification of rigorously evaluated treatment (Silverman, 1992). Examples such as the development of retinopathy of prematurity (ROP) secondary to the use of unrestricted oxygen therapy and development of kernicterus from the use of sulfisoxazole underscore the importance of evidence-based practice (Silverman, 1992). Moving evidence to practice will be imperative to improving neonatal outcomes (Cumming, Hutchinson, Scott, Norton, & Estabrooks, 2010; Straus, Graham, & Mazmanian, 2006).

IMPACT OF BIRTH OF ELBW INFANTS

Decision Making in the Delivery Room

Appropriate for gestational age (AGA) infants less than 23 weeks' gestation and less than 500 g birth weight are considered too immature to survive based on data collected over the past 10 to 15 years (Seri & Evans, 2008). For example, the EPICure study undertaken in the United Kingdom found that less than 1% of infants born at 22 to 23 weeks' gestation survived and were discharged from the hospital (Costeloe, Hennessy, Gibson, Marlow, & Wilkinson, 2000). In contrast, most infants born greater than or at 25 weeks' gestation and greater than or at 600 g survive, and about half survive without severe long-term disabilities (Seri & Evans, 2008). A single study from Canada revealed that only 4% of infants born less than 500 g survived, all survived infants had short-term morbidities, and 27% of survived infants had no long-term neurodevelopmental impairments (Bashir et al., 2017). In another study from the United States, the survival rates of infants born at 22, 23, and 24 weeks' gestation were 31%, 42%, and 64%, respectively (Anderson et al., 2016). In Japan, the survival rates of infants with birth weight less than or equal to 300 g, 301 to 400 g, and 401 to 500 g were 18%, 41%, and 60%, respectively (Inoue et al., 2017). A review of studies showed a progressive increase in the rate of survival of infants born between 22 to 25 weeks' gestational age (American College of Obstetricians and Gynecologists [ACOG] & Society for Maternal–Fetal Medicine [SMFM], 2017; Ancel et al., 2015; Costeloe et al., 2012; Moore, Lemyre, Barrowman, & Daboval, 2013; Rysavy et al., 2015; Stoll et al., 2010). The survival and outcome of outborn infants are not similar to that of inborn infants. Outborn infants have been shown to have significantly higher risk of death or neurodevelopmental impairments, death alone, and cerebral palsy compared to inborn

preterm infants admitted to Canadian NICUs (Amer et al., 2018). ELBW infants, particularly those with birth weights between 500 and 599 g, have uncertainty and remained in the "gray zone" in terms of both survival and their long-term neurodevelopmental outcomes (Seri & Evans, 2008). As a result, issues related to moral status (Smith, 2005) and judgments about survival and unacceptable quality of life pose a dilemma for healthcare professionals, parents, and society (Powell et al., 2012; Seri & Evans, 2008).

An ELBW infant gains status as a patient and in a social sense as a member of a family once the infant is born. Healthcare professionals owe the ELBW infant a duty of ethical treatment and care because of this status (Smith, 2005). Whether to resuscitate and to initiate and continue intensive care raises questions related to the primacy of the newborn's best interest, respect for persons and legal rights, and the healthcare providers' consideration of ethical principles of beneficence, nonmaleficence, autonomy, justice, and futility. Ethical principles are difficult to implement in practice (Lorenz, 2003; Powell et al., 2012; Seri & Evans, 2008; Wilder, 2000). Treatment decisions for the ELBW infant reflect varied opinions on the proper approach to resuscitation and initiation of intensive care for these infants. The best interest of the child, which supports the universal right to life, is regulated by law in many countries (e.g., United States of America, United Kingdom, and Canada; Albersheim, 2008; Kopelman, 2005; Schoonakker & Smith, 2007) and is supported by the Hippocratic Oath and professional medical organizations (Haward, Kirshenbaum, & Campbell, 2011). Clinicians would therefore be inclined to initiate all necessary life support, at least temporarily, to permit assessment of the harm-to-benefit ratio based on projected suffering and burden as determined by current data or "best guess" (Smith, 2005). This approach includes an opportunity for survival while minimizing risk of long-term disability if the child is incorrectly judged to be nonviable and survives (Wilder, 2000).

The best interest standard is, however, difficult to apply for decision making in the delivery room, given the subjective nature of appraising the mortality and morbidity of infants in the "gray zone" or threshold of viability. Additionally, care providers must consider parents' or guardians' expectations, values, and religious beliefs, as they are the primary caregivers and will have the ultimate responsibility of care (Haward et al., 2011; Kopelman, 2005; Schoonakker & Smith, 2007). A "negative" analysis of the best interest of the child has been proposed, as it permits considerations of available options based on a range of moral, social, and legal issues. It also permits involvement of parents in decision making (Kopelman, 2005; Schoonakker & Smith, 2007). The American Academy of Pediatrics (AAP) promotes involvement of parents early in the decision-making process regarding survival and disability; hence, it incorporates parents' wishes to be involved in decision making (Schoonakker & Smith, 2007). A single approach or philosophy on care that is appropriate for all countries, cultures, or communities is an unreasonable expectation. Individual and societal values; long-term outcomes; associated physical, psychological, emotional, and financial costs; and finite resources will play a significant role in decision making regarding whether or not to resuscitate and continue care for ELBW infants. The marked variation in the frequency with which aggressive resuscitation is initiated in the zone of uncertainty is not surprising given the various ways in which competing values may be balanced by different individuals, cultures, and societies (Lorenz, 2003).

Ideally, a resuscitation plan should be in place prior to delivery. The most recent Neonatal Resuscitation Program (NRP) guidelines (7th edition), released by the AAP (Weiner & Zaichkin, 2016; Finan, Campbell, Aziz, & McNamara, 2017) recommend an individualized approach to management decisions regarding the aggressive resuscitation of ELBW infants. The other key changes in delivery room resuscitation include a focus on teamwork, communication, leadership skills, and predelivery briefing (Weiner & Zaichkin, 2016; Finan et al., 2017). Statistical modeling is being employed to identify factors (e.g., higher birth weight, female sex, singleton gestation, antenatal corticosteroids) that can assist clinicians in predicting morbidity and mortality and guide decision making (Powell et al., 2012; Tyson, Parikh, Langer, Green, & Higgins, 2008). In many instances though, there is often little time to make informed decisions about the reasonableness of resuscitation and initiation of intensive care (Powell et al., 2012). Contextual factors such as the woman's pain, labor, or deteriorating maternal or fetal condition, and inconsistent and conflicting information provided by multiple care providers pose a barrier to effective communication and decision making regarding resuscitation and delivery room care (Tomlinson, Kaempf, Ferguson, & Stewart, 2010). A standardized evidence-based approach to counseling that included recommendations for and against treatment was well received by patients, who found the process useful and consistent and the information understandable. More importantly, patients were comfortable with the decisions they made for themselves and their families (Tomlinson et al., 2010).

Ethical decisions regarding the extent of resuscitation efforts should be based on multiple factors including gestational age, birth weight, and fetal condition on antenatal ultrasound; the infant's condition at birth, survival, and morbidity data; and the parents' wishes. Information should be provided in a consistent manner, and a multidisciplinary approach will ensure that a range of concerns and areas of clinical care are addressed (ACOG & SMFM, 2017). The plan should be based on consensus decision making by parents and all healthcare professionals involved in the provision of care to the mother and ELBW infant (Powell et al., 2012; Wilder, 2000).

Survival of ELBW Infants

Data based on gestational age are more appropriate than data based on birth weight for projecting survival and future disability in infants. However, unreliable gestational age estimates, and earlier reporting practices of rounding off gestational age to the nearest week of gestation, can have a significant impact on survival statistics (Ho & Saigal, 2005). Population-based, international neonatal network studies examining survival between 24 and 29 weeks' gestational age of infants, weighing less than 1,500 g report marked variation in survival rates among different geographic areas (Helenius et al., 2017). These variations are likely a reflection of management styles such as proactive versus less aggressive resuscitation and initiation of intensive care, and manner in which outcomes are reported (e.g., duration of survival; Haward et al., 2011; Ho & Saigal, 2005; Lorenz, 2004). Table 28.1 illustrates the variation in survival rates of ELBW infants around the world by comparing countries such as the United States, Europe, Canada, and Japan. As is evident, with each additional week of gestational age, there is a large improvement in survival rates (Haward et al., 2011). At comparable gestational age and birth weight, mortality rates are higher for males compared to females (ACOG & SMFM, 2017).

Morbidity in ELBW Infants

Intraventricular hemorrhage (IVH), bronchopulmonary dysplasia (BPD), necrotizing enterocolitis (NEC), ROP, and disabilities in mental and psychomotor development, neuromotor function, or sensory and communication function are major neonatal morbidities associated with ELBW (ACOG & SMFM, 2017; Ho & Saigal, 2005; Håkansson, Farooqi, Holmgren, Serenius, & Högberg, 2004).

Bronchopulmonary Dysplasia. BPD, the most prevalent multifactorial morbidity in ELBW infants, occurs in 10,000 to

TABLE 28.1

SURVIVAL RATES TO HOSPITAL DISCHARGE AMONG INFANTS BORN 22 TO 25 WEEKS GESTATION

Cohort	Year	Denominator	22 Weeks	23 Weeks	24 Weeks	25 Weeks
Japan: Single center (Iijima, Arai, Ozawa, Kawase, & Uga, 2009)	1991–2006	Live births	25%	47%	50%	–
EPICure (United Kingdom, Ireland; Wood, Marlow, Costeloe, Gibson, & Wilkinson, 2000)	1995	Population-based (LB + SB)	1%	11%	26%	44%

15,000 infants annually in the United States (Jensen & Schmidt, 2014). The risk of BPD in ELBW infants is approximately 40% (Horbar et al., 2017). The rate of BPD varies from 57% to 70% in infants born at 23 weeks' gestational age. At 24 weeks' gestational age, rates of BPD range from 33% to 89%, and at 25 weeks' gestational age rates range from 16% to 71%. BPD is also associated with poor nutrition and growth, poor feeding skills, prolonged hospitalization, and episodes of nosocomial infection, and thus can have influences on later life and development. The "new BPD" (post surfactant disease, post acinar arrest during lung development) that occurs primarily in ELBW infants is thought to have a qualitatively different pathogenesis marked by immaturity and alveolar hypoplasia rather than the hyperoxic barotrauma or volutrauma typically seen in surfactant-deficient lungs (Narendran et al., 2003). Given the controversy and limitations of the current clinical definitions of BPD, two new definitions of BPD were proposed in the United States and Canada. These new definitions were noninvasive ventilation support and radiographic changes to objectively grade the severity of BPD (Higgins et al., 2018; Isayama et al., 2017). Based on these two new definitions (Higgins et al., 2018; Isayama et al., 2017), and gestational age, the prevalence of BPD and the risk of neurodevelopmental impairments will be different in infants with BPD and require further investigation.

The aim is to reduce the risk of BPD in ELBW infants by adopting a multipronged approach. Early delivery room or prophylactic surfactant prior to stabilization with continuous positive airway pressure (CPAP) regardless of respiratory status has demonstrated beneficial outcomes such as reduced delivery room intubations and days on mechanical ventilation, use of postnatal steroids, lowered oxygen saturation goals, fewer infants discharged home on oxygen, and decreased incidence and severity of BPD (Geary, Caskey, Fonseca, & Malloy, 2008; Meyer, Mildenhall, & Wong, 2004; Narendran et al., 2003). However, a recent systematic review concluded that there are no clear benefits of using prophylactic surfactant when infants are routinely managed on CPAP. With routine application of CPAP as standard of practice, the risk of BPD or death was lower with selective treatment with surfactant when compared with prophylactic use of surfactant (Rojas-Reyes, Morley, & Soll, 2012). Postnatal steroids, especially dexamethasone treatment, have been found to have no effect on BPD and are associated with gastrointestinal perforation and decreased growth in ELBW infants (Stark et al., 2001). More importantly, a systematic review reported a dramatic increase in neurodevelopmental impairment in preterm infants treated with glucocorticoids in the postnatal period (Barrington, 2001). A recent randomized controlled trial showed that extremely preterm infants who received a low dose of prophylactic hydrocortisone have a better rate of survival without BPD at 36 weeks post menstrual age (PMA; Baud et al., 2016). Also, those infants who received low-dose hydrocortisone and were born at 24 and 25 weeks' gestation had better neurodevelopmental outcomes (Baud et al., 2019). Chronic oxygen dependency in BPD infants who were discharged home with oxygen does not increase the extra risk of neurodevelopmental impairments compared to infants with BPD alone (Lodha et al., 2014).

Poets et al. have suggested some possible strategies to prevent the risk of BPD, including nasal CPAP in place of intubation and mechanical ventilation, exogenous surfactant via minimally invasive administration technique with a thin tracheal catheter/nasogastric tube, volume targeted ventilation if mechanical ventilation is necessary, synchronized intermittent positive pressure ventilation (iPPV), early use of caffeine, vitamin A, consideration of low-dose hydrocortisone for the first 10 postnatal days, and consideration of intravenous dexamethasone in infants who required mechanical ventilation at the end of their second postnatal week (Poets & Lorenz, 2018).

Necrotizing Enterocolitis. NEC, an acquired gastrointestinal disease that complicates the neonatal course of survivors, affects 1 to 3 infants per 1,000 live births (Guthrie et al., 2003; J. S. Lee & Polin, 2003). ELBW infants are particularly susceptible and have a higher incidence of NEC; however, the clinical presentation is relatively similar to that for other affected neonates. The cause of NEC remains unclear but most likely represents a complex interaction of factors with a final common pathway of intestinal ischemia. In epidemiologic studies, prematurity is consistently identified as an independent determinant of NEC (J. S. Lee & Polin, 2003). Other factors include feeding practices, intestinal ischemia, and bacterial colonization (Kliegman, 1990). The risk of NEC associated with blood transfusion is increasing, but the causality of the blood transfusion itself or the underlying anemia remains unresolved. Currently, we believe that transfusion/anemia-associated NEC is a possible biological plausibility (Maheshwari, Patel, & Christensen, 2018).

Manifestations of NEC include abdominal distention, increased gastric residuals, vomiting and/or bilious aspirates, bloody stools, metabolic acidosis, cellular destruction, and gut necrosis. Hallmarks of NEC include pneumatosis intestinalis, hepatic portal venous gas, perforation, and pneumoperitoneum; these are evident on abdominal radiograph (Meerstadt & Gyll, 1994; Walsh & Kliegman, 1986). Treatment focuses on medical stabilization and interventions including bowel rest, gastric decompression, broad-spectrum systemic antibiotics, and parenteral nutrition. Infants with perforation either are operated on or have a peritoneal drainage (J. S. Lee & Polin, 2003). The catastrophic nature of NEC and the fragility of ELBW infants are evident in the overall mortality of the disease, which is approximately 50% (Blakely et al., 2005). Once NEC develops, the long-term consequences may include growth delay and severe neurodevelopmental impairments (Dilli, Eras, Özkan Ulu, Dilmen, & Durgut şakrucu, 2012; Salhab, Perlman, Silver, & Sue Broyles, 2004; Soraisham, Amin, Al-Hindi, Singhal, & Sauve, 2006). Infants with NEC requiring surgical treatment are associated with significantly lower mental developmental index (MDI) and psychomotor development index (PDI) scores (Allendorf et al., 2018). Consequently, prevention of NEC has been the primary focus, resulting in numerous approaches being proposed to prevent NEC (Neu & Walker, 2011).

Provision of small volumes of exclusive human milk (Meinzen-Derr et al., 2009) or human milk fortified with a human milk–derived fortifier (Sullivan et al., 2010) has been found to be safe (i.e., lower incidence of NEC). Standardized feeding regimens have been introduced in an attempt to reduce the incidence of NEC by minimizing variations in enteral feeding practices. A systematic review and meta-analysis of observational studies ("before" and "after") reported a reduced incidence of NEC after the introduction of a standardized feeding regimen (Patole & de Klerk, 2005). A retrospective cohort study reported an association between prolonged duration of initial (i.e., in the first 3 postnatal days) antibiotic course and increased risk of NEC or death (Cotten et al., 2009). Based on a recent systematic review of randomized controlled trials, it has become evident that the use of prophylactic probiotics reduced the risk of NEC (stage 2 and greater) by 44% and also reduced the risk of mortality (Deshpande, Jape, Rao, & Patole, 2017). Therefore, most NICUs are using probiotics as a standard of care in their units; however, controversy remains with regard to the type of probiotic that should be used to reduce the risk of NEC. In another study from Germany, Denkel et al. (2017) recommend the routine use of dual-strain probiotics in standard neonatal care of infants born less than 1,000 g for prevention of NEC. Use of oral immunoglobulin (Foster, Seth, & Cole, 2017) as a preventative strategy for NEC is not supported in preterm or LBW

infants; however, the strategy has not been studied exclusively in ELBW infants. Supplementation of *L*-arginine in extreme preterm infants may also be protective in prevention of NEC (Mitchell et al., 2014). The roles of pentoxifylline and/or lactoferrin in prevention of NEC are not yet well studied in a large randomized controlled trial, and therefore evidence is still lacking for use of either agent as the standard of care in modern NICUs (Pammi & Haque, 2015; Pammi & Suresh, 2017).

Retinopathy of Prematurity. ROP, a vascular proliferative disorder of the immature retina (i.e., abnormal growth of retinal capillaries during vascularization), causes acuity defects, refractive errors (particularly myopia), gaze abnormalities, and blindness (Andersen & Phelps, 2000). Vascularization of the retina is complete by 40 weeks' gestational age (Brion, Bell, & Raghuveer, 2003). The developing retinal capillaries are susceptible to injury; hence, preventative strategies (e.g., control of exogenous oxygen delivery) are aimed at reducing stress contributing to injury, while other treatment approaches (e.g., cryosurgery or laser ablation) are aimed at controlling or arresting progression of neovascularization (Phelps & Watts, 2001).

The prevalence of ROP (any stage) in infants born less than 27 weeks' gestational age was reported at 73% and the prevalence of severe ROP was reported at 35% (Austeng, Källen, Ewald, Jakobsson, & Holmström, 2009). In developed countries, the population at risk for blinding ROP has changed, with studies (Hardy et al., 2004) suggesting that ELBW infants are at greatest risk of advanced stages of ROP requiring treatment (Gilbert et al., 2005). In contrast, in low- and moderate-income countries, it is the larger, more mature infants that are at risk of developing severe ROP (Gilbert et al., 2005). To facilitate earlier identification and timely intervention for prethreshold ROP in at-risk infants (i.e., ELBW), it is recommended that the timing of an eye examination be based on chronologic age of 4 to 6 weeks rather than 31- to 33-week postconceptional age being used (Subhani, Combs, Weber, Gerontis, & DeCristofaro, 2001). Fierson et al., (2013) recommend the use of the international classification system (2005) to grade severity of ROP based on retinal examinations. Subsequent eye examinations, depending on the results, occur at least every 1 to 2 weeks until the retina is fully vascularized. Continued ophthalmologic follow-up of ELBW infants with severe ROP is essential as ROP may represent a lifelong disease, as evidenced by the number of eyes, both cryotherapy-treated and noncryotherapy-treated, that developed retinal detachment, blindness, and other related complications between ages 10 and 15 years (Palmer et al., 2005).

In premature infants, factors such as change in oxygen exposure have been proposed to cause distribution in the vascularization. In a systematic review, supplementation with vitamin E, an antioxidant agent, was not supported, given that there was an increased risk of sepsis and reduced risk of severe retinopathy and blindness among VLBW infants who were given vitamin E supplements (Brion et al., 2003). Darlow and Graham (2011) found that with vitamin A supplementation fewer infants required oxygen at 36 weeks' PMA (numbers needed to treat 13, 95% CI 7, 100). Supplementation with vitamin A, the precursors of which have antioxidant properties, has been shown in a systematic review to be a potential protective therapy for ROP in ELBW infants as there was a trend toward reduced incidence of ROP in treated infants. Askie, Henderson-Smart, and Ko (2009) performed a systematic review of studies of unrestricted oxygen use and outcomes in premature infants. They found that if oxygen levels were not monitored closely, morbidity in this population rose. Oxygen levels, therefore, must be watched and controlled carefully; however, the optimal range of oxygen levels remains unknown (Askie et al., 2009). Hyperoxia may produce vascular endothelial growth factor (VEGF) in the process of development of severe ROP. Intravitreal bevacizumab/ranibizumab, an anti-VEGF agent, is being used as a newer monotherapy for severe ROP and reduces the risk of refractive errors during childhood. It does not reduce the risk of retinal detachment or recurrence of ROP in infants with severe ROP (Sankar, Sankar, & Chandra, 2018).

Cryotherapy and laser therapy are standard care for threshold ROP (Palmer et al., 2005). Given the substantial proportion of eyes treated with cryotherapy that developed retinal detachment and unfavorable distance visual acuity, current research is focusing on early treatment for ROP (Hardy et al., 2004; Subhani et al., 2001). A systematic review by Andersen and Phelps (2009) has reported early treatment with peripheral retinal ablation to be effective for treating eyes determined to be at high risk for a poor outcome or prethreshold ROP. Treatment resulted in reduced risk of adverse structural outcome at 12 months and 5½ years with corresponding reduction in adverse acuity. When laser therapy has been used in conjunction with bevacizumab/ranibizumab, it has been shown to reduce the risk of retinal detachment and recurrence of ROP in infants with type 1 ROP. However, this treatment needs a large randomized controlled trial to determine the efficacy of intravitreal bevacizumab/ranibizumab in combination with laser treatment in severe ROP (Sankar et al., 2018).

Neurodevelopment. Major neurologic impairments include cerebral palsy, motor impairment, visual and hearing impairments, and cognitive deficits (Ho & Saigal, 2005; Wood et al., 2000). A recent systematic review of nine high quality studies reported severe neurodevelopmental delay in preterm infants born at 22, 23, 24, and 25 weeks' gestational age were 31%, 17%, 21%, and 14%, respectively, whereas rates of moderate-to-severe neurodevelopmental delay were 43%, 40%, 28%, and 24%, respectively (Moore et al., 2013). Significant variation in neurodevelopmental outcomes is reported in various cohorts of extremely preterm children (Haward et al., 2011). Variability in morbidity reported in various cohorts of extremely preterm children (Haward et al., 2011) is striking (Lorenz, 2003) and may be due to chronologic age at evaluation, varying criteria for defining and reporting neurologic impairments (i.e., instruments to measure disability and functional capacity; Haward et al., 2011; Ho & Saigal, 2005), differences in center demographics, antenatal interventions, and neonatal clinical practice or interventions (Vohr et al., 2004).

A study of 219 ELBW infant survivors admitted between 1992 and 1995 to Rainbow Babies and Children's Hospital in Cleveland, Ohio, and assessed at 8 years of age reported the following outcomes: (1) major neurosensory impairment, including cerebral palsy, deafness, and blindness (16%); (2) asthma requiring therapy (21%); (3) functional limitations including delay in growth or development, mental or emotional delay, need to reduce or inability to participate in physical activities, difficulty seeing, hearing, speaking, or communicating, and inability to play or socialize with others (64%); (4) one or more compensatory dependence needs, including prescribed medication, life-threatening allergic reactions, prescribed special diet, special equipment to see, hear, or communicate, and need for help or special equipment for walking, feeding, dressing, washing, and toileting (48%); and (5) services needed above routine, including visiting a physician regularly for a chronic condition, nursing care or medical procedures, occupational or physical therapy, special school arrangements, or an individualized education program (65%). The findings of this study may not be representative of all ELBW survivors, as this was not a population-based study. A recent population-based study of ELBW infants found up to 50% prevalence of neurodevelopmental

disability that remained throughout childhood (Johnson et al., 2009).

The ELBW infant follow-up group of the Vermont Oxford Network (VON) examined data from 33 North American VON centers for 1998, noting severe disability in 34% of infants (n = 3,567) assessed at 18 to 24 months' corrected age (CA; Mercier et al., 2010). Despite improvements in perinatal interventions, extremely preterm infants are still at an increased risk for adverse outcomes at 18 to 22 months CA (Hintz, Kendrick, et al., 2011). Neurodevelopmental outcomes for infants born at less than 25 weeks' estimated gestation age remained unchanged in infants born between 1991 and 2001 versus those born between 2002 and 2004: moderate-to-severe cerebral palsy (adjusted odds ratio [aOR] 1.52, 95 confidence interval [CI] 0.86, 2.71); p = .15), mental developmental index less than 70 (aOR 1.3, 95% CI 0.91, 1.87; p = .15), and neurodevelopmental impairment diagnosed in 50% of surviving infants (aOR 1.4, 95% CI 0.98, 2.04; p = .07; Hintz, Kendrick, et al., 2011). Neurodevelopmental and cognitive impairments have been found to remain stable between 6 and 11 years of age, with minimal shifts in severity of disability (Johnson et al., 2009). The proportion of ELBW survivors with adverse outcomes increases with decreasing gestational age (Haward et al., 2011), with poor chances of intact outcomes for infants at 23 and 24 weeks' gestation. At comparable gestational age and birth weight, disability rates (e.g., cerebral palsy) are higher for males than for females (ACOG & SMFM, 2017; Johnson et al., 2009). Gestational age and gender have independent effects on neurodevelopmental outcomes (Haward et al., 2011). In a recent study including 11 centers affiliated with the NICHD Neonatal Research Network in the United States, the survival of extreme premature infants between 22 to 24 weeks' gestation with neurodevelopmental impairments with or without neurosensory impairments is shown in Table 28.2 (Younge et al., 2017).

Severe brain injury as evidenced by abnormal cerebral ultrasound findings predicts major morbidity such as quadriparesis and severe cerebral palsy in ELBW infants (Kuban et al., 2009). Interventions such as prophylactic indomethacin therapy have been used in clinical practice to reduce the occurrence of severe IVH or periventricular leukomalacia, which are significant short-term predictors of neurodevelopmental morbidity in ELBW infants. Although prophylactic administration of indomethacin reduces the incidence of severe IVH (Schmidt et al., 2007), it does not improve neurodevelopmental outcomes (Fowlie, Davis, & McGuire, 2010; Schmidt et al., 2001). Magnesium sulfate given to mothers at risk of preterm birth has been shown to have neuroprotective effects, improving long-term outcomes of infants born preterm (Doyle, 2012); however, the most effective regimen remains to be determined (Bain, Middleton, & Crowther, 2012). The Caffeine for Apnea of Prematurity (CAP) trial, which enrolled infants less than 1,250 g, initially reported reduced rates of cerebral palsy and cognitive delay at 18 months of age; however, rates of disability were no different at 5 years CA (Schmidt et al., 2012).

Among other contributing factors, neurodevelopmental morbidity has been partially attributed to the stressful nature of the intensive care unit (Gorski, 1991). Neurodevelopment can be promoted if the potential impact of the environment is recognized and interventions including one or more elements such as control of external stimuli (e.g., light, noise, minimal stimulation), clustering of care activities, and positioning or swaddling are implemented (Venkataraman, Kamaludeen, Amin, & Lodha, 2018). There is evidence that this broad category of interventions, referred to as developmental care, offers the following benefits to preterm infants: improved short-term growth and feeding outcomes, decreased respiratory support needs, decreased length and cost of hospital stay, and improved neurodevelopmental outcomes to 24 months CA (Symington & Pinelli, 2006).

TABLE 28.2

NEURODEVELOPMENTAL OUTCOMES AT 18 TO 22 MONTHS OF CORRECTED AGE

Outcomes	Epoch 1 (2002–2003) No./Total No. (%)	Epoch 2 (2004–2007) No./Total No. (%)	Epoch 3 (2008–2011) No./Total No. (%)
All infants—survival with NDI	207/1,391 (14.9)	209/1,535 (13.6)	211/1,348 (15.6)
All infants—survival with NSI	73/1,380 (5.3)	66/1,533 (4.3)	92/1,348 (6.8)
Infants born at 22 weeks—survival with NDI	4/241(1.6)	9/274 (3.3)	5/234 (2.1)
Infants born at 23 weeks—survival with NDI	63/496 (12.7)	41/489 (8.4)	51/450 (11.3)
Infants born at 24 weeks—survival with NDI	140/654 (21.4)	159/772 (20.6)	155/664 (23.3)

NDI, neurodevelopmental impairment; NSI, neurosensory impairments.

COMPLICATIONS OF BEING ELBW

In the immediate neonatal period, ELBW infants are more susceptible to all the possible complications of premature birth because of their very vulnerable state of development. The balance of this chapter is an overview of typical problems experienced by ELBW infants and some of the outcomes for these infants. The chapter also addresses the key areas for care where nurses can contribute to the scientific basis for practice.

Thermoregulation

Cold stress is associated with increased mortality and morbidity (e.g., hypoglycemia, respiratory distress, and metabolic acidosis) in premature infants (Hazan, Maag, & Chessex, 1991; McCall, Alderdice, Halliday, Jenkins, & Vohra, 2010). Quality improvement data for infants less than 750 g indicate that the incidence of temperature less than 36.5°C or 97.6°F varies between NICUs (Bhatt et al., 2007). In the first 12 hours of life, ELBW infants are not able to conserve heat, given poor vasomotor control (Knobel, Holditch-Davis, Schwartz, & Wimmer, 2009). A high body surface area-to-body weight ratio (Lyon, Pikaar, Badger, & McIntosh, 1997), and decreased ability to produce heat because of decreased brown fat stores and decreased glycogen supply, makes ELBW infants particularly vulnerable to hypothermia (defined as <36.5°C) (Knobel, Wimmer, & Holbert, 2005; McCall et al., 2010; Sauer, Dane, & Visser, 1984). Provision of warmth is the first step in the resuscitation of the newborn because the risk of cold

stress is greatest at birth (Knobel et al., 2005). Hence, clinicians should maintain the delivery room temperature at 23°C to 25°C (Weiner & Zaichkin, 2016). A systematic review (McCall et al., 2010) found that early intervention in the delivery room, particularly the application of plastic wraps (for infants <28 weeks' gestational age) or transwarmer mattresses (infants <1,500 g) immediately after birth, prevents hypothermia, keeping infants warmer on admission to the NICU. These early interventions are in addition to "routine" care implemented immediately after birth such as drying the infant thoroughly, especially the head, removing any wet blankets, wrapping the infant in a prewarmed blanket, covering the infant's head with a cap, keeping the temperature of the ventilator at greater than or equal to 34.0°C to 35.0°C, utilizing heated humidified gases, and prewarming any contact surfaces. Further research is required to facilitate firm recommendations of these early interventions in clinical practice for ELBW.

The "gold standard" for nursing preterm infants in incubators or under radiant warmers is to maintain the body temperature at which the metabolic rate reaches the minimum or thermoneutral temperature (Rieger-Fackeldey, Schaller-Bals, & Schulze, 2003). In the first week of life, this thermoneutral temperature depends on gestational age and postnatal age, after which time it depends on body weight and postnatal age (Sauer et al., 1984). However, for ELBW infants, this optimal body temperature is not known (Rieger-Fackeldey et al., 2003).

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS), a common problem among ELBW infants, has a pathogenesis dominated by surfactant deficiency complicated by an overly compliant chest wall. Surfactant deficiency leads to decreased lung compliance, reduced alveolar ventilation, atelectasis, and alveolar hypoperfusion, which clinically manifests as grunting respirations, retractions, nasal flaring, cyanosis, and increased oxygen requirement shortly after birth. The findings of RDS on chest radiograph include low lung volume, reticulogranular pattern, ground glass appearance, air bronchograms, and difficult delineation of cardiac and lung borders (Hellmann, Millman, & Lodha, 2005). Clinical management includes prevention of RDS, surfactant replacement, and respiratory support. The prevention strategies include antenatal corticosteroids (Crowther, McKinlay, Middleton, & Harding, 2015; Roberts, Brown, Medley, & Dalziel, 2017). The mainstay of medical management is administration of surfactant in addition to supplemental oxygen, CPAP, humidified high-flow nasal cannula system, and/or ventilatory support, and the clinical course may be complicated by air leaks, significant shunting through the patent ductus arteriosus (PDA), or BPD (Hamvas, 2011; Rojas-Reyes et al., 2012).

Prophylactic (delivery room) and rescue (after established RDS) administration of surfactant reduces mortality associated with RDS in preterm infants (Rojas-Reyes et al., 2012). Prophylactic administration of surfactant has been reported to decrease the incidence of pneumothorax, the risk of pulmonary interstitial emphysema, and the risk of BPD (Rojas-Reyes et al., 2012). However, these differences were no longer evident when comparing infants routinely being managed on CPAP who received prophylactic versus rescue surfactant treatment. In fact, the risk of BPD or death was lower in the latter (Rojas-Reyes et al., 2012). Prophylactic administration of synthetic surfactant when compared to animal-derived surfactant has been noted to show a trend toward decreased mortality in the neonatal period and at 36 weeks PMA. No significant differences in risk of BPD were found between groups (Pfister, Soll, & Wiswell, 2009).

Endotracheal suctioning for mechanically ventilated patients in the NICU is customary nursing practice aimed at reducing buildup of secretions and tube obstruction, which can cause discomfort, hypoxemia, hypercapnia, and lobar collapse. Closed suctioning, that is, suctioning without disconnecting intubated ventilated neonates, may have certain short-term benefits: for example, reduction in episodes of hypoxia (typical relative risk 0.48, 95% CI 0.31, 0.74), smaller percentage change in heart rate (weighted mean difference 6.77, 95% CI 4.01, 9.52), and fewer number of infants experiencing bradycardia (typical relative risk 0.38, 95% CI 0.15, 0.92; Taylor, Hawley, Flenady, & Woodgate, 2011). Noninvasive ventilation including CPAP, synchronized iPPV, and nasal bilevel-CPAP significantly changed the management of RDS in the modern era of NICUs to prevent mechanical trauma due to ventilation pressure and volume (Salvo et al., 2017). Several other strategies for the management of RDS are under experiment, such as the use of noninvasive respiratory support with minimally or less invasive surfactant therapy (Kribs & Hummler, 2016). The less invasive surfactant administration (LISA) technique for surfactant delivery reduces the duration of mechanical ventilation and the composite outcome of death and/or BPD and BPD alone at 36 weeks' PMA in infants with RDS (Aldana-Aguirre, Pinto, Featherstone, & Kumar, 2017).

Hyperbilirubinemia

Among ELBW infants, differences in neurodevelopmental outcomes have been attributed to differences in maximum levels of serum bilirubin levels and duration of phototherapy (Mazeiras et al., 2012). High levels of unconjugated bilirubin are associated with kernicterus, a form of brain damage with sequelae such as deafness, mental retardation, and cerebral palsy. In ELBW infants, kernicterus can occur at low levels of serum bilirubin (Moll, Goelz, Naegele, Wilke, & Poets, 2011), and many clinicians have been inclined to initiate phototherapy at low serum bilirubin levels (<7–10 mg/dL; i.e., aggressive phototherapy; Ambalavanan & Whyte, 2003). These studies, however, may be biased toward overestimating bilirubin toxicity because most problems that cause developmental delay are also associated with hyperbilirubinemia (Ambalavanan & Whyte, 2003). A randomized controlled trial examining the benefits or harms of aggressive phototherapy versus conservative phototherapy at 18 to 22 CA months found no significant difference in the rate of death or neurodevelopmental impairment. However, subgroup analysis showed reduced death or neurodevelopmental impairment, and a significant reduction in the rates of hearing loss and profound neurodevelopmental impairment without an increase in the rate of death or other adverse outcomes (e.g., cerebral palsy, MDI score). Although aggressive phototherapy reduced neurodevelopmental impairment in infants weighing 501 to 750 g at birth, the rate of death was higher, thereby counterpoising the benefits of aggressive phototherapy treatment (Morris et al., 2008). When comparing risk-adjusted outcomes between ELBW infants who received phototherapy with those who did not receive phototherapy, phototherapy was not independently associated with death or neurodevelopmental impairment (Hintz, Stevenson, et al., 2011). However, the rate of profound delay as measured by Bayley Scales Mental Developmental Index less than 50 was higher in infants 501 to 750 g birth weight who did not receive phototherapy (Hintz, Stevenson, et al., 2011).

In VLBW infants, phototherapy may increase insensible water loss (Bell, Neidich, Cashore, & Oh, 1979) secondary to heat generated by the phototherapy equipment (Kjartansson, Hammarlund, & Sedin, 1992), thereby complicating fluid management. Other known harmful effects of phototherapy include an increase in the incidence of PDA (Rosenfeld et al., 1986), as well as a potential increase in the incidence of ROP (Yeo, Perlman, Hao, & Mullaney, 1998). The benefits and known and unknown adverse effects of phototherapy need to be weighed in decision making regarding initiation of phototherapy at low serum bilirubin levels (Ambalavanan &

Whyte, 2003). Nurses' vigilance in monitoring input and output and signs and symptoms of PDA can guide medical decision making regarding risks and benefits of phototherapy, as well as identify adverse consequences of phototherapy in the event treatment is initiated. Mild unconjugated hyperbilirubinemia may be physiologic in nature and it could be attributable to breastfeeding or breast milk jaundice, but it is essential to exclude significant pathologic conditions. Conjugated hyperbilirubinemia is always pathologic in nature and needs extensive laboratory workup (Feldman & Sokol, 2013; Martin, Fanaroff, & Walsh, 2015).

Apnea of Prematurity

Apnea is generally defined as periodic pauses in respirations lasting greater than 20 seconds, or shorter pauses associated with cyanosis, pallor, hypotonia, or bradycardia. However, varied definitions are also found with the proposed duration of pause being shorter (e.g., 15 seconds; Spitzer, 2012). A proposed pathophysiologic mechanism thought to contribute to AOP involves immaturity of reflex pathways initiated by hypercapnia, hypoxia, and upper airway afferents (Martin, Abu-Shaweesh, & Baird, 2004). Nevertheless, there are multiple secondary etiologic factors such as birth trauma, meningitis, seizures, cardiac causes (cyanotic congenital heart disease, hypertension or hypotension, PDA, increased vagal tone), infection, gastroesophageal reflux (GER), NEC, anemia or hypoxemia, metabolic disorder, drug therapy, and temperature instability that may contribute to apnea. AOP is a diagnosis of exclusion in infants less than 37 weeks' gestational age (Martin et al., 2004; Stokowski, 2005). There is uncertainty about the long-term consequence of recurrent AOP; however, concern relates to the impact of multiple prolonged episodes of hypoxemia and reflex bradycardia on organ systems such as the brain leading to brain injury and poor neurodevelopmental outcome (Henderson-Smart & De Paoli, 2010; Janvier et al., 2004). Extremely preterm infants who had prolonged hypoxemic episodes during the first 2 to 3 months after birth and survived to 36 weeks' PMA had adverse outcomes at 18 months CA (Poets et al., 2015).

The incidence of AOP increases as gestational age decreases. In ELBW infants, apneic and bradycardic episodes persist beyond term gestation, most likely secondary to the higher incidence of BPD. These persistent apneic and bradycardic episodes complicate and contribute to variability in management decisions related to discharge planning and may prolong hospital stays (Eichenwald, Aina, & Stark, 1997). Clinical interventions for AOP include tactile stimulation, oscillating mattress (kinesthetic stimulation), provision of thermoneutral environment, methylxanthine therapy, flow through nasal cannula, CPAP or ventilatory support, nasal CPAP or noninvasive positive pressure ventilation (NIPPV), and olfactory stimulation (Al-Alaiyan, Dawoud, & Al-Hazzani, 2014; Lemyre et al., 2017; Marlier, Gaugler, & Messer, 2005; Martin et al., 2004; Osborn & Henderson-Smart, 2000; Stokowski, 2005). Although some of these interventions such as methylxanthines (Henderson-Smart & De Paoli, 2010), doxapram (Henderson-Smart & Steer, 2004), and NIPPV (Lemyre et al., 2017) have been shown in a systematic review to be effective in reducing the number of apneic and bradycardic episodes in preterm infants, more research is required before these interventions can be recommended as standard therapy in ELBW infants specifically. The common side effects of doxapram include an increase in blood pressure, abdominal distension, jitteriness, irritability, increased gastric residuals, emesis, and seizures. There is insufficient evidence at this time to support the use of doxapram in regular practice.

Although current practice standards require nurses to document apnea/bradycardia episodes in order to facilitate management decisions, these records underestimate the frequency of events when compared to recordings (Razi, Humphreys, Pandit, & Stahl, 1999). Nurses spend a significant amount of time monitoring, assessing, and managing apneic and bradycardic episodes, given that nearly all ELBW infants experience AOP. There is a need to develop evidence-based criteria for a minimal safe observation period between the time of last apneic episode and hospital discharge (Eichenwald et al., 1997). It is commonly recommended to stop caffeine at 34 weeks' PMA and monitor for apneas at least 7 days before newborn discharge home at 36 weeks and beyond. Furthermore, a clear understanding of the impact of use of technology (e.g., home monitoring) on hospital discharge, subsequent rehospitalization, post discharge morbidities (Eichenwald et al., 1997), and family functioning and coping is required.

Patent Ductus Arteriosus

Premature infants, particularly ELBW infants, have a significant incidence of persistent PDA, a vascular connection between the aorta and pulmonary artery (Dollberg, Lusky, & Reichman, 2005). Reliable diagnosis of PDA in the first 4 days of life depends on echocardiography because of poor specificity of clinical signs (e.g., murmur, wide pulse pressure, bounding pulses, and increased precordial activity; Skelton, Evans, & Smythe, 1994). A cardiac murmur is more reliable after this time (Skelton et al., 1994). Metabolomics entails the measure of low molecular weight metabolites to determine the phenotype of a cell, tissue, or organism. Preliminary findings suggest that "the metabolomics analysis of the first urine passed by preterm infants can predict the persistent patency of the ductus arteriosus at 3 to 4 days of life, as demonstrated by echocardiography performed by an expert cardiologist" (Fanos, Antonucci, Barberini, Noto, & Atzori, 2012). Consequently, metabolomics may facilitate diagnosis of PDA (Fanos et al., 2012).

In a small proportion of ELBW infants, the PDA may close spontaneously or persist without clinical consequences. Studies show that premature infants born less than 30 weeks' gestational age have a spontaneous closure of the PDA greater than 50% of the time (Herrman, Bose, Lewis, & Laughon, 2009; Schmidt et al., 2001; Van Overmeire et al., 2004). Nevertheless, approximately 55% of ELBW infants require pharmacologic treatment as they are symptomatic (e.g., evidence of left to right shunting, difficulty weaning mechanical ventilation, or increased mechanical support because of worsening pulmonary status; Koch et al., 2006; Richards, Johnson, Fox, & Campbell, 2009). Treatment decisions for a diagnosed PDA are based on the clinical significance or clinical effect, the criteria for which vary among neonatologists (Wyllie, 2003). Infants with persistent PDA experience increases in mortality and morbidities such as more prolonged and severe RDS, BPD, and NEC (Dollberg et al., 2005) that may be attributed to their prematurity or PDA (Koch et al., 2006). The use of pharmacologic intervention and surgical ligation has recently decreased in VLBW infants with PDA (Ngo, Profit, Gould, & Lee, 2017).

Prophylactic treatment circumvents the challenges of deciding whether or not a PDA is significant (Wyllie, 2003). Prophylactic administration of indomethacin, a nonselective cyclooxygenase, reduces the incidence of symptomatic PDA and the need for surgical duct ligation. Adverse effects of indomethacin, including NEC, excessive bleeding, or sepsis, were no different between preterm infants receiving prophylactic indomethacin and controls. The incidence of oliguria was increased; however, this was not associated with major renal impairment. Although prophylactic administration of indomethacin reduces the incidence of severe IVH, it did not improve neurodevelopmental outcomes (Fowlie et al., 2010; Schmidt et al., 2001). Furthermore, approximately 64% of preterm infants are medicated unnecessarily (Wyllie, 2003). Values attached by healthcare providers and parents to the benefits and

risks of prophylactic treatment with indomethacin will guide the implementation of this intervention (Fowlie et al., 2010). According to Fanos, Pusceddu, Dessì, and Marcialis (2011), indomethacin prophylaxis should be abandoned as it "unethically exposes newborns who will never have a persistent PDA to the side effects of drugs" and "cannot be recommended for the prevention of long-term morbidities and mortality, especially in centers where severe IVH is comparable to the national average and surgical complications are minimal." Similarly, ibuprofen, also a cyclooxygenase inhibitor, unnecessarily compromises the infant's renal and gastrointestinal systems without conferring benefits in those ELBW infants with spontaneous closure of PDA. Consequently, prophylactic ibuprofen is not recommended (Fanos et al., 2011; Ohlsson & Shah, 2011). Advantages of prophylactic surgical closure of PDA include reduced incidence of stage II and III NEC; however, no reductions were noted in mortality or BPD. Again, given the rate of spontaneous closure of PDA in ELBW infants and potential risks associated with surgery, prophylactic surgical closure is not recommended (Fanos et al., 2011; Ohlsson & Shah, 2011).

Both ibuprofen and indomethacin are effective in closing a PDA diagnosed either clinically or by echocardiogram at less than 28 days. No statistically significant difference was noted in failure of ductal closure, all causes of mortality, neonatal mortality, infant mortality, and common neonatal morbidities (e.g., BPD, IVH, ROP, and infection). Ibuprofen was deemed superior based on biochemical and physiologic data suggesting that it has less adverse effects on organs (e.g., kidneys, gastrointestinal system, and brain; Ohlsson, Walia, & Shah, 2010). Other interventions include fluid restriction and use of diuretics; however, there is little evidence to support their routine use in clinical practice (Wyllie, 2003). Furosemide, which increases prostaglandin production, is often given in conjunction with indomethacin to prevent indomethacin-related toxicity. Current evidence does not support this practice (Brion & Campbell, 2001). Surgical closure is undertaken when medical intervention fails or is contraindicated (Malviya, Ohlsson, & Shah, 2008; Wyllie, 2003).

Nursing care of the ELBW infants includes assessing, documenting, and reporting clinical signs of PDA such as bounding pulses, increased heart rate, and increasing pulse pressure (Koch et al., 2006). Nurses should monitor trends in oxygenation requirements and ventilation support in order to promote timely identification of infants with worsening pulmonary status. Reviewing weekly patterns will ensure that subtle increases in oxygen or ventilation needs over the course of a few days are not missed. Recording when radiographic examination(s) or echocardiograms have been ordered and completed will ensure findings are interpreted and treatment decisions are made promptly. Nurses should be familiar with contraindications of pharmacologic treatments for PDA to prevent or reduce risk of harm. ELBW infants receiving treatment should be monitored for oliguria, evidence of active gastrointestinal bleeding, platelet dysfunction, and spontaneous intestinal perforation. As such, clinical or biochemical (e.g., creatinine) changes should be reported, as this will assist the medical team to modify treatment regimens in ELBW infants experiencing complications secondary to treatment.

Hypotension

There is no uniform definition of hypotension in neonates. In research studies, hypotension is defined as any value that falls below the 5th or 10th percentile for gestational age and postnatal age (Kent & Chaudhari, 2013; Zubrow, Hulman, Kushner, & Falkner, 1995). Hypotension clinically manifests as low blood pressure, reduced cutaneous perfusion, and metabolic acidosis (Osborn & Evans, 2004). It is unclear what drop in blood pressure constitutes hypotension in ELBW infants (Ambalavanan & Whyte, 2003); hence, the threshold for treatment with crystalloids or cardiotropic medications varies among clinicians (Sehgal, 2011). A recent prospective study of infants born at less than 28 weeks' gestational age showed that hypotension in the first 24 hours following birth was not associated with ultrasound findings, suggesting cerebral white matter damage and diagnosis of cerebral palsy at 24 months CA (Logan et al., 2011). ELBW infants with hypotension but prior to treatment were found to have similar cerebral blood flow velocity as infants in the control group matched for gestational age and birth weight that had normal blood pressure (Lightburn, Gauss, Williams, & Kaiser, 2009). Sehgal (2011) asserts that hypotension alone may not reduce perfusion of organs such as the brain, heart, kidneys, and gastrointestinal system in ELBW infants.

Strategies for management of hypotension include volume expansion, inotropes, or corticosteroids (Osborn & Evans, 2004). Generally, corticosteroids are used as a last-chance therapy in managing hypotension (Ibrahim, Sinha, & Subhedar, 2011). Use of corticosteroids is supported based on our current understanding of pathophysiology (e.g., adrenocortical insufficiency, lower levels of cortisol concentration; Ibrahim et al., 2011; Sasidharan, 1998). In preterm infants without cardiovascular compromise, evidence does not support the routine use of early volume expansion (Osborn & Evans, 2004). Dopamine has been shown to be more effective than albumin (Osborn & Evans, 2004) and dobutamine (Subhedar & Shaw, 2003), but no firm recommendations can be made, as there is a paucity of evidence regarding effects on systemic oxygen delivery or cerebral perfusion and long-term benefit of dopamine (Barrington, 2011; Osborn & Evans, 2004; Subhedar & Shaw, 2003). According to Barrington (2011), the extremely low gestational age newborn (ELGAN) study published by O'Shea et al. (2009) demonstrates that treatment for hypotension (i.e., fluid boluses or inotrope/vasopressors) was not guided by the degree of illness or degree of hypotension but rather by "fashion and taste" (p. F317). Barrington (2011), based on the review of recent publications on hypotension in ELBW including the Logan et al. (2011) study, concluded:

- Many infants with low blood pressure have normal systemic flow.
- There is no clear evidence that infants with numerically low blood pressures but without evidence of shock have worsened outcomes.
- There is no evidence that treating numerically low blood pressures improves outcomes.
- There is no evidence base to determine the choice of one intervention over another (p. F317).

According to Sehgal (2011), in ELBW infants, multiple factors may contribute to hemodynamic instability (e.g., PDA, pulmonary vascular resistance, and myocardial function); as such, a varied approach to care may be more appropriate than consensus-based protocols. "A physiology-driven approach" framework is proposed using point-of-care echocardiography that will permit assessment of the ductus arteriosus, the muscles of the heart, and pulmonary and systemic hemodynamics. **Quality and Safety: Together with clinical context, this approach will help clinicians identify the etiology of cardiovascular compromise and permit individualized treatment decisions for ELBW infants** (Sehgal, 2011). Since clinical context will continue to be an important marker, nurses must systematically assess the ELBW infants' cardiovascular health by monitoring heart rate, capillary refill time, blood pressure, difference in pulse pressure, quality of pulses (i.e., bounding), presence of murmur(s), and precordial activity.

Fluid and Electrolytes

In ELBW infants, the first days after delivery are characterized by fluid shifts resulting from both physiologic changes and pathophysiologic events. "Physiologic weight reduction," the contraction of the extracellular compartment of body water, can be exacerbated as a result of insensible water loss (water lost from skin surface and the respiratory tract) and sensible water loss (water lost through urine and stool). Insensible water losses are extremely high and variable, making it challenging to predict total fluid intake. Given that the ELBW infant's kidneys have limited ability to compensate for varying water and solute intake (i.e., to adjust the concentration of urine), dehydration, fluid overload, and electrolyte imbalance are common events during the immediate postnatal period (Bell & Acarregui, 2008; Gaylord, Wright, Lorch, Lorch, & Walker, 2001; Lorenz, Kleinman, Ahmed, & Markarian, 1995).

A Cochrane systematic review concluded that restricted water intake in which physiologic needs are met reduced risk of PDA and NEC but increased postnatal weight loss. Since there was a trend toward an increased risk of dehydration, although the difference was not significant, it would be important to monitor infants closely for dehydration. **Emergency Alert: Certain complications such as BPD, IVH, and adverse events such as death were reduced with restricted fluid intake, though differences were not statistically significant when compared with liberal fluid intake** (Bell & Acarregui, 2008). Since ELBW infants were not well represented in this systematic review, a restrictive fluid management strategy cannot be universally applied to ELBW infants (Bell & Acarregui, 2008).

Some NICUs use swamping (piping highly humidified air into the isolette) when the infant is under a radiant warmer in an effort to reduce insensible water losses and promote thermoregulation. Incubators with the ability to regulate and deliver precise levels of humidification have been introduced in the NICU with the aim of reducing transepidermal water loss. Retrospective studies revealed that using humidified incubators in ELBW infants led to improved fluid management (Gaylord et al., 2001; Kim, Lee, Chen, & Ringer, 2010). High humidity is often provided to reduce water loss; however, the optimal level and duration of humidity remains unknown (Sinclair & Sinn, 2009). **Emergency Alert: High humidity may increase the risk of nosocomial infection in ELBW infants who are already compromised. New incubators have advanced systems of humidification (e.g., sterile humidity in gaseous vapor state) to minimize risk of infection.** High humidity may decrease the amount of light energy or irradiance delivered by phototherapy devices and thus may reduce the efficacy of phototherapy treatment (de Carvalho, Torrao, & Moreira, 2011).

Fluid requirements of ELBW infants must be monitored closely by nurses, as fluid disturbances can affect overall risk of death (Bell & Acarregui, 2008) and exacerbate morbidities such as PDA, congestive heart failure (Bell, Warburton, Stonestreet, & Oh, 1980), NEC, and BPD (Bell & Acarregui, 2008). **Quality and Safety: Daily weights, regular monitoring of electrolytes, strict documentation of fluid intake and output, cumulative fluid balance recordings, and graphic trends of growth should be maintained to facilitate decisions related to fluid management in ELBW infants.** ELBW infants receiving high humidity, as well as those receiving phototherapy, should be observed closely for signs and symptoms of infection. The irradiance of light should be monitored on an ongoing basis to ensure effectiveness of phototherapy treatment.

Metabolic Considerations

In ELBW infants, maintaining normoglycemia is difficult because of insufficient glycogen stores, stress, high metabolic rates, and variability in fluid requirements. Parenteral nutrition further elevates the risk of hyperglycemia and hypoglycemia in ELBW infants (Arsenault et al., 2012). **Emergency Alert: Hyperglycemia has been associated with increased risk of death** (Hays, Smith, & Sunehag, 2006; Kao et al., 2006), **IVH** (Hays et al., 2006), **NEC, late-onset sepsis** (Kao et al., 2006), **and prolonged hospital stay** (Hays et al., 2006). Routine use of insulin infusions to prevent hyperglycemia reduced the risk of hyperglycemia in VLBW infants, as well as ELBW infants. However, the systematic review concluded that given the increased risk of death before 28 days and hypoglycemia, routine use of insulin infusion to prevent hyperglycemia is not recommended (Sinclair, Bottino, & Cowett, 2011). At present, there is no consensus regarding cutoff values for hypoglycemia, or any strong evidence to provide guidance about specific approaches to treatment (Arsenault et al., 2012). **Quality and Safety: A blood glucose concentration persistently less than 36 mg/dL (2.0 mmol/L) or, in a symptomatic infant, a blood glucose concentration less than 45 mg/dL (2.5 mmol/L) is considered an indication for clinical intervention** (Cornblath et al., 2000; Kalhan & Devaska, 2011). If an infant has low blood sugar and requires intravenous glucose, it is preferable to administer 10% dextrose slowly at 2 mL/kg in order to reverse the hypoglycemia. Rapid or high-concentration boluses are not advisable, because rebound hypoglycemia can occur. There are a number of additional causes of hypoglycemia that may need individualized management (e.g., hyperinsulinism). Clinical management of hypoglycemia and hyperglycemia with devices such as the continuous glucose-monitoring sensor may prove beneficial in ELBW infants but still needs more validation in NICUs (Beardsall, Ogilvy-Stuart, Ahluwalia, Thompson, & Dunger, 2005). In a recent guideline for the management of hypoglycemia in newborns from the Canadian Neonatal Network, it has been recommended that asymptomatic, at-risk babies receive at least one effective feed before a blood sugar check at 2 hours of age, every 3 to 6 hours after this, and should be encouraged to feed regularly (Aziz, Dancey, & Canadian Paediatric Society, Fetus and Newborn Committee, 2004). **Quality and Safety: At-risk babies with regular feeding who repeatedly have low blood sugar of less than 2.6 mmol/L should be considered for intravenous therapy** (Aziz et al., 2004). Blood sugar testing may be discontinued after 12 hours in large for gestational age (LGA) infants and in infants of diabetic mothers if blood sugar levels remain at greater than or equal to 2.6 mmol/L. In SGA and preterm infants, once the feeding is established and blood sugar remains at 2.6 mmol/L or higher for 36 hours, there is no need to continue blood sugar estimation.

Nutrition

In ELBW infants, endogenous nutritional stores are limited as their bodies are primarily water. These endogenous nutritional stores are quickly depleted under conditions of starvation as metabolic needs are high. As a result, early nutrition is imperative to ensure the infants' continued survival. Nourishing ELBW infants is an important clinical concern, particularly in the first weeks of life, as significant nutritional deficits (e.g., protein and energy) may accrue over the hospitalization, resulting in postnatal or extrauterine growth restriction (Ehrenkranz, 2010; Ehrenkranz et al., 2006; Embleton, Pang, & Cooke, 2001). Early patterns of growth have been shown to have an independent effect on growth and neurodevelopment, including cognition and behavior (Ehrenkranz et al., 2006; Stephens et al., 2009; Ziegler, Thureen, & Carlson, 2002). ELBW infants are at an increased risk for poor somatic growth, with the poorest growth being seen in those infants who have comorbidities (e.g., feeding problems, respiratory illness, neurologic and developmental difficulties; Wood et al., 2003). **Emergency Alert: Malnutrition also impacts the structure**

(e.g., reducing number of replication cycles, reducing total brain DNA and connections between neurons and limiting arborization) and function (e.g., neurotransmitter levels) of the brain and development of the retina (Uauy & Mena, 2001).

Although little is known about the optimal requirement and quality of nutrition, nutritional goals for ELBW infants include weight gain that is similar both in rate and composition to the normal fetus at the same PMA (Adamkin, 2006). Early aggressive nutrition, defined as providing nutrition at or beyond the established standards (Ziegler et al., 2002), has been the focus in hopes of promoting adequate nutrition and limiting the negative consequences associated with nutritional deficits. Given that ELBW infants may be slow to tolerate the introduction of enteral feeds because of delayed gastric emptying and immaturity of intestinal motor activity, aggressive parenteral nutrition should be established soon after birth (within a few hours; Ziegler et al., 2002). Parenteral nutrition with 2.5 to 3.0 g/kg/day protein intake should be the target, with a stepwise increase commencing when energy intakes reach 70 kcal/kg/day. Protein requirement of about 4 g/kg/day is believed to be physiologic, and increased blood urea nitrogen suggests effective utilization of amino acids and is in keeping with the high fetal urea productions noted in the human fetus (Adamkin, 2006; Ziegler et al., 2002). However, this higher amount of protein is necessary when enteral nutrition is not provided for long periods of time and should be used with care as efficacy and safety have not been examined in a systematic way (Ziegler et al., 2002). Provision of high-protein and energy intake to ELBW infants was shown to limit catabolism and improve both growth and neurodevelopmental outcomes in ELBW infants (Maggio et al., 2007; Stephens et al., 2009).

Intravenous lipids should be commenced within 24 hours of birth as this provides essential fatty acids and an exogenous source of long-chain polyunsaturated fatty acids. ELBW infants are prone to essential fatty acid deficiency as they have little adipose tissue at birth and are unable to produce adequate amounts of long-chain polyunsaturated fatty acids (Uauy & Mena, 2001; Ziegler et al., 2002). Twenty percent lipid emulsion should be started by 24 hours of age, usually at a rate of 0.5 to 1 g/kg/day and increased by 0.5 g/kg/day every 24 to 48 hours up to 3 g/kg/day while monitoring triglyceride levels. Although lipid emulsions can displace bilirubin from albumin-binding sites, slow infusion rates (<150 mg/kg/hour) combined with slow increases in stepwise fashion to 3.0 g/kg/day should limit adverse effects (Ziegler et al., 2002). Aggressive intake of amino acids and intralipid administration of 3.5 g/kg/day of amino acids and 3 g/kg/day of intralipid are being advocated immediately after birth (within 1 hour) in VLBW infants and have been shown to be effective and safe (Ibrahim, Jeroudi, Baier, Dhanireddy, & Krouskop, 2004).

Use of trophic feeding or minimal enteral nutrition, defined as small-volume feeding of less than 24 mL/kg/day shortly after birth, is intended to achieve a biologic effect on the gastrointestinal system of VLBW infants in whom nutritional feeding is delayed (Bombell & McGuire, 2009). Although trophic feeding is well supported based on our understanding of the anatomic and physiologic disadvantages of delaying feeding (Premji, Paes, Jacobson, & Chessell, 2002), there is insufficient evidence regarding beneficial or harmful effects to make recommendations to inform clinical practice. Initiating trophic feedings within 48 hours of birth permits assessment of physiologic stability in ELBW infants (Premji et al., 2002). For ELBW infants, the continuous tube feeding method may be more energy efficient, as a subgroup analysis of infants included in a systematic review suggested that infants weighing less than 1,000 g gained weight significantly faster when fed by this method (Premji & Chessell, 2011). Further research is required to discern the benefits and risk of continuous tube feeding methods in ELBW infants.

Feeding ELBW infants while on noninvasive ventilation is challenging as evidence from clinical trials is lacking. However, in a recent observational quality improvement study, it was found that "Safe Individualized Nipple-Feeding Competence" (SINC) is feasible in ELBW and VLBW infants (Dalgleish, Kostecky, & Blachly, 2016). Using this SINC algorithm, 38% and 26% of the infants on the study received their first breastfeed or bottlefeed, respectively, while on nasal CPAP (Dalgleish et al., 2016).

ELBW infants are at increased risk of NEC, and earlier studies have demonstrated an association between timing of enteral feeding and rapid increases in feedings and NEC. Current evidence provides limited guidance regarding the effect of delayed (i.e., no advancement in first 5 days) versus earlier progression of feeding beyond trophic feeds on clinical outcomes in VLBW infants (Morgan, Young, & McGuire, 2014). Furthermore, slow advancement of feedings (i.e., 15–20 mL/kg) in VLBW infants results in delay in regaining birth weight and reaching full enteral feedings and does not reduce the risk of NEC. Numerous detrimental effects of total parenteral nutrition are cited in the literature, including metabolic complications, infection, and changes in the structural integrity and function of the gastrointestinal system. Consequently, more studies need to examine advancing feeding volumes in ELBW infants. Given that information regarding safety is unclear, a feeding advancement of not more than 30 mL/kg/day has been advocated (Premji et al., 2002). Refinement of feeding strategies that facilitate quick transition from parenteral to minimal enteral nutrition to progressive enteral nutrition and advancement of feedings that meet the specific needs of ELBW infants should be the focus of future research.

Human milk is considered the best feeding substrate for premature infants as it confers biologic (e.g., easier to digest and absorb), immunologic (e.g., lower rate of infection and incidence of NEC), and developmental (e.g., improved intelligence quotient) advantages (Lucas & Cole, 1990; Lucas, Morley, Cole, Lister, & Leeson-Payne, 1992; Schanler, 1995). A cohort study of 1,035 ELBW infants reported higher MDI scores at 18 months CA in infants who received more breast milk versus formula during hospitalization in the NICU (Vohr et al., 2006). However, preterm human milk does not have sufficient quantities of protein, sodium, phosphate, and calcium to meet estimated needs for growth. Fortification of human milk is therefore essential to maintain adequate growth, nutrient retention, and biochemical homeostasis (Atkinson, 2000; Schanler, 1995). Commercially available fortifiers come in liquid or powder form. Potential complications of fortification include distended abdomen, increased osmolarity, and bacterial contamination. In a systematic review, protein supplementation of human milk in relatively healthy preterm infants resulted in short-term growth; however, the adverse effects of protein supplementation could not be discerned (Kuschel & Harding, 2000). Nurses can support mothers to express breast milk soon after birth, as well as assist mothers to maintain adequate milk supply by encouraging mothers to pump at least 8 to 12 times in a day. Strategies such as kangaroo care, which may facilitate milk production and growth of the infant, should be routine aspects of care.

Currently, there is controversy with respect to concurrent feeding and indomethacin therapy. The reduced mesenteric diastolic blood flow associated with indomethacin therapy may be counteracted by minimal enteral nutrition, thereby exerting a protective influence on the gastrointestinal system. However, clinical practice varies between units, with some following the conventional wisdom of withholding enteral feeding during indomethacin therapy to prevent NEC (Premji et al., 2002). A recent randomized controlled trial showed that infants who were receiving indomethacin or ibuprofen treatments and also receiving trophic enteral

feeds required less time to reach to the feeding volume endpoint (Clyman Pediatrics, 2013).

Patole and de Klerk (2005) propose that clinical variation in practice determines risk of NEC. Neonatologists' lack of comfort with initiating and advancing protein and energy intake contributed to significant differences in practices, despite instituting guidelines for aggressive protein and energy intake (Stephens et al., 2009). Nursing management of feeding is also inconsistent, and variability in the practice of withdrawing feeding and management of feeding residuals (Hodges & Vincent, 1993) and selection of feeding route (e.g., nasogastric vs. orogastric) (Birnbaum & Limperopoulos, 2009) has been shown. A better understanding is required of nursing practice related to tube feeding in order to facilitate a standardized systematic evidence-based approach founded on the current state of scientific knowledge (Premji, 2005).

Physiologic, behavioral, and neurologic immaturity contributes to feeding problems experienced by ELBW infants. **Quality and Safety: A prerequisite to safe and successful oral feeding is effective sucking behavior and intact gag and cough reflexes** (Medoff-Cooper & Ray, 1995; Shaker, 1990). Transitioning ELBW infants from tube feeding to oral feeding is a major challenge for nurses, as no criteria exist to guide practice (Hawdon, Beauregard, Slattery, & Kennedy, 2000; Pickler & Reyna, 2003), and hence the practice is variable and based on custom (McCain, Gartside, Greenberg, & Lott, 2001). An evidence-based neonatal oral feeding protocol has been developed to create positive feeding experiences while assisting high-risk infants to achieve full oral feedings (Premji, McNeil, & Scotland, 2004). Infant characteristics (not postconceptional age) are the primary determinants used to plan physiologically appropriate feeding experiences for each stage—preoral stimulation, nonnutritive sucking, and nutritive sucking—of progression to oral feeding. The mainstay of this protocol is a professional resocialization in the way nurses view and engage in feeding interactions, with emphasis on the quality of the feeding interaction rather than the quantity of milk consumed by the infant. For continued improvement in nutritional management of ELBW infants, it is imperative that nurses engage in protocol appraisal and self-appraisal of practice, and that they review new evidence.

Gastroesophageal Reflux

Another complication related to digestion is GER disease, a maturational phenomenon caused by transient lower esophageal sphincter relaxation (Ambalavanan & Whyte, 2003; Omari et al., 2004). Placement of a feeding tube across the gastroesophageal junction has been shown to increase the incidence of GER (Peter, Wiechers, Bohnhorst, Silny, & Poets, 2002). Other factors that may influence the presence of GER include supine position and large volume of fluid intake. Clinical signs of GER include visible regurgitation, and infants may cry, be irritable, or have altered sleeping patterns (e.g., remain awakened; Poets & Brockmann, 2011). GER is also considered a risk factor for aspiration and subsequent pneumonia (Ambalavanan & Whyte, 2003). The association between BPD and GER is thought to be due to greater diagnostic suspicion in infants with chronic lung disease (Fuloria, Hiatt, Dillard, & O'Shea, 2000; Poets & Brockmann, 2011). GER does not appear to increase the risk of delayed growth (<10th percentile) or development (Bayley Mental Developmental and Psychomotor Developmental Indices of <70) in VLBW infants (Fuloria et al., 2000). GER is considered pathologic based on the quality rather than quantity of the refluxate (Poets & Brockmann, 2011). GER is difficult to diagnose, as current techniques of esophageal pH monitoring cannot reliably detect GER in preterm infants. This is because frequent feeding causes esophageal acidification to pH less than 4 (Grant & Cochran, 2001; Omari et al., 2004). Consequently, the contribution of GER to neonatal morbidity and the efficacy of therapies for GER are difficult to evaluate.

The association between GER and AOP is biologically plausible as the refluxate can stimulate laryngeal chemoreceptors; hence, it is not surprising that studies (Omari, 2009) have demonstrated a relationship between GER and apnea. There are studies (Peter, Sprodowski, Bohnhorst, Silny, & Poets, 2002) that also show no temporal relationship between apnea and GER in preterm infants (Peter, Sprodowski, et al., 2002). Poet and Brockmann (2011) concluded, given the lack of consistent evidence and the fact that antireflux medications have not been useful in managing AOP, that apneas are not related to GER.

At present, there is lack of consensus with regard to optimal management of GER in ELBW infants, as there are few randomized controlled trials to guide practice (El-Mahdy, Mansoor, & Jadcherla, 2017). Pharmacologic measures (e.g., metoclopramide, domperidone; Ambalavanan & Whyte, 2003) should be used sparingly, as the consequence of GER remains to be established in ELBW infants (Poets & Brockmann, 2011). Though prokinetic reflux medications improve the lower esophageal sphincter basal pressure, lower esophageal peristalsis, and increase esophageal acid clearance and gastric emptying, they have some adverse effects including ventricular arrhythmias, extrapyramidal effects, and prolonged QT interval especially with domperidone (El-Mahdy et al., 2017). The use of metoclopramide is now obsolete in neonatology due to its side effects such as dystonic and dyskinetic reactions (El-Mahdy et al., 2017). It is advisable to perform ECG before and after starting domperidone in neonates to assess for prolonged QT interval and associated arrhythmias. The use of H_2 receptor antagonist and proton pump inhibitors for a long time period may cause serious side effects such as bacterial colonization, community acquired pneumonia, diarrhea, and increased bone fractures (El-Mahdy et al., 2017). Prone and left lateral positioning have been shown to reduce the number and duration of reflux episodes (Corvaglia et al., 2007; Ewer, James, & Tobin, 1999).

Anemia

The primary cause of anemia, particularly in the first 2 weeks of life, is phlebotomy losses resulting from intensive laboratory testing. Other causes include an inability to increase erythropoietin concentration and erythropoiesis, and severely limited blood volume based on body weight (Ohls, 2002). In the preterm infant, typically there is a physiologic fall in hemoglobin and hematocrit levels by approximately 6 weeks of age. The decline in hematocrit in ELBW infants is associated with clinical findings necessitating packed red blood cell transfusion, and hence is not considered "physiologic" (Aher & Ohlsson, 2014). It is uncertain what hematocrit levels precipitate clinical signs of anemia of prematurity and what is the minimal acceptable level for infants requiring ventilatory support (Ohls, 2002). Low hemoglobin and hematocrit levels often guide decisions regarding blood transfusion (Aher & Ohlsson, 2014). Based on the premature infants in need of transfusion (PINT) study and a Cochrane review, the need for transfusion should be based on the individual targets for patient's health rather than based on using low threshold hemoglobin levels (Kirpalani et al., 2006; Whyte & Kirpalani, 2011). Neither study found any difference in the outcomes (death or disability) based on the low threshold criteria (Kirpalani et al., 2006; Whyte & Kirpalani, 2011). As a result of more stringent transfusion guidelines (i.e., lower threshold for transfusion), the number of blood transfusions have decreased over the past decade (Maier et al., 2000). No statistically significant differences were noted in death

or neurodevelopmental impairment between those maintained at low hemoglobin levels (i.e., restrictive) versus those with high hemoglobin levels (i.e., liberal). Although infants in the restrictive group had lower hemoglobin levels in the first few weeks of life, at 18 months CA, these differences were no longer evident (Whyte et al., 2009). Post hoc analysis, however, revealed significantly higher rates of cognitive delay (i.e., MDI score <85) in the restrictive hemoglobin group (Whyte et al., 2009). In contrast, a retrospective study of ELBW infants revealed that the number of blood transfusions was significantly associated with severity of ROP (Englert, Saunders, Purohit, Hulsey, & Ebeling, 2001). Other benefits of reducing the number of packed red blood cell transfusions include reduced risk of transmission of viral infections, reduced risk of incompatibility, and reduced cost (Aher & Ohlsson, 2014).

Delayed cord clamping (DCC, optimally for 30–180 seconds) for preterm infants has some beneficial effects, especially reducing the number of blood transfusions these infants require (Lemyre, Sample, Lacaze-Masmonteil, & Canadian Paediatric Society, 2015). In a systematic review and meta-analysis of DCC versus immediate cord clamping (ICC) in preterm infants, Fogarty et al. (2018) found that infants who were in the DCC group received 10% less blood transfusions compared to those in the ICC group.

A meta-analysis reported that administration of recombinant erythropoietin in the first week of life resulted in a moderate reduction in the proportion of VLBW infants requiring blood transfusion. Subgroup analysis revealed that ELBW infants were less likely to avoid transfusion if treated with recombinant erythropoietin (Kotto-Kome, Garcia, Calhoun, & Christensen, 2004). As per Canadian Pediatric Society recommendations, routine use of erythropoietin is not recommended (Lemyre, Sample, Lacaze-Masmonteil, & Canadian Pediatric Society, Fetus and Newborn Committee, 2015). A recent Cochrane systematic review also concluded that early erythropoietin, that is, administration of erythropoietin before 8 days of age, is not recommended as there is no strong evidence for its neuroprotective role: no impact on mortality, limited clinical importance of reduction in blood cell transfusions, volume of red blood cells transfusions, and significant increase in the rate of ROP (stage ≥3; Aher & Ohlsson, 2014). Consequently, strategies or interventions (e.g., point-of-care devices) that reduce phlebotomy losses and blood transfusions throughout the infant's hospital stay warrant further investigation (Madan et al., 2005; Moya, Clark, Nicks, & Tanaka, 2001). Additionally, the nurse can act as an advocate to eliminate unnecessary laboratory monitoring.

Infection

Infections are frequent complications of ELBW infants, with approximately 50% to 65% of infants having at least one infection during hospitalization. There are multitudes of nonspecific signs and symptoms of sepsis, namely, temperature instability, apnea and bradycardia, feeding intolerance, abdominal distention, lethargy, septic shock, and increased need for oxygen or ventilatory support (Craft, Finer, & Barrington, 2000). Infection rates increase with decreasing birth weight and gestational age and are associated with increased mortality and poor neurodevelopmental and growth outcomes in childhood (Schlapbach et al., 2011; Stoll et al., 2004; Tolsma et al., 2011). The ELGAN study, which followed 1,059 infants born at less than 28 weeks' gestational age, identified definite late neonatal bacteremia as an independent risk factor for ROP (Tolsma et al., 2011).

Early-onset infection (before 72 hours) is due to maternal factors (congenital) and is uncommon, but can be life threatening (Ambalavanan & Whyte, 2003). Risk of early-onset sepsis (e.g., *group B streptococcal* infection) may be decreased with intrapartum antibiotic prophylaxis, but there is concern that it may mask infection, with onset of signs of sepsis taking longer. In almost all ELBW infants, antibiotics (ampicillin or penicillin and aminoglycoside) for suspected sepsis are initiated after birth, and if the infant is asymptomatic and culture is negative, antibiotic therapy is discontinued after 48 to 72 hours. It is unclear what impact the frequent and empiric use of antibiotics has on the incidence and resistance pattern of late-onset bacterial infection (Ambalavanan & Whyte, 2003). Prior use of broad-spectrum antibiotics has been associated with invasive candidiasis, which in ELBW infants may be fatal, ranking second among the leading causes of infection-related deaths in ELBW infants (Benjamin et al., 2010). A recent study indicated that just by observing clinical presentations in neonates as a part of the management, the need for antibiotics in chorioamnionitis-exposed infants has been dramatically reduced (Joshi et al., 2018). Guidelines for early-onset sepsis recommending limited use of broad-spectrum antibiotics, as well as reduced duration of treatment, were found to be effective (i.e., did not "increase the risk of infectious relapse") when implemented for infants less than 35 weeks' gestational age, as well as near-term and term infants. Their efficacy and safety need to be established in ELBW infants (Labenne, Michaut, Gouyon, Ferdynus, & Gouyon, 2007). The use of a web-based sepsis risk calculator in the daily clinical practice in NICU may significantly reduce the use of antibiotics and laboratory testing in the early-onset sepsis and may prevent antibiotic-resistant organisms (Dhudasia, Mukhopadhyay, & Puopolo, 2018). After use of this calculator, empirical antibiotics use among newborns within 72 hours of life has dramatically decreased by 42% and laboratory testing declined by 82% (Dhudasia et al., 2018). The use of biomarkers including procalcitonin and interleukin-8 have greater than 80% predictability in detecting early-onset sepsis (Nakstad, 2018). However, these markers are not routinely used in the modern NICUs due to various feasibility and budgetary reasons.

Late-onset sepsis (after 72 hours), referred to as nosocomial infection, is an acquired infection with *coagulase-negative staphylococci* being the most common cause of bacteremia (Craft et al., 2000). According to Craft et al. (2000), the risk of acquired infection is high because ELBW infants have an immature immune system; they often lack the protection of passive immunity, they have poor epidermal and gastrointestinal barrier function, and they may have central arterial or venous catheters (e.g., umbilical lines and percutaneous central venous catheters). In a large prospective cohort study, infections among ELBW infants were associated with poor neurodevelopmental outcomes (Cerebral palsy; range of odds ratios [Ors: 1.4–1.7], MDI [Ors: 1.3–1.6], and PDI [Ors: 1.5–2.4]) and poor growth outcomes at 18 to 22 months CA (Stoll et al., 2004). In another study, preterm infants born at less than 28 weeks' gestational age who had late-onset sepsis during postnatal weeks 2 to 4 have been shown to be at higher risk of low IQ at school age (Bright et al., 2017). The adverse long-term outcomes in preterm infants with sepsis with other morbidities like NEC or BPD may become higher compared to sepsis alone (Adams-Chapman, 2012).

Evidence-based practices that prevent or control the spread of bacterial and viral infections such as hand hygiene are not always adhered to in practice. These variations in practice may explain the different rates of infection reported in the literature by different NICUs (Higgins, Baker, & Raju, 2010). In ELBW infants, oral lactoferrin may reduce the incidence of late-onset sepsis (Pammi & Abrams, 2011), while pentoxifylline given as an adjunct to antibiotic treatment may reduce mortality without adverse effects (Haque & Pammi, 2011), but more research is required before these strategies can be routinely adopted in practice. Similarly, vancomycin for prophylaxis against sepsis has been found to be

effective in reducing the incidence of sepsis, although further research is required as organisms may develop resistance to vancomycin (Craft et al., 2000).

Skin breakdown, another pathway for infection, occurs more frequently in ELBW infants, and it is proposed that topical ointment therapy may serve as a protective barrier leading to improved skin integrity and a decreased risk of nosocomial infection (Conner, Soll, & Edwards, 2004). **Quality and Safety: Application of a preservative-free emollient ointment improves skin condition and reduces transepidermal water loss, but is associated with adverse outcomes.** The risk of *coagulase-negative staphylococcal* infection and any nosocomial infection (e.g., bacterial and fungal organism) increased with the application of ointment (Conner et al., 2004). Other potential strategies to minimize skin breakdown, thereby reducing the risk of infection, include use of as little tape as possible, and changing the infant's position frequently to prevent abrasions and pressure areas. It is important to remember that other treatments, procedures, and conditions may aggravate the problem (e.g., steroid therapy; use of blood products, leading to thrombocytopenia or lymphocytopenia; invasive procedures; changes in the pH of the skin as a result of bathing practices). Renal function is compromised in ELBW infants. It is imperative that nurses give medications (particularly nephrotoxic drugs such as gentamicin) with careful consideration of renal function. If renal function is compromised, a toxic level of this drug can be reached quite quickly, leading to permanent renal and auditory damage. The nurse should consider where the drug is metabolized and cleared through the body. If the site is the renal system and if output is severely diminished, use of the medication may need to be suspended temporarily.

Given the spectrum of issues that may be encountered by an ELBW infant, an individualized approach to care is crucial. Consistent and sound clinical reasoning based on history and physical examination, comprehensive data (e.g., essential laboratory findings), and knowledge (e.g., research evidence) should guide nursing practice decisions. Moreover, parents' wishes should be considered in making judgments about best practices, as they hold the ultimate moral and legal authority to make decisions about the infant's treatment. The ethical imperative is shared decision making (Penticuff & Arheart, 2005).

FAMILIES OF ELBW INFANTS

The birth of an ELBW infant generates a cascade of parental emotions and fears beginning with decisions related to resuscitation and to uncertainty regarding survival of the infant (Sydnor-Greenberg & Dokken, 2000). An interpretive phenomenologic analysis of mothers' lived experience of giving birth to an ELBW infant revealed that "being the mother" entailed being worried and scared about the uncertainty of the outcome and thinking the worst (Schenk & Kelley, 2010). Parental grief over the death of an ELBW infant, loss of a desired child, loss of pregnancy, or past losses may be adversely influenced by external factors. Nursing behaviors can influence this grief, which is a multidimensional complex process (Golish & Powell, 2003; Sydnor-Greenberg & Dokken, 2000).

Effective communication that incorporates support (physical or social) and teaching will assist parents to find their own unique paths to meaningful involvement (Sydnor-Greenberg & Dokken, 2000). It is important that nurses realize that there will be individual differences depending on the race, religion, nationality, and cultural background of the families. Although it may seem daunting at times, nurses should attempt to accurately interpret and respond to various behaviors by parents to facilitate meaningful involvement in caring for their infant (Sydnor-Greenberg & Dokken, 2000). Principles of family-centered care combined with principles of developmental care are an excellent framework to encourage families to participate as fully as possible in caring for and making decisions about their infant, and to form mutually beneficial and supportive partnerships in the NICU (Lester et al., 2011). A new family-centered program called Family Integrated Care (FICare) and its role in the NICU was recently studied in level III NICUs (O'Brien et al., 2017). The study empowered parents to become the primary caregivers to their infants and resulted in improved outcomes for both families and infants (O'Brien et al., 2017).

A crucial element in caring for ELBW infants is to engage families to participate collaboratively in deciding on appropriate care. The ability of the families to understand accurately their infant's medical condition, prognosis, and treatment options depends on the healthcare professional's ability to take a participatory approach to care (Penticuff & Arheart, 2005).

SUMMARY

This chapter presented a brief overview of the mortality and morbidities associated with being born ELBW, care required for the problems encountered by ELBW infants, and potential areas for future research. There are many unknowns; however, there is hope: a trust in the future of life. Nurses, physicians, other healthcare providers, and parents can make a difference if they are aware of the potential problems and know how to detect or recognize them early.

CASE STUDY

Michael was born at 23 weeks' gestational age by VD to a 23-year-old G2 P1 mother HBsAg-negative, VDRL nonreactive, GBS-negative after failed tocolysis × 3 hours. Apgars 2/8. Intubated and given surfactant in DR. Transported to NICU in incubator.

■ Admission Assessment

- GENERAL: 778 g, TPR: 96, HR 168, RR 60 (ventilated), BP 24
- SKIN: mottled, cool, extensive bruising on both legs
- HEENT: normocephalic, fontanelle soft and flat, palate intact
- NECK: no masses, clavicles intact
- LUNGS: BBS equal, coarse rales
- CV: RRR, no murmur, CFT 4 seconds
- ABD: soft, flat, liver palpable at RCM, UAC in place, two arteries, one vein visible
- GENITALIA: normal preterm male genitalia, patent anus
- EXT: moves all extremities, pulses × 4
- NEURO: poor tone, AGA 23 weeks
- IMPRESSION: 23-week, preterm AGA, male newborn with respiratory distress

■ Questions to Consider

What is the first differential diagnosis for Baby Michael?
Respiratory distress syndrome secondary to surfactant deficiency versus sepsis versus hypothermia
What will the initial management plan include?

1. Ventilatory support at lowest settings needed to maintain oxygenation; wean as possible using O_2 saturations and arterial blood gas (ABG)
2. Incubator with temperature and humidity control

3. IV fluids
4. Monitor blood pressure; consider bolus
5. Ampicillin and gentamicin
6. Talking to parents

What diagnostic tests will likely be ordered?

1. CBC with differential
2. Blood culture
3. ABG
4. Bedside glucose
5. Blood chemistries, bilirubin levels
6. Chest x-ray

On day 2 of life, Michael's parents ask you, "Is he going to be okay?" What would you tell them?

There is no answer to this question, because we don't know all the answers. That is a good way to begin your answer. The editors hope that reading this book will better prepare you to answer these and other questions.

EVIDENCE-BASED PRACTICE BOX

Use of Human Milk in the Early Neonatal Period

Human milk is recognized as the ideal nutrition for preterm neonates because of the protection it confers to ELBW infants through its biologic and immunologic properties (Higgins et al., 2012). For ELBW infants, prevention of NEC is important, as it is a leading cause of mortality and morbidity. Neonates fed human milk have lower rates of NEC overall and those who develop NEC have lower mortality and late-onset sepsis, compared to neonates fed preterm formula (Schanler, Lau, Hurst, & Smith, 2005; Vohr et al., 2007). Human milk has a dose–response relationship in reducing the risk of NEC in the first 14 to 28 days of life (Meinzen-Derr et al., 2009; Vohr et al., 2007). The amount of human milk received in early life is also related to health outcomes in later life (e.g., 30 months of age) in a dose–response fashion (Vohr et al., 2007). Slower weight gain in infants who were fed human milk did not preclude them from being discharged earlier (Schanler et al., 2005). Overall weight gain at 18 months was found to be no different in those receiving human milk when compared to those receiving formula in early life (Vohr et al., 2006). Human milk also reduces risk of atopy and rates of rehospitalization, and promotes developmental outcomes (Higgins et al., 2012; Vohr et al., 2007). Although donor human milk is associated with a lower risk of NEC when compared to formula feeding, no conclusions can be made given the quality of the evidence (Boyd, Quigley, & Brocklehurst, 2007).

PARENT VOICES

Jennifer Degl

What do nurses need to know about ELBW infants and their families? This is a very difficult question to answer because I have always felt as if I did not get to parent my micropreemie while she was in the NICU. I now know that I did what I could and I was parenting her as best that I could, given our situation. I did not get to hold her when she cried or feed her when she was hungry because my daughter (born at 23 weeks) had a feeding tube and went straight to the incubator after her birth. I was not able to touch her for a few days, and that's not what was "supposed" to happen. I had to

(*continued*)

(*continued*)

sanitize my hands before I stuck my finger in the opening on the side of the incubator. Parents are meant to touch their baby for the first time in this manner. Parents of healthy newborns get to hold their baby immediately after birth and then hold them as much as possible. But that was not our reality. I was not able to hold my daughter for one month, with the first time lasting only a few minutes. Parenting a baby in the NICU depends on the baby's individual medical needs and the parents' cultural traditions and comfort level. For over a month, I would open up the portal on the side of the incubator and talk and sing to my daughter while I was there. At first, I would speak in a very quiet voice, as I was nervous and shy around the staff and other parents in the room, but gradually I relaxed and became more comfortable with the staff and my new home, and I would speak to her in a normal voice so that she knew I was there. I learned how to participate in her care activities, like taking her temperature and changing her diaper every few hours. Eventually she could come out of the incubator for feeds and I would hold the vial of breast milk while she "ate," although she was tube-fed for months. While I really did not do much myself, these simple acts allowed me to feel more like her mother. This was a very different type of parenting than how I parented my other children, but I did what I could. It's not easy. Once they are comfortable with the NICU environment, I would suggest that parents ask the nurses about ways they can be more involved in their baby's care. NICU nurses can be very creative and will involve parents in the care activities when they can. Sometimes they just have to ask. This will encourage happier and more involved parents and it will also foster feelings of bonding.

Jenny R. McCormick

Walking into the NICU and meeting my incredibly tiny baby for the first time is an experience I will never forget. The myriads of machines, wires, and alarms are not only overwhelming, but left me with the intense gut-wrenching fear that this fragile new life might not make it home. The most natural tasks such as holding your baby, soothing, and caring for him/her become unnatural as you learn to do all of these things in a sterile and oftentimes chaotic environment. Nursing staff need to remember that most parents walking into the NICU are not walking in with a medical degree. The sights, sounds, smells, and watching your child grow outside of you are not only overwhelming experiences but also traumatizing. The simple act of holding a micropreemie is incredibly scary. Learning how to advocate for your preemie and develop the NICU lingo takes time. Patience is key. Empathy is everything.

Jennifer M. Driscoll

Our daughter, Lilian Hope, was born 7 weeks premature, weighing only 2 lb 12 oz and 15 inches long. Lily's lungs were her main problem, as they are for many preemies, because the lungs are the last thing to develop. On the day she was born, she was doing well, but still needed a continuous positive airway pressure (CPAP) machine to help her breathe. As the day progressed, her condition worsened. She was given nitric oxide, put onto a ventilator to breathe for her, and an oscillator to vibrate the lungs to help the flow of oxygen. Due to the force of the ventilator and oscillator, an air sac in her lungs burst and she had a chest tube inserted. Additionally, she had an erratic blood pressure and jaundice and needed multiple blood transfusions.

I remember a few days into her NICU stay, one of the nurses offered for me to help change her diaper and I remember feeling so scared. I don't have siblings and it had been years since I was a babysitter. I knew I would have to change a diaper, but I assumed it would be a big, happy, healthy baby's diaper I would be changing. I felt like I didn't know what I was doing. How do I change her preemie diaper that was WAY too big for her? How do I do it around her wires and tubes? How do I not hurt her? I did it . . . and remember feeling a connection to her because it was my first "mom" experience. The miracle continued as she began to gain strength inside herself; she came off the oscillator after 7 days and took out the ventilator herself. By day 8, a nurse offered for us to hold her for the first time. This was an incredible day, yet frightening and overwhelming at the same time because she still had tubes and wires hanging from her. It was an amazing feeling holding her, and we celebrated with our first family picture together.

These two tiny gestures by her nurses created the pathway to helping me feel more confident not only as a new mother, but also as a new mother caring for a sick baby.

CHAPTER 29

The Late Preterm Infant

Maureen F. McCourt

INTRODUCTION

Late preterm infants are infants born between 34-0/7 and 36-6/7 weeks, and are of increasing interest to medical providers caring for them throughout the country and around the world. In 2011, preterm births affected approximately 11.7% of all births with 71% being late preterm infants (Ramachandrappa & Jain, 2015).

There are two main etiologic categories of late preterm births, spontaneous late preterm births and babies born after induction of labor or cesarean section. Spontaneous late preterm births result from complications of preterm labor and premature rupture of membranes. Inductions of labor or cesarean sections are indicated for many fetal and maternal factors including maternal medical conditions, advanced maternal age, assisted reproductive techniques, multiple births, planned cesarean sections, and maternal request (Mohan & Jain, 2011).

Late preterm infants are larger in size than most premature infants, but they are proving to have many challenges associated with immaturity and delayed transition. These infants have higher rates of morbidity and mortality, as well as increased medical complications, neonatal intensive care unit (NICU) admissions, and prolonged hospitalization (Raju, 2017; Ramachandrappa & Jain, 2015). Late preterm infants require closer monitoring and specialized medical and nursing care for this higher risk population with stricter discharge criteria and follow-up care. These infants have a higher rehospitalization rate and long-term sequelae. Additional research is needed to gain a better understanding of late preterm infants. This knowledge will help to guide obstetrical and neonatal care to reduce the late preterm infant birth rate and provide specialized care to improve patient outcomes in the future (Raju, 2017; Ramachandrappa & Jain, 2015).

DEFINITION

Since 1950, the definition for premature infants has been infants born before 37 completed weeks' gestation (259th day), counting from the first day of the last menstrual period. This definition was established by the World Health Organization (WHO), and the American Academy of Pediatrics (AAP) and American Congress of Obstetricians and Gynecologists (ACOG) concur (Raju, Higgins, Stark, & Leveno, 2006). Within the premature infant category, there are subgroups with definitions including extremely preterm infants (infants <28 weeks' gestation) and very preterm infants (infants <32 weeks' gestation). However, there is less clarity regarding infants born between 32 and 37 weeks' gestation. In July 2005, the National Institute of Child Health and Human Development (NICHD) of the National Institutes of Health (NIH) defined late preterm infants as infants born between 34 0/7 and 36 6/7 weeks (Raju et al., 2006). In developing this definition, many factors were taken into account, especially 34 weeks' gestation being a maturational milestone in which surfactant is usually present. Labeling infants born between 34 0/7 and 36 6/7 weeks late preterm infants was critical in reminding caregivers that these infants are still premature and can develop physical and neurocognitive sequelae and will help discourage early elective deliveries and encourage specialized care optimizing outcomes (Horgan, 2015; Raju, 2017; Ramachandrappa & Jain, 2015; Shapiro-Mendoza & Lackritz, 2012).

INCIDENCE AND EPIDEMIOLOGY

There had been an increase in the preterm birth rate between 1981 and 2006 of 33% that has almost entirely been due to late preterm infant births. In 2008, 12.5% of all births in the United States were infants less than 37 weeks. Of these infants, 72% were late preterm infants born between 34 and 36 weeks. Vital statistics from 2013 to 2014 showed preterm birth rates declined for seven straight years; in 2014 they reached 9.57%, with the low birth weight unchanged at 8% (Murphy, Mathews, Martin, Minkovitz, & Strobino, 2017; Shapiro-Mendoza & Lackritz, 2012). However, for the last two years, premature birth rates in the United States have risen with late preterm infants contributing the largest part of this rise to 9.8% in 2017 (March of Dimes, 2017).

Of these late preterm births, multiple gestations have an elevated birth rate compared with singletons and triplet births as well as higher order birth rates that are decreased in 2014. Overall, between 2013 and 2014, the infant mortality rate decreased by 2.3%, the neonatal mortality rate decreased by 2.5%, and the perinatal mortality rate did not significantly change (Murphy et al., 2017; Shapiro-Mendoza & Lackritz, 2012).

ETIOLOGIC FACTORS CAUSING LATE PRETERM INFANT BIRTHS

The etiologic factors contributing to late preterm births are complex and multifactorial. There are two main categories leading to late preterm births: spontaneous late preterm births and induction of labor or cesarean section for maternal or fetal indications (Gyamfi-Bannerman, 2012; Mohan & Jain, 2011).

The first category, spontaneous late preterm births, relates to conditions where prevention of delivery is typically unavoidable. Maternal risk factors include preterm labor and premature rupture of membranes. This is especially prevalent when infection and inflammation are a concern. Research in the area of expeditious deliveries with preterm labor or PPROM versus expectant management to 37 weeks' gestation is ongoing (Gyamfi-Bannerman, 2012; Mohan & Jain, 2011). The second category includes late preterm births related to inductions of labor and cesarean sections for maternal or fetal indications. The indications for delivery in this group include preeclampsia, eclampsia, intrauterine growth restriction (IUGR), and planned cesarean sections. There has been a dramatic increase in cesarean sections due to increased fetal surveillance and interventions, increasing age of women giving birth, increase in multiple births due to fertility treatments, and heightened concerns of physicians and mothers regarding risks of vaginal births (Mohan & Jain, 2011).

Other factors that impact late preterm births include maternal medical conditions, advanced maternal age, assisted reproductive technologies, and multiple births, which are all associated with preterm births. Gestational age assessments and obstetric practice guidelines can also impact late preterm births. Inaccurate gestational age assessment during elective deliveries can lead to late preterm deliveries, especially with maternal obesity and gestational diabetes. In 2012, the ACOG recommended avoidance of nonmedically indicated early-term deliveries before 39 weeks. There was a decrease in late preterm births from 2006 to 2014 (Raju, 2017). Vink and Gyamfi-Bannerman (2017) have dedicated a two-part series in Seminars of Perinatology to use a diverse group of experts to provide the most up-to-date information from cutting edge research to decrease preterm births.

Decisions regarding obstetric intervention lie with risks and benefits of continuing the pregnancy versus early delivery. Understanding the risks of a suboptimal uterine environment and the risks of late preterm infants is critical to help guide optimal clinical decision making. Further research in this area is necessary to guide clinical practice (Shapiro-Mendoza & Lackritz, 2012).

PATHOPHYSIOLOGIC IMMATURITY OF THE LATE PRETERM INFANT

Late preterm infants can be deceiving: They appear to be larger and mature, but are in fact physiologically and metabolically immature. Their immature systems can predispose them to medical complications, with increased morbidity and mortality rates. A systematic review of their potential immature systems follows.

Respiratory System

Late preterm infants are at higher risk for an immature respiratory system. These infants are at risk for an immature lung structure associated with the interruption of the transition from alveoli lined with cuboidal type II and flat type I epithelial cells (terminal sac period) to mature alveoli lined with thin type I epithelial cells (alveolar period). This can be associated with delayed intrapulmonary fluid absorption, surfactant deficiency and insufficiency, as well as inefficient gas exchange. Late preterm infants are often delivered by cesarean section that occurs without the benefit of labor. Without labor, adrenergic and steroid hormones are not released, leading to a deficit in surfactant production and release. This leaves the late preterm infant at risk for respiratory disorders including transient tachypnea of the newborn (TTN), respiratory distress syndrome (RDS), persistent pulmonary hypertension of the newborn (PPHN), and respiratory failure (Ramachandrappa & Jain, 2015).

The late preterm infant can also have an increased risk of hypoxic respiratory depression, decreased central chemosensitivity to carbon dioxide, immature pulmonary irritant receptors, increased respiratory inhibition sensitivity to laryngeal stimulation, as well as decreased upper airway dilator muscle tone that can leave them at risk for apnea. Apnea in this group can also be due to centrally mediated apnea related to central nervous system immaturity (Ramachandrappa & Jain, 2015).

Cardiac System

There is less understanding of the cardiac pathophysiology in the late preterm infant. It appears these infants are at risk for cardiovascular structure and function immaturities, leading to decreased cardiac reserve during times of stress. There can also be delayed ductal arteriosus closure and persistent pulmonary hypertension, which can complicate their recovery from respiratory disorders (Ramachandrappa & Jain, 2015).

Metabolic System

Immaturities can leave the late preterm infants with decreased stores of brown-fat adipose and white adipose tissue, insufficient concentrations of hormones responsible for brown-fat metabolism, and a decreased surface area to body weight. This leads to an inability to generate heat combined with an increased loss of heat, leading to thermoregulation issues with resultant hypothermia (Ramachandrappa & Jain, 2015).

Late preterm infants have a decreased activity of hepatic uridine diphosphoglucuronate glycuronosyltransferase enzyme, which typically binds bilirubin to glucuronic acid, making it more soluble and more easily secreted in the stool and urine. These infants have a decreased stool frequency and are often dehydrated with a low urine output, making bilirubin excretion difficult. They also have an increased enterohepatic circulation related to immature gastrointestinal function and motility, with a decreased ability for hepatic uptake and conjugation of bilirubin. These factors leave late preterm infants at risk for elevated serum bilirubin levels, with resultant hyperbilirubinemia (Ramachandrappa & Jain, 2015).

Late preterm infants also have an immature hepatic glycogenolysis and adipose tissue lipolysis, as well as hormone dysregulation and less hepatic glyconeogenesis and ketogenesis. This leaves them less able to respond to the abrupt loss of maternal glucose after birth with resultant hypoglycemia (Ramachandrappa & Jain, 2015).

Gastrointestinal System

Immature feeding patterns are a common occurrence when introducing enteral feeds in the late preterm infant. This is related to low oral motor tone with lower intraoral pressure during sucking and neuronal immaturity with resultant poor coordination of suck and swallow patterns (Ramachandrappa & Jain, 2015). These infants also have decreased peristalsis and sphincter control in the esophagus, stomach, and intestines. These immaturities lead to a compromised nutritional status (Ramachandrappa & Jain, 2015).

Central Nervous System

Late premature infants are at risk for neurologic immaturity, with brain weights of only 65% and cerebral volume 53% compared with term infants. These infants have a cerebral cortex that is still smooth, gyri and sulci that are not fully formed, and incomplete myelination and interneural connections. If injury occurs during this neurologic growth period, the infant is at risk for white and gray matter injury, especially in the thalamic region and periventricular white matter. This leaves the late preterm infant at risk for neurologic disorders including poor development and long-term outcome (Ramachandrappa & Jain, 2015).

MORBIDITY AND MORTALITY OF THE LATE PRETERM INFANT

Late preterm infants are at increased risk for morbidity and mortality (Horgan, 2015; King, Gazmarian, & Shapiro-Mendoza, 2014). Cheng, Kaimal, Bruckner, Halloran, and Caughey (2011) researched singleton live births between 34 and 40 weeks of gestation. Infants at 34 weeks were found to be at greatest risk for hyaline membrane disease, mechanical ventilation use greater than 6 hours, and antibiotic use. At 35 weeks, infants had a greater use of surfactant, ventilation greater than 6 hours, and NICU admission. Infants at 36 weeks had an overall higher risk of morbidities when compared to infants 37 to 40 weeks of gestation. The researchers concluded that although the risk of neonatal complications decreased with increasing gestational age, neonatal complications are higher for late preterm infants than their term infant counterparts.

The morbidities that the late preterm infants are at increased risk for include TTN, RDS, PPHN, respiratory failure, apnea, hyperbilirubinemia, hypoglycemia, hypothermia, feeding difficulties, and neonatal sepsis. These health issues place the infants at increased risk for admission to the NICU, requiring treatments including mechanical ventilation, intravenous fluids, and sepsis evaluation (Horgan 2015; Mally, Hendricks-Munos, & Baily, 2013).

Preterm infants also have higher mortality rates. King et al. (2014) found that infant mortality rates for late preterm infants were three times higher than for infants born at 39 to 41 weeks. **Quality and Safety:** **The three leading causes of infant mortality in all infants studied were congenital malformations, sudden infant death, and accidents (unintentional injury).** Crump, Sundquist, Sundquist, and Winkleby (2011) found late preterm infants had a higher mortality rate when compared with term infants during early childhood and young adulthood. Causes of death in young adulthood were related to congenital anomalies, as well as respiratory, endocrine, and cardiovascular disorders.

MEDICAL AND NURSING CARE OF THE LATE PRETERM INFANT

It is clear that late preterm infants are different from term infants and should be monitored more closely. Infants born less than 35 weeks' gestation or less than 2,300 g birth weight should be admitted to an area where they can be observed more closely than in the normal nursery. These infants are at increased risk for delayed transition. These infants should have a physical examination and accurate gestational age assessment on admission. Vital signs and pulse oximeter checks should be done on admission, every 3 to 4 hours in the first 24 hours, and every other shift thereafter. Strong feeding plans should be developed with a formal breastfeeding evaluation done by a trained lactation consultant or neonatal nurse. Serum glucose monitoring should be done to assess for hypoglycemia. Transfer to normal nursery or mother's room should be considered only when the late preterm infant shows signs of stability. If an oxygen hood is needed in excess of 40%, the infant should be transferred to a NICU or tertiary care facility for further management (Horgan, 2015; Phillips et al., 2013; Ramachandrappa & Jain, 2015).

Late preterm infants are at increased risk for TTN, RDS, PPHN, respiratory failure, apnea, hyperbilirubinemia, hypothermia, hypoglycemia, feeding difficulties, neonatal sepsis, and NICU admission with a prolonged hospital stay as well as having mothers with increased emotional distress. These medical problems need careful assessment and treatment (Mally et al., 2013; Phillips et al., 2013; Ramachandrappa & Jain, 2015).

Respiratory Disorders

Late preterm infants are at increased risk for respiratory complications. They include TTN, RDS, PPHN, respiratory failure, and apnea (Horgan, 2015; Mally et al., 2013; Montenegro et al., 2017).

Researchers have found the incidence of RDS was 3% at 36 weeks' gestation, 4% at 35 weeks' gestation, and 9% at 34 weeks' gestation compared to term 40-week infants of 0%. Late preterm infants have an increased need for mechanical ventilation and surfactant replacement, as well as continuous positive airway pressure compared to term infants (Mally et al., 2013; Ramachandrappa & Jain, 2015). **Emergency Alert:** **Late preterm infants should be observed for respiratory symptoms including tachypnea, retractions, nasal flaring, grunting, and cyanosis.** Babies should be admitted to the NICU if respiratory disorders are suspected for monitoring, oxygen therapy, intubation, and surfactant as needed (Ramachandrappa & Jain, 2015).

Late preterm infants are at higher risk for apnea (Horgan, 2015; Mally et al., 2013). Infants should be monitored for apnea and transferred to the NICU for an appropriate workup and treatment as needed. It is important to rule out other causes of apnea such as sepsis. If central apnea is suspected, treatment options include monitoring of apneic events in mild cases and the use of caffeine for more persistent episodes of apnea (Horgan, 2015; Ramachandrappa & Jain, 2015). Researchers in Boston found outpatient management was a cost-effective option for late preterm infants with persistent apnea of prematurity controlled with caffeine and on home monitoring (Montenegro et al., 2017).

Hyperbilirubinemia

Late preterm infants are at risk for hyperbilirubinemia due to an increased bilirubin load and decreased bilirubin excretion. Late preterm infants are also at increased risk of developing kernicterus since many infants are breastfeeding with inadequate maternal supports and insufficient follow-up. These infants should be observed for jaundice as well as have a risk assessment plan for jaundice. A predischarge bilirubin check should be done (serum or transcutaneous) with phototherapy as needed. Careful follow-up should be done to assess for jaundice since bilirubin levels are likely to peak at day 5 to 7 (Horgan, 2015; Ramachandrappa & Jain, 2015).

Hypoglycemia

Late preterm infants are at greater risk for hypoglycemia. It is important to prevent hypoglycemia because even moderate hypoglycemia can have serious neurodevelopmental consequences in the late preterm infants. **Quality and Safety:** **These infants should have their blood sugars monitored frequently, every hour for 4 hours or until greater than 50 twice. Late preterm infants should be monitored for symptoms of hypoglycemia including poor feeding, hypothermia, crying, irritability, jitteriness, seizures, and apnea.**

Treatment will be necessary for a glucose level less than 40 to 50. These treatments include early enteral feeds, intravenous dextrose (2 mL/kg) bolus or maintenance IV fluids (GIR 4–6 mg/kg/minute, Total Fluids 80 mL/kg/day), or a combination of these therapies (Horgan, 2015; Ramachandrappa & Jain, 2015).

Infants of diabetic mothers are often delivered early and will be at greater risk for hypoglycemia. Most institutions have glucose monitoring and protocols that should be followed as needed.

Hypothermia

Thermoregulation is a challenge for the late preterm infant. **Quality and Safety: Late preterm infants' temperatures should be monitored closely after birth, every hour for 6 hours, and then every 6 hours until discharge.** The normal range is 36.5°C to 37.4°C (97.7°F–99.3°F; Horgan, 2015; Ramachandrappa & Jain, 2015).

Infants should be monitored for cold stress symptoms including tachypnea, poor color, cyanosis, pallor, mottling, altered pulmonary vasomotor tone, metabolic acidosis, and lethargy. Hypothermia can worsen respiratory transition and hypoglycemia. **Emergency Alert: These symptoms combined with hypothermia can also suggest infection. Therefore, it is important to prevent these symptoms and an unnecessary costly workup for sepsis** (Ramachandrappa & Jain, 2015).

It is important to keep the infant normothermic using strategies including skin-to-skin contact with the mother, keeping a dry hat on the infant, and using warm blankets in the delivery room. It is also important to keep the infant warm when weighing and postponing a bath until stable (Horgan, 2015; Ramachandrappa & Jain, 2015).

Feeding Difficulties

The gastrointestinal tract of late preterm infants typically tolerates feedings, but these infants often have difficulty in coordination while sucking, swallowing, and breathing. Poor feedings can lead to weight loss, dehydration, hypoglycemia, and hyperbilirubinemia. **Quality and Safety: Feeding challenges place late preterm infants at risk for a prolonged hospital stay and rehospitalization** (Horgan, 2015). Lau, Bhat, Potak, and Schanler (2015) proposed a new feeding assessment tool to examine late preterm infants' oral feeding skills on their first feed to help identify infants at risk for feeding issues. It is important to evaluate feeding patterns and provide appropriate interventions as needed, which may include occupational therapy consults and lactation support (Horgan, 2015; Meier, Patel, Wright, & Engstrom, 2013).

Early and Late Neonatal Sepsis

Late preterm infants are at increased risk for infection. Late preterm deliveries can often result from preterm labor and premature rupture of membranes with the etiology of infection. These infants undergo more sepsis workups than term infants as well as more antibiotic therapy. **Quality and Safety: Providers should look at risk factors for sepsis and signs and symptoms of infection, including temperature instability, lethargy, jitteriness, irritability, hypotonia, respiratory distress, hypotension, poor perfusion, poor feedings, vomiting, diarrhea, glucose instability, rashes, and jaundice.** A CBC with differential, blood cultures, and antibiotic therapy should be implemented with signs of infection. Appropriate length of treatment of antibiotics should be determined (Ramachandrappa & Jain, 2015).

Admission to NICU and Prolonged Hospital Stay

Late preterm infants are more likely to require admission to the NICU and prolonged hospitalization compared to term infants. Admission depends on gestation age, comorbidities, and each institution's organization of care. The duration of the NICU stay is inversely proportional to gestational age. Approximately 33% of NICU admissions each year are for infants who are greater than 34 weeks' gestational age. Common reasons for infant NICU stays include RDS, poor feeding, hypoglycemia, temperature instability and hyperbilirubinemia (Horgan, 2015; Ramachandrappa & Jain, 2015).

DISCHARGE, FOLLOW-UP CARE, AND REHOSPITALIZATION OF THE LATE PRETERM INFANT

Discharge

When planning discharge transitioning to outpatient care, the process should begin on admission and requires a coordinated multidisciplinary approach. Late preterm infants should delay discharge until greater than 48 hours of age to assure infant stability. Infant stability will reflect physiologic maturity, and includes successful feeding without vomiting for at least 24 hours without excessive weight loss, normal vital signs on room air, with absence of medical illness such as no signs of infection, a risk assessment for the development of severe hyperbilirubinemia, and follow-up arranged as needed. The infant must have good temperatures in a crib and proper voiding and stooling. **Quality and Safety: A physical examination must be performed within 24 hours of discharge, with no evidence of active bleeding at the circumcision site for at least 2 hours, hepatitis B vaccine administration, metabolic screens according to state recommendations, passed car seat safety test, hearing assessment, a family environment and social risk factor assessment, and parent training.** Family teaching regarding care of the late preterm infant is essential. Pediatric follow-up 24 to 48 hours after hospital discharge is critical. Good discharge planning will allow a smooth transition for the infant from the hospital environment to home and it will also help reduce hospital readmissions (Phillips et al., 2013; Ramachandrappa & Jain, 2015).

Follow-Up Care

It is important to provide follow-up care for late preterm infants and resources for the family for healthy growth and rehospitalization prevention. Follow-up should begin in the hospital and continue once the late preterm infant is discharged (Phillips et al., 2013).

Close follow-up should be provided by the primary care provider, having a visit 24 to 48 hours after hospital discharge. The primary care provider should assess the infant's continued stability, review screening results, ensure ongoing safety, and evaluate support systems. **Quality and Safety: Late preterm infants should be followed weekly until the infant displays stability and is 40 weeks' gestation. Additional visits may be required for weight and bilirubin checks** (Phillips et al., 2013). Consultant follow-up including medical consultants, Visiting Nurses Association (VNA), and early intervention should be used as needed.

It is important for the late preterm infants' mothers to obtain breastfeeding support from the pediatric nurse practitioner and visiting nurse because often these infants are discharged early and lack sufficient time for breastfeeding support. These infants often have an immature suck and swallow pattern that can lead to poor feeding, dehydration, hyperbilirubinemia, and rehospitalization. Late preterm infants are at greater risk for breastfeeding-associated rehospitalization compared to term infants. Follow-up is critical for late preterm healthy growth and development (Ahmed, 2010; Lau et al., 2015; Radtke, 2011).

Rehospitalization

There is an increased risk for rehospitalization of late preterm infants, most often related to jaundice and feeding difficulties (Kuzniewicz, Parker, Schnake-Mahl, & Escobar, 2013; Moyer et al., 2014; Ray & Lorch, 2013). Moyer et al. (2014) found a 3.6% rehospitalization rate within the first 28 days of birth. Late preterm infants required readmission due to hyperbilirubinemia (75%), feeding difficulties (34%), hypothermia (12%), and suspected sepsis (4%). They found hyperbilirubinemia readmission occurred most often around day 4.5, feeding challenges around 10.4 days, hypothermia around 9.3 days, and suspected sepsis around 13 days.

Goyal, Zubizarreta, Small, and Lorch (2013) found a similar hospital readmission rate of 3% within 7 days of discharge. Researchers found no reduction in 7 days readmission rate associated with longer admission hospital length of stay. They suggest further research needed in this area.

Ray and Lorch (2013) studied hospital readmission of early, late preterm infants and term infants in the first year of life. Research found late preterm infants experienced an increase in prehospitalization within 14 days of discharge at 3.6%, which was similar to early preterm infants at 3.7% and term infants at 2.2%. Late preterm infants most often were readmitted for hyperbilirubinemia with bacterial and nonspecific infection as a secondary cause but far less common.

Hospital readmission rates were significantly higher for late preterm infants never admitted to the NICU. Additionally, late preterm infants who are discharged at less than 24 hours of age also had higher readmission rates (Ramachandrappa & Jain, 2015).

LONG-TERM OUTCOMES

Research has shown that late preterm infants have an increased risk of medical problems and poor health-related outcomes. They also have long-term adverse developmental outcomes including cognitive delay with poor school performance as well as social and behavioral challenges. Although the absolute risk of poor long-term outcome in the late preterm infant population is low, it is significantly higher than their term counterparts (Odibo et al., 2016; Shah, Kaciroti, Richards, Oh, & Lumeng, 2016; Vohr, 2013; Woythaler, McCormick, Mao, & Smith, 2015).

Late preterm infants in the first year of life had an increased risk for poor health-related outcomes during the birth hospitalization. Medical challenges included hyperbilirubinemia, infection, and respiratory issues including asthma. They found a statistically significant increase in healthcare utilization during the first year of life, including increased total hospital time, increased hospital and outpatient costs, as well as overall total healthcare costs (Odibo et al., 2016; Vohr, 2013).

Late preterm infants requiring NICU admission had increased need for interventional therapies: 30% required early intervention services, 28% physical therapy, 16% occupational therapy, 10% speech therapy, and 6% special education (Kalia, Visintainer, Brumberg, Pici, & Kase, 2009; Vohr, 2013). Woythaler, McCormick, and Smith (2011) found late preterm infants have a poorer developmental outcome than term infants at 24 months of age, including more mild and severe mental and psychomotor developmental delays.

Late preterm infants were found to have an increased incidence of cerebral palsy (CP), developmental delay, and mental retardation (MR). These infants were three times more likely to be diagnosed with CP than their term counterparts and at marginally higher risk for developmental delay and MR. Late preterm infants were not at increased risk for seizures, as noted in this study (Petrini et al., 2009).

Late preterm infants are at increased risk for poor school performance compared to their term counterparts (Woythaler et al., 2015). Talge et al. (2010) found late preterm infants exhibited poorer cognitive performance with IQ scores at age 6. They also found increased behavioral problems at age 6, including higher levels of internalizing and attention problems. Lipkind, Slopen, Pfieffer, and McVeigh (2012) found late preterm infants had an increased need for special education services and lower math and English scores in grade 3 when compared with term infants. Shah et al. (2016) research showed late preterm infants had poorer school performance, especially in preschool and kindergarten, with reading and math skills.

Rogers et al. (2014) found late preterm infants were at risk for altered brain development, particularly in the right temporal and parietal cortices resulting in increased rates of anxiety symptoms that persist until school age.

SUMMARY

Late preterm infant births, infants born at 34 0/7 to 36 6/7 weeks, are on the rise. Late preterm deliveries are due to spontaneous preterm labor and inductions for fetal and maternal indications. These infants are at increased risk for physiologic immaturity, as well as higher morbidity and mortality rates. They also have more medical complications, NICU admissions, and prolonged hospitalizations. It is important to understand these risks and provide closer monitoring and expert medical and nursing care, as well as stricter discharge criteria, follow-up care, and strategies to prevent rehospitalization. Late preterm infants are at increased risk for long-term sequelae. More research is needed in this population to understand how to prevent late preterm births and optimize care for successful outcomes.

CASE STUDY

■ **Identification of the Problem.** Baby boy M was born at 35 weeks' gestation and developed respiratory distress at 4 hours of life in the normal newborn nursery.

■ **Assessment: History and Physical Examination.** Baby boy M was born at 35 weeks weighing 2,090 g to a 31-year-old G1 P0 now 1, blood type A positive, antibody screen negative, rapid plasma reagin nonreactive, Rubella immune, hepatitis B surface antigen negative, HIV negative, group B streptococcus negative mother. This pregnancy was complicated by gestational diabetes, diet-controlled, and preterm labor. Maternal antibiotics were given. Labor persisted, and the infant was born by normal vaginal delivery. A nurse practitioner was at the delivery due to prematurity; the infant emerged crying and was brought to the warmer. Routine drying and stimulation was provided, and Apgars were 8 and 9. The infant transitioned nicely and was transferred to the normal nursery. At 4 hours of age, the infant was tachypneic, grunting, retracting, and flaring and requiring face mask oxygen to keep saturations above 90%. The infant was transferred to the NICU. On admission to the NICU, the baby was noted to have a hood oxygen requirement of 25%, a dextrostix of 30, and a temperature of 36°C.

■ **Physical Examination**

- GENERAL APPEARANCE: alert and active, mild distress
- HEAD: fontanelle soft and flat; no eye drainage, positive red reflex; ears normally set and rotated; nares patent; moist mucous membranes, palate intact

- SKIN: warm, well perfused, no lesions
- NECK: clavicles intact, no crepitus
- RESPIRATORY: lungs are clear to auscultation, breath sounds equal, expiratory grunting, nasal flaring, mild intercostal retractions, chest wall within normal limits, cry normal
- CARDIOVASCULAR: regular heart rate and rhythm without murmur, femoral pulses 2 plus bilaterally, well perfused, capillary refill less than 2 seconds
- ABDOMEN: soft, nontender, not distended, normal bowel sounds, no hepatosplenomegaly, three-vessel umbilical cord
- GENITOURINARY: normal male genitalia, testes descended bilaterally, anus patent
- MUSCULOSKELETAL: no sacral dimple, no hip clunk, normal upper and lower extremities
- NEUROLOGIC: alert, moving all extremities times 4, normal tone and strength, Moro complete, normal grasp and suck, no focal deficits

■ **Differential Diagnoses.** Respiratory diagnoses: respiratory distress syndrome (RDS), transient tachypnea of the newborn (TTN), pneumonia, pulmonary hypertension

- Rule out sepsis
- Hypoglycemia
- Hypothermia

■ Diagnostic Tests

- Chest radiography
- Arterial blood gas
- Blood glucose and dextrostix monitoring
- CBC with differential
- Blood culture

■ **Working Diagnosis.** Baby M had a chest x-ray with prominent perihilar interstitial markings and fluid in the minor fissure, which is most consistent with TTN. He had blood gas pH 7.40, P_{CO_2} 42, P_{O_2} 80, and a base excess of 1, which further supports the diagnosis. Baby M had a normal CBC with differential, a white blood count of 15.6, hematocrit of 17, and platelets of 211. The differential showed 46 neutrophils, 2 bands, 40 lymphocytes, 7 monocytes, and 5 eosinophils. The working diagnosis ruled out sepsis since the actual infection risk is low. The maternal group B streptococcus (GBS) status was negative, and the baby's physical examination was within normal limits except for the respiratory symptoms that point to TTN.

The dextrostix on admission to the NICU was 30. Baby M is a late preterm infant at risk for hypoglycemia due to metabolic immaturity. Additionally, baby M's mother had gestational diabetes, which puts the infant at risk for transient hypoglycemia.

Baby M had a temperature of 36°C, which is common in late preterm infants. Metabolic immaturities lead to transient hypothermia.

■ **Development of Management Plan.** The respiratory plan was to wean the oxygen as tolerated, keeping oxygen saturations greater than 90%. Baby M had an IV started due to his dextrostix of 30, given a bolus of dextrose 10 in water (2 mL/kg), and started on maintenance IV fluids (GIR 5.6 mg/kg/minute, total fluids of 80 mL/kg/day). Dextrostixs were to be performed every 1 to 3 hours until greater than 45. Baby M was placed on a warmer for his temperature of 36°C.

■ **Implementation and Evaluation of Effectiveness.** Baby M weaned to room air, and the respiratory symptoms resolved by 12 hours of life. Baby M's repeat dextrostix was 45 after the glucose bolus and IV fluids, with the resolution of the hypoglycemia. He started feeding at 24 hours of life and had difficulty with poor coordination of feeds and weight loss, which took 7 days to resolve. Baby M had difficulty maintaining his temperature and finally weaned to a crib after 4 days.

■ **Outcome.** Baby M experienced many of the typical medical complications related to late preterm infants' physiologic and metabolic immaturity, which resulted in a NICU admission and prolonged hospital stay. Baby M went home after a 7-day admission to the NICU. He will have close primary care provider follow-up to promote healthy growth and prevent rehospitalization.

EVIDENCE-BASED PRACTICE BOX

Late preterm infants are infants born between 34 0/7 and 36 6/7 weeks' gestation and are increasing in number throughout the country and around the world. These infants have higher rates of morbidity and mortality, as well as increased medical complications, NICU admissions, and prolonged hospitalization (Engle, 2011; Engle et al., 2007; Ramachandrappa & Jain, 2009). Late preterm infants require closer monitoring and specialized medical and nursing care with stricter discharge criteria and follow-up care. These infants have a higher rehospitalization rate and long-term sequelae.

It is clear that late preterm infants are different from term infants and should be monitored more closely. Late preterm infants are at increased risk for TTN, RDS, PPHN, respiratory failure, apnea, hyperbilirubinemia, hypothermia, hypoglycemia, feeding difficulties, neonatal sepsis, and NICU admission with a prolonged hospital stay as well as having mothers with increased emotional distress. These medical problems need careful assessment and treatment (Martin et al., 2011). Late preterm infants are more likely to require admission to the NICU and prolonged hospitalization compared to term infants.

When planning discharge of the late preterm infant, criteria developed for both high-risk infants and healthy term infants should be considered. Discharge for term infants after a vaginal delivery is typically less than 48 hours. In 1995 with a revision in 2004, the AAP recommended a minimum eligibility of 38 to 42 weeks' gestation as discharge criteria for early discharge, less than 48 hours (AAP, Committee on Fetus and Newborn, 1995, 2004). Goyal et al. (2011) found 40% of late preterm infants were discharged early, prior to 48 hours. The AAP continues to recommend discharge after 48 hours.

(*continued*)

EVIDENCE-BASED PRACTICE BOX (*continued*)

Engle et al. (2007) have recommended discharge criteria that reflect evidence of physiologic maturity, feeding competences, thermoregulation, maternal education, assessment, and planned intervention for medical, family, environmental, and social risk factors, and follow-up arrangements. Important minimal discharge criteria should include the following: accurate gestational age determination, meeting of feeding-based competencies, thermoregulation and absence of medical illness, and social risk factors (usually after 48 hours); pediatric follow-up 24 to 48 hours after hospital discharge; vital signs within the normal range for 12 hours preceding discharge; passage of at least one stool spontaneously; 24 hours of successful feeding; a risk assessment for the development of severe hyperbilirubinemia and follow-up arranged as needed; physical examination with no abnormalities requiring hospitalization; no evidence of active bleeding at circumcision site for at least 2 hours, hepatitis B vaccine administration or an appointment for administration; metabolic screens according to state recommendations, passed car seat safety test; hearing assessment; family environment and social risk factor assessment, and parent training (AAP Committee on Fetus and Newborn, 2008; Engle, 2011; Martin et al., 2011).

Good discharge planning will allow a smooth transition for the infant from the hospital environment to home. It will also help reduce hospital readmissions.

PARENT VOICES

Crystal Duffy

To be a parent of a late preterm infant in the NICU is like being pushed aside, left on your own, and disregarded because your baby is doing "great." We must not forget that every patient no matter if they spend 4 hours in the NICU or 18 months, should receive the same compassion and quality of care.

CHAPTER 30

Neonatal Abstinence Syndrome

Gail A. Bagwell

INTRODUCTION

Opiate addiction and neonatal abstinence syndrome (NAS) have become major health problems for pregnant women and neonates in the United States. NICU and special care units (SCN) have been inundated with babies that are withdrawing not only from opiates but from other licit and illicit substances that they were exposed to in-utero. This chapter discusses the history, incidence, and diagnosis of NAS, the screening tools, and nonpharmacological and pharmacological management involved, the importance of nonjudgmental care of the mother–infant dyad, and the long-term outcomes of the NAS neonate.

HISTORY OF OPIATE ADDICTION

Opioid use during pregnancy is not a new phenomenon in the United States. Opioid addiction in the United States is as old as our country is, as it dates back to the American Revolution where both American and British soldiers were given opium for illness and injuries (Courtwright, 2001). With the discovery of morphine in 1803 and then the invention of the hypodermic syringe and needle in 1856, many feel that the first true opiate addiction occurred with the Civil War in the United States. Morphine was used like opium was in the American Revolution, for the sick and injured soldiers, but was also used to treat diseases of the uterus, ovaries, and nervous conditions of women. Morphine during this time did not require a prescription, so it was readily used. By 1895, one in 200 Americans had an opiate addiction problem, with 60% of them being upper-class or middle-class white women (Courtwright, 2001). The use of morphine for women was largely due to a lack of understanding and training by physicians at the time; as medical education became more rigorous and knowledge of problems increased, and with the release of a new analgesic called aspirin in 1897, the use of morphine decreased. While the opiate addiction problem didn't go away, the addict profile changed from war veterans and upper-class or middle-class white women to lower-class males and new immigrants, with the opening of opium dens in America in the early 1900s. With the changing profile of the addict, legal ramifications began to take hold in the United States making possession of opium and heroin illegal, but these did not deter use.

In the 20th century, the heroin epidemic in the 1950s and 1960s brought attention to drug use by pregnant women and concern about the effects of drugs on the developing fetus. In the late 1970s and the 1980s, heroin fell out of favor and cocaine became an issue, but by the 2000s heroin started to gain popularity again.

The resurgence of heroin is attributed in large part to the prescription drug abuse that began in the 1990s. Simultaneously several events occurred that led to prescription drug abuse: The Joint Commission instituted the mandatory assessment of pain as the fifth vital sign; a new opiate medication, oxycodone, was promoted to practitioners as a nonaddictive opiate analgesic; insurance companies tightened their belts on what nonpharmacological treatments that they would pay for, limiting what a practitioner could do for patients in acute pain; and healthcare practitioners and healthcare facilities began patient satisfaction surveys. These events resulted in practitioners overprescribing oxycodone and other narcotics to patients, which led many to addiction, as we now know that oxycodone is as powerful as or more powerful than heroin (Quinones, 2015).
