COMPREHENSIVE NEONATAL NURSING CARE

Comprehensive Neonatal Nursing Care

Carole Kenner, PhD, RN, FAAN, FNAP, ANEF, is the Carol Kuser Loser Dean/Professor of the School of Nursing, Health, and Exercise Science at The College of New Jersey. Dr. Kenner received a bachelor's of science in nursing from the University of Cincinnati and her master's and doctorate in nursing from Indiana University. She specialized in neonatal/perinatal nursing for her master's and obtained a minor in higher education for her doctorate. She has authored more than 100 journal articles and 30 textbooks.

Her career is dedicated to nursing education and to the health of neonates and their families, as well as educational and professional development of healthcare practices in neonatology. Her dedication includes providing a healthcare standard for educating neonatal nurses nationally and internationally. Her passion led her to begin the journal *Newborn and Infant Nursing Reviews*, in which she served as editor and then associate editor. She worked with the National Coalition on Health Professional Education in Genetics (NCHPEG) and the American Nurses Association to develop genetic competencies. She helped develop the End-of-Life Nursing Education Consortium (ELNEC) Neonatal/Pediatric modules. She served as the co-chair of the Oklahoma Attorney General's Task Force on End of Life/Palliative Care. She also helped develop program recommendations for perinatal/neonatal palliative care as part of a family-centered/developmental care project sponsored by the National Perinatal Association. She serves on the Consensus Committee of Neonatal Intensive Care Design Standards, which sets recommendations for Neonatal Intensive Care Unit designs, and serves on the March of Dimes Nursing Advisory Committee. She is a fellow of the American Academy of Nursing (FAAN), a fellow in the National Academies of Practice, a fellow in the Academy of Nursing Education, past president of the National Association of Neonatal Nurses (NANN), and founding president of the Council of International Neonatal Nurses (COINN), the first international organization representing neonatal nursing-setting standards globally. She is the 2011 recipient of the Audrey Hepburn Award for Contributions to the Health and Welfare of Children Internationally.

Leslie B. Altimier, DNP, RNC, MSN, NE-BC, is the director for clinical innovation and research for Phillips HealthTech, where she is responsible for developing clinical analytic support algorithms and research tools for future NICU technology. She received her BSN from Kent State University, MSN from the University of North Carolina, DNP from Northeastern University in Boston, and she completed a postdoctoral fellowship in compassionate healthcare through the Northeastern University in collaboration with the Schwartz Center for Compassionate Healthcare and the Jonas Center for Nursing and Veterans Healthcare. In her 30-year nursing career, she has worked in a variety of neonatal, pediatric, and adult intensive care units, and has been a clinical director of nursing for a hospital network consisting of a 50-bed level III NICU and multiple level II NICUs.

Dr. Altimier is a renowned clinician who lectures internationally and has published over 100 articles, chapters, and books on topics related to the care of neonates and families, NICU design, and organizational leadership. She was the editor-in-chief of *Newborn and Infant Nursing Reviews (NAINR)* journal and most recently is the editor-in-chief of the *Journal of Neonatal Nursing (JNN)*, the official journal of the Neonatal Nurses Association (NNA). She is a member of NANN (the National Association of Neonatal Nurses), COINN (Council of International Neonatal Nurses, Inc.), and INANE (the International Academy of Nurse Editors). She also holds a nursing executive certification by the AANC (American Nurses Credentialing Center).

Dr. Altimier has contributed to nursing through practice, education, leadership, research, and publications. She is passionate about neuroprotective developmental care, family-integrated care, and compassionate care and has earned the Neonatal Developmental Care Specialist Designation from NANN. Her goal is to create a culture of change in healthcare worldwide.

Marina V. Boykova, PhD, RN, is an assistant professor of nursing in the School of Nursing and Allied Health Professions, Holy Family University, Philadelphia, Pennsylvania. Dr. Boykova received her Diploma in Nursing Practice from the School of Nursing #3, Saint Petersburg, Russia; a Certificate in Theory and Practice of Nurse Education, Medical College #1, Saint Petersburg, Russia; a Certificate in Theory and Practice of Nurse Education, Chester, United Kingdom; Bachelor of Science with Honours in Professional Practice (Nursing), University of Liverpool, Chester, United Kingdom; Diploma of Higher Education in Nursing, Novgorod University of Y. Mudrogo, Novgorod, Russia; Master of Science in Health Promotion (Distinction), University of Liverpool, Chester, United Kingdom; and Doctor of Philosophy in Nursing, University of Oklahoma, Oklahoma City, Oklahoma. She is a member of Sigma Theta Tau International. She serves as a nonexecutive director for the Council of International Neonatal Nurses, Inc. (COINN). Dr. Boykova's clinical background is neonatal intensive care nursing. Her research interests center on transition from hospital to home and to primary care for parents of preterm infants. She has published in this area as well as neonatal care topics. She coauthored a policy brief on Reducing Preterm Births for the American Academy of Nursing.

I wish to first express my appreciation, love, and support for my dad, who died in 2017 at the age of 105½. He always got excited when a new edition published.
—Carole

I would like to thank my children, Jen, Julie, and Kevin, for their love, support, and encouragement for me as a mom and as a professional.
—Leslie

For my mom, whose love and support were endless.
—Marina

Together we would like to express our appreciation for the assistance of Margaret Zuccarini, from Springer Publishing Company, who is a longtime trusted colleague who guided this project, along with Elizabeth Nieginski, who took over from Margaret, to a successful birth. Thank you for believing in this project. A special thank-you goes to Joanne Jay from Springer for all the assistance and guidance through the development and publication. We really enjoyed working with all of you. Finally, we want to thank the professionals across the globe who take care of the babies and their families.
—Carole Kenner, Leslie Altimier, and Marina Boykova

Foreword

Comprehensive Neonatal Nursing Care has been the go-to resource for evidence-based and practical guidance for novice and expert neonatal nurses in classroom and clinical settings since 1993. As we have come to expect and rely upon, the new *sixth edition* includes the latest information on neonatal embryology, physiology, medical and surgical management, psychosocial care, emerging infections, neuroprotection, pain control, care of the late preterm infant, and much more. The textbook is organized with a focus on integrative management of the newborn and family. There is extensive use of research findings in each of the chapters to provide evidence to support practice strategies and clinical decision-making. Complete references are found at the end of each chapter.

In the new *sixth edition*, the chapters have been thoroughly updated and refreshed with the latest research and practice tips, written by authors who are recognized experts in their fields. New features include callouts highlighting parent perspectives, quality and safety practice points, and emergency alerts. There are new chapters on trauma-informed care, neonatal abstinence, and support for families. Uniquely among neonatal textbooks, the *sixth edition* of *Comprehensive Neonatal Nursing Care* includes a focus on the neonatal care ecosystem, with chapters on emerging trends in research and care delivery, genetics and genomics, and competency-based education and support for neonatal unit managers and directors.

In today's world, neonatal nurses are faced with the constant threat of information overload and ever-present concerns about the accuracy and relevance of what appears in print, online, and in videos, blogs, podcasts, or instant messages. It is therefore reassuring—and indeed essential—to have the well-written, accessible, thoroughly researched and accurate *Comprehensive Neonatal Nursing Care* as our constant and trustworthy companion as we strive to provide high-quality care to all newborns and their families. The editors and authors are to be congratulated for maintaining such a high standard of excellence and practical application. Your dedication enables neonatal nurses everywhere to provide essential care to the more than 30 million sick and premature newborns and their families who depend on nurses to survive and thrive.

Thank you!

Linda S. Franck, PhD, RN, FRCPCH, FAAN

University of California, San Francisco

Preface

One of the most complex issues in healthcare is the care of sick or premature infants and those with multiple, severe congenital anomalies. Despite advanced technology and knowledge, preterm delivery continues to be a significant problem in the United States. Maternal risk factors have changed over the past decade. For example, more women with congenital heart anomalies and chronic illnesses, such as diabetes or sickle cell anemia, are giving birth to infants with consequent health problems. The rise of in vitro fertilization has resulted in increased multiple births and prematurity. Many infants in neonatal intensive care units (NICUs) have been exposed to substances or are born to mothers with other risk factors such as delayed childbearing or childhood cancers.

The care of these at-risk infants requires the use of more and more complex technology. Surfactant administration, nitric oxide administration, high-frequency jet ventilators, neurally adjusted ventilatory assist (NAVA; Stein & Firestone, 2014), and new hybrid ventilators providing high-frequency and conventional modes of ventilation are being used in Europe and are likely to be brought to the United States for Food and Drug Administration (FDA) approval. New technologies now can provide continuous, noninvasive monitoring of endotracheal tube position and obstruction (Hütten et al., 2015). Servo-controlled oxygen administration, which leads to greater compliance with targeted oxygen saturation ranges, is being developed (Claure & Bancalari, 2015). Near-infrared spectroscopy (NIRS), amplitude-integrated EEGs (aEEGs), dialysis, organ transplantation, and other extraordinary measures are becoming commonplace. Better integration of technologies (both electronic medical records [EMRs] and medical devices) will be the basis for decision support and predictive analytics. However, in the midst of these high-tech interventions, neuroprotective developmentally supportive care interventions such as olfactory and gustatory support, using visible rather than audible alarms, music therapy, cycling lights, using more physiologically and developmentally appropriate positioning, and skin-to-skin contact are being recognized as evidence-based neuroprotective interventions, due to increasing evidence regarding the importance of maintaining a developmentally supportive NICU environment for improved long-term infant/child and family outcomes. Some consequences of prematurity are caused by early parent–infant separation and a lack of parents' participation in the care of their infant during traditional neonatal intensive care. The family is an essential partner in decision-making and care for their infant, and family-centered care is being expanded to family-integrated care, a paradigm shift from nurse caring to nurse coaching for parents providing the care.

Providers of neonatal care need up-to-date accurate and comprehensive information as a basis for providing care to newborns. A thorough understanding of normal physiology as well as the pathophysiology of disease processes is necessary for well-designed care practices. Knowledge about associated risk factors, genetics, critical periods of development, principles of nutrition and pharmacology, and current neonatal research findings are all essential in providing optimal care for neonates. A newer concept called de-implementation refers to the science of abandoning and unlearning practices built on the scaffolding of habit. Practices that are novel but yet not fully tested, unproven practices (those that lack supporting evidence), and practices of habit (practices that continue despite contradictory evidence) should go through the process of de-implementation. Care practices need to be based on best evidence-based practices available, rather than on tradition and habits.

A multidisciplinary approach has been replaced by an integrated interprofessional approach to care. All these elements form the foundation for assessment, planning, implementation, and evaluation of the effectiveness of neonatal care. The nurse plays a vital role in the provision of integrated healthcare to newborns. During the past decade, the nurse's role has included added responsibilities, which are recognized at both the staff and advanced practice levels. For the purposes of this book, we define the roles of the neonatal staff nurse, clinical nurse specialist (CNS), and neonatal nurse practitioner (NNP).

NEONATAL STAFF NURSE

The neonatal staff nurse role requires accurate and thorough assessment skills, excellent ability to communicate with other health professionals and patients' families, and a broad understanding of physiology and pathophysiology on which to base management decisions. It requires highly developed technical skills as well as critical decision-making skills. With healthcare delivery changes, the role also requires supervision of ancillary

personnel and an informed delegation of certain patient-oriented tasks. These changes require the staff nurse to possess even better assessment skills and sound knowledge of physiology and pathophysiology than in the past because some decision-making will be done in concert with other, less highly trained personnel. Additionally, the neonatal nurse is an essential contributor to the decision-making process surrounding the care of the critically ill neonate, including involvement in the ethical challenges that may occur regarding the level of care provided. In a recent position statement (#3067) by the National Association of Neonatal Nurses (NANN; Conway-Orgel, 2016), it was recommended that nursing be a part of the multidisciplinary team that facilitates decision-making affecting the health and well-being of the infant throughout the hospital stay.

In 2014, as the professional voice of neonatal nurses, NANN published a position statement (#3061) recommending that subspecialty NICUs (Level II, III, and IV NICUs) be staffed with a sufficient number and an appropriate mix of qualified registered nurses to attend to the emergent and complex care requirements of critically ill and convalescent infants (NANN, 2014c).

CLINICAL NURSE SPECIALIST

CNSs are advanced practice registered nurses (APRNs) who have graduate preparation (master's or doctorate) in nursing. Like other APRNs, they are trained in physiology, pharmacology, and physical assessment in addition to their particular areas of specialty. CNSs are expert clinicians with advanced education and training in a specialized area of nursing practice who work in a wide variety of healthcare settings. Regardless of specialty or setting, CNSs provide leadership in clinical expertise, nursing practice, and systems innovation. CNSs provide for the diagnosis, treatment, and ongoing management of patients. CNSs diagnose, develop plans of care for, treat, and provide ongoing management of complex patients. In many states, the CNSs can prescribe medications and offer durable medical equipment and therapies. They also provide expertise and support to nurses caring for patients at the bedside, help drive practice changes throughout the organization, and ensure the use of best practices and evidence-based care to achieve the best possible patient outcomes. Research and demonstration projects have shown that the CNS role is uniquely suited to lead implementation of evidence-based quality improvement actions that also reduce cost throughout the healthcare system (National Association of Clinical Nurse Specialists, 2016).

NEONATAL NURSE PRACTITIONER

The NNP is a registered nurse with clinical expertise in neonatal nursing who has received formal education at either the master's or doctoral level, with supervised clinical experience in the management of sick newborns and their families. The NNP manages a caseload of neonatal patients with consultation, collaboration, and general supervision from a physician; however, many state legislatures are following the Institute of Medicine's (IOM's) recommendation for autonomous NNP practice by repealing restrictive practice laws, thereby increasing healthcare access for millions of patients (American Association of Nurse Practitioners, 2018; Barton Associates, 2019). As a result, NNPs have increasing authority and responsibility. Using extensive knowledge of pathophysiology, pharmacology, and physiology, the NNP exercises independent or intradependent (in collaboration with other health professionals) judgment in the assessment, diagnosis, and initiation of certain delegated medical processes and procedures. As an advanced practice neonatal nurse, the NNP is additionally involved in education, consultation, and research at various levels.

NANN and the National Association of Neonatal Nurse Practitioners (NANNP), a division of NANN, published position paper #3059, a synthesis of previous efforts, which discusses the role, preparation, and scope of practice of the neonatal APRN (NANN, 2014b). NANN and NANNP define the educational and preparation standards for those pursuing the NNP role. NANN published a position statement in 1990, reaffirmed the definition of the NNP in 2000, and in 2009 issued another position statement that defined the NNP competencies (NANN, 2009). NANN (2014a) reaffirmed these core competencies for NNPs in its *Education Standards and Curriculum Guidelines for Neonatal Nurse Practitioner Programs* in 2014, which were further elaborated upon by NANNP in the development and revision of its *Competencies and Orientation Toolkit for Neonatal Nurse Practitioners* (NANNP, 2014). In 2017, NANN and NANNP published a document describing the minimum standards necessary for preparation of NNPs, titled *Education Standards and Curriculum Guidelines for Neonatal Nurse Practitioner Programs* (NANN, 2017).

In the current practice environment, outcome measures specific to the NNP must now be incorporated into professional requirements. To guide the process of continuous practice evaluation, individual practice standards have been provided by The Joint Commission in the form of ongoing professional practice evaluation or as focused professional practice evaluation (The Joint Commission, 2015). To accomplish this goal, NNPs must participate, direct, and develop performance metrics to evaluate their individual (direct) and collaborative (aggregate) contributions to improving patient and family care and outcomes while demonstrating decreased healthcare expenditures (Snapp, Wilson, Puchalski, & Wallace, 2016). Developing these outcome evaluation tools and processes will assist in the benchmarking and validation of care provided by NNPs.

The American Association of Colleges of Nurses (AACN) has proposed a change in the educational preparation for APRNs. The proposal recommends that the nurse practitioner be prepared at a "doctor of nursing practice" (DNP) level. This will likely affect the NNP role, as well as other APRNs, over the next few years.

PURPOSE AND CONTENT

The book's sixth edition provides a comprehensive assessment and examination of the care of neonates from a physiologic and pathophysiologic approach appropriate for any health professional concerned with neonatal care.

This text provides a complete physiologic and embryologic foundation for each neonatal body system. Additionally, it includes medical, surgical, and psychosocial care because the integrative management approach is absolutely imperative to the well-being of the newborn and family. Appropriate diagnostic tests and their interpretation are included in each organ-system chapter. There is extensive use of research findings in the chapters to provide evidence to support practice strategies and demonstrate the rationale for clinical decision-making. Complete references for more in-depth reading are found at the end of each chapter so that the reader may pursue more specific information on a topical area. Use of tables and illustrations further supports material that is presented in the narrative portions. New to this edition are special emergency alerts, quality and/or safety issues, and parent

voices, which are infused into applicable chapters. New chapters include Neonatal Abstinence Syndrome, The NICU—Through a Mother's Eyes (interview with a mother), and Touch a Life, Impact a Lifetime: Trauma-Informed Care in the NICU.

In the United States, the economic impact of preterm births is well over $25 billion per year (Behrman & Butler, 2007). Greater cost savings can be derived from technology that reduces labor costs, as NICU RN and respiratory therapy labor expenses account for over 60% of total neonatal care (Rhine, 2016). Now more than ever, neonatal care providers must examine patient, family, and staff outcomes to meet the demands for providing cost-effective and high-quality care. Research is critical to support both the art and science of neonatal care. Whenever possible, the contributors remind the reader of areas in need of further study. This book is not a quick reference; it provides comprehensive in-depth discussions along with detailed physiologic principles and collaborative management strategies. It provides a sound basis for safe and effective neonatal care; however, the format should make the information easier to find.

We begin the sixth edition with the impact of environmental influences and critical periods on the developing fetus. This transitions into the aspects of perinatal care, the high-risk pregnancy, the effects of labor on the fetus, and postpartal risk factors. The text then focuses on more specific neonatal topics, starting with resuscitation and stabilization of the newborn, assessment of the newborn and infant, followed by the normal term infant. Each organ system is discussed in depth, including the respiratory system, its complications and new technologies, followed by assessment of, and management strategies for, the cardiovascular, gastrointestinal, metabolic, endocrine, immunologic, integumentary, hematopoietic, musculoskeletal, neurologic, auditory, ophthalmic, and genitourinary systems. The thread of integrative management is interwoven throughout the text. Foundational topics such as fluids, electrolytes, and acid–base balance, nutrition management, pharmacology, and pain management, as well as emerging technologies and healthcare simulation are included, in addition to fetal therapy, surgical considerations, and emerging infections. Vulnerable populations cared for frequently in NICU settings are included, such as infants undergoing transplants, extremely low birth weight infants, late preterm infants, and unfortunately a growing population of infants withdrawing from opioids/neonatal abstinence syndrome. Chapters addressing environmental health and family-centered care in the NICU and beyond include neurobehavioral development, management of the NICU environment, trauma-informed care, family partnerships, palliative and end-of-life care, postdischarge care of the newborn, and, new to this section, the NICU through a mother's eyes. The final group of chapters covers neonatal care in the new millennium with topics including trends in neonatal care delivery, informatics, human genetics and genomics, trends in neonatal research and evidence-based practice, legal issues, global perspectives in neonatal care, and competency-based education and continuous competency. The sixth edition recognizes that neonatal nursing and care are global issues. The last section includes neonatal diagnostic and evidence-based care protocols pulled out separately, so they are easy to find and use. New protocols introduced in the sixth edition include neuroprotective interventions and neuroprotection of skin-to-skin contact.

To provide depth to these topical areas, physicians, nurses, infant developmental specialists, and other health professionals concerned with neonatal care from across the country and around the world have contributed in all editions. The attempt was made not only to tap the experts in the neonatal field but also to have them represent as wide a geographic area as possible. We hope that the broad geographic distribution of contributors and reviewers will help minimize the effect of regional differences in clinical practice.

We hope that you will find the text's information very useful and helpful to you in providing high-quality care to newborns and their families.

Acknowledgments

The idea for this book was born in the basement office of the lead editor (Dr. Carole Kenner) in Cincinnati, Ohio. In 1992, we recognized there was not a comprehensive book about nursing care for neonates. The first edition of the book was created in 1993. Over the course of the next two decades, we have refined the content to reflect new trends in neonatal care. This edition has two new editors who are committed to excellence in neonatal nursing care. I am grateful to Drs. Leslie Altimier and Marina Boykova for taking this journey with me.

Comprehensive Neonatal Nursing Care

CHAPTER 1

Fetal Development: Environmental Influences and Critical Periods

Carole Kenner

INTRODUCTION

In this chapter, the major events of prenatal development are described, and critical development periods for the major organ systems are identified. A brief review of the events beginning with fertilization is included, but the reader is referred to an embryology text for a more thorough account. Human genetics is discussed in Chapter 40, Human Genetics and Genomics: Impact on Neonatal Care.

EARLY FETAL DEVELOPMENT

The process of human development begins with the fertilization of an ovum (female gamete) by a spermatocyte (male gamete). The fusion of the ovum and sperm initiates a sequence of events that causes the single-celled zygote to develop into a new human being. During the 38 to 42 weeks of gestation, dramatic growth and development occur that are unequaled during any other period of life.

Fertilization

Large numbers of spermatozoa are necessary to increase the chances for conception because the spermatozoa must traverse the cervical canal, uterus, and uterine (fallopian) tubes to reach the ovum; approximately 200 to 600 million sperm are deposited in the posterior fornix of the vagina during ejaculation. The usual site of fertilization is in the ampulla, the widest portion of the uterine tubes, located near the ovaries. Sperm are propelled by the movement of the tails, aided by muscular contractions of the uterus and fallopian tubes. The spermatozoa undergo two physiologic changes to penetrate the corona radiata and zona pellucida, the barriers around the secondary oocyte. The first change is capacitation, an enzymatic reaction that removes the glycoprotein coating from the spermatozoa and plasma proteins from the seminal fluid. Capacitation generally occurs in the uterus or uterine tubes and takes about 7 hours. The second change, the acrosome reaction, occurs when a capacitated sperm passes through the corona radiata, causing structural changes that result in the fusion of the plasma membranes of the sperm and the oocyte. Progesterone released from the follicle at ovulation stimulates the acrosome reaction. Three enzymes are released from the acrosome to facilitate entry of the sperm into the ovum. Hyaluronidase allows the sperm to penetrate the corona radiata, whereas trypsin-like enzymes and zona lysin digest a pathway across the zona pellucida (Moore, Persaud, & Torchia, 2015; Sadler, 2015).

Only about 300 to 500 spermatozoa actually reach the ovum. When a spermatozoon comes into contact with the ovum, the zona pellucida and the plasma membrane fuse, preventing entry by other sperm. After penetration by a single sperm, the oocyte completes the second meiotic cell division, resulting in the haploid number of chromosomes (22,X) and the second polar body. The chromosomes are arranged to form the female pronucleus (Moore et al., 2015; Sadler, 2015).

As the spermatozoon moves close to the female pronucleus, the tail detaches, and the nucleus enlarges to form the male pronucleus. The male and female pronuclei fuse forming a diploid cell called the zygote. The zygote contains 23 autosomes and 1 sex chromosome from each parent (46,XX or 46,XY). The genetic sex of the new individual is determined at fertilization by the contribution of the father. The male parent (XY) may contribute either an X or a Y chromosome. If the spermatozoon contains an X chromosome, the offspring is female (46,XX). If the spermatozoon receives one Y chromosome, the offspring is male (46,XY). Individual variation is the result of random or independent assortment of the autosomal chromosomes (Moore et al., 2015; Sadler, 2015).

Cleavage

Mitotic cell division occurs after fertilization as the zygote passes down the uterine tube, resulting in the formation of two blastomeres (Figure 1.1). The cells continue to divide, increasing in number, although decreasing in size. The term *cleavage* is used to describe the mitotic cell division of the zygote (Figure 1.2). When the number of cells reaches approximately 16 (usually on the third day), the zygote is called a morula, because of its resemblance to a mulberry. The zygote reaches the morula stage about the time it enters the uterus. The morula consists of groups of centrally located cells called the inner cell mass and an outer cell layer. At this stage, the individual cells are called blastomeres. The outer cell layer forms the trophoblast, from which the placenta develops. The inner cell mass, called the embryoblast, gives rise to the embryo (Moore et al., 2015; Sadler, 2015).

After the morula penetrates the uterine cavity, fluid enters through the zona pellucida into the intercellular spaces of the inner cell mass. The fluid-filled spaces fuse, forming a large cavity known as the blastocyst cavity about the fourth day after fertilization. The morula is now called the blastocyst. This outer cell layer, known

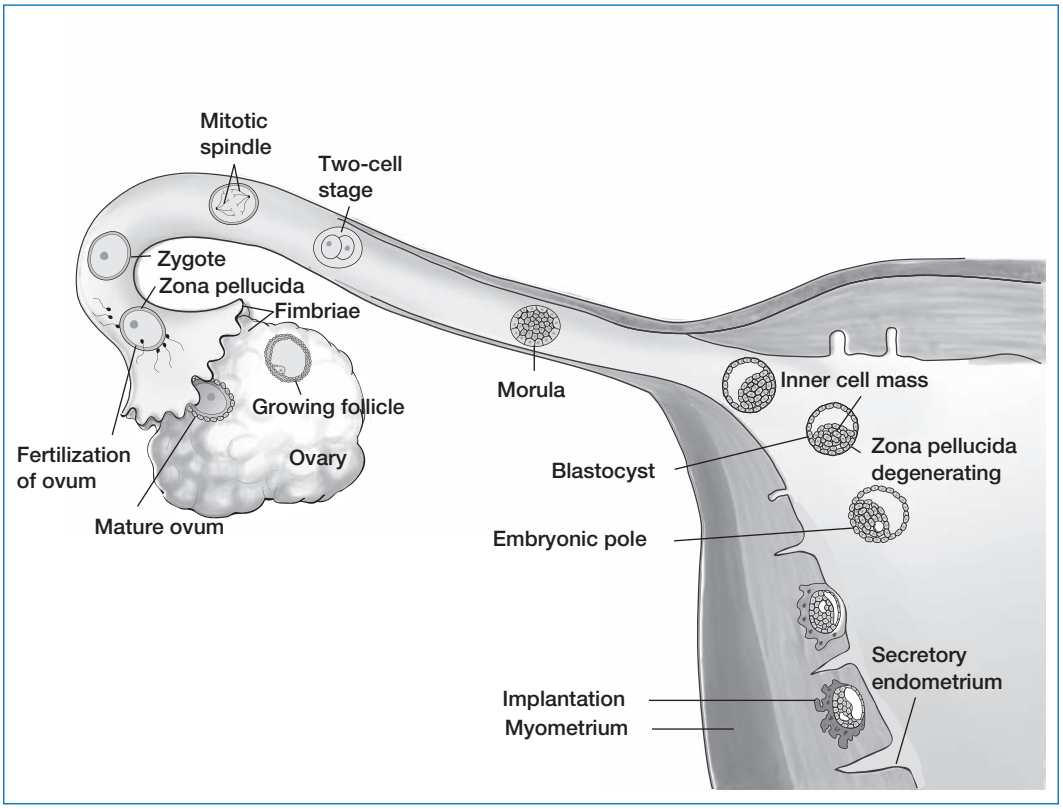

FIGURE 1.1 Fantastic voyage. From fertilization to implantation. The journey through the fallopian tubes takes approximately 4 days. During this time, mitotic cell division occurs. Implantation occurs on about day 9 through 12.

as the trophoblast, forms the wall of the blastocyst, which later becomes the placenta, and the embryoblast projects from the wall of the blastocyst into the blastocyst cavity. The uterine secretions nourish the blastocyst until implantation occurs (Moore et al., 2015; Sadler, 2015).

Implantation

Degeneration of the zona pellucida occurs on about the fifth day after fertilization, allowing the blastocyst to attach to the endothelium of the endometrium on about the sixth day. The trophoblasts then secrete proteolytic enzymes that destroy the endometrial endothelium and invade the endometrium. Two layers of trophoblasts develop; the inner layer is made up of cytotrophoblasts, and the outer layer is composed of syncytiotrophoblasts. The syncytiotrophoblast has finger-like projections that produce enzymes capable of further eroding the endometrial tissues. By the end of the seventh day, the blastocyst is superficially implanted (Figure 1.3).

Formation of the Bilaminar Disk

Implantation is completed during the second week. The syncytiotrophoblast continues to invade the endometrium and becomes embedded. Spaces in the syncytiotrophoblast, called lacunae, fill with blood from ruptured maternal capillaries and secretions from eroded endometrial glands. This fluid nourishes the embryoblast by diffusion. The lacunae give rise to the uteroplacental circulation. The lacunae fuse to form a network that then becomes the intervillous spaces of the placenta. The endometrial capillaries near the implanted embryoblast become dilated and eroded by the syncytiotrophoblast. Maternal blood enters the lacunar network and provides circulation and nutrients to the embryo. Maternal embryonic blood circulation provides the developing embryo with nutrition and oxygenation and removes waste products before the development of the placenta. Finger-like projections, primary chorionic villi, of the chorion develop into the chorionic villi of the placenta at about the same time (Moore et al., 2015; Sadler, 2015).

The inner cell mass differentiates into two layers: the hypoblast (endoderm), a layer of small cuboidal cells, and the epiblast (ectoderm), a layer of high columnar cells. The two layers form a flattened, circular bilaminar embryonic disk. The amniotic cavity is derived from spaces within the epiblast. As the amniotic cavity enlarges, a thin layer of epithelial cells covers the amniotic cavity. During the development of the amniotic cavity, other trophoblastic cells form a thin extracoelomic membrane, which encloses the primitive yolk sac. The yolk sac produces fetal red blood cells. Other trophoblastic cells form a layer of mesenchymal tissue, called the extraembryonic mesoderm, around the amnion and primitive yolk sac. Isolated coelomic spaces in the extraembryonic mesoderm fuse to form a single, large, fluid-filled cavity surrounding the amnion and yolk sac, with the exception of the area where the amnion is attached to the chorion by the connecting stalk. The primitive yolk sac decreases in size, creating a smaller secondary yolk sac (Moore et al., 2015; Sadler, 2015).

Two layers of extraembryonic mesoderm result from the formation of the extraembryonic cavity. The extraembryonic somatic mesoderm lines the trophoblast and covers the amnion, and the extraembryonic splanchnic mesoderm covers the yolk sac. The chorion is made up of the extraembryonic somatic mesoderm, the cytotrophoblast, and the syncytiotrophoblast. The chorion forms the chorionic sac, in which the embryo, the amniotic sac, and the yolk sac are located. By the end of the second week, there is a slightly thickened area near the cephalic region of the hypoblastic disk, known as the prochordal plate, which marks the location of the mouth (Moore et al., 2015; Sadler, 2015).

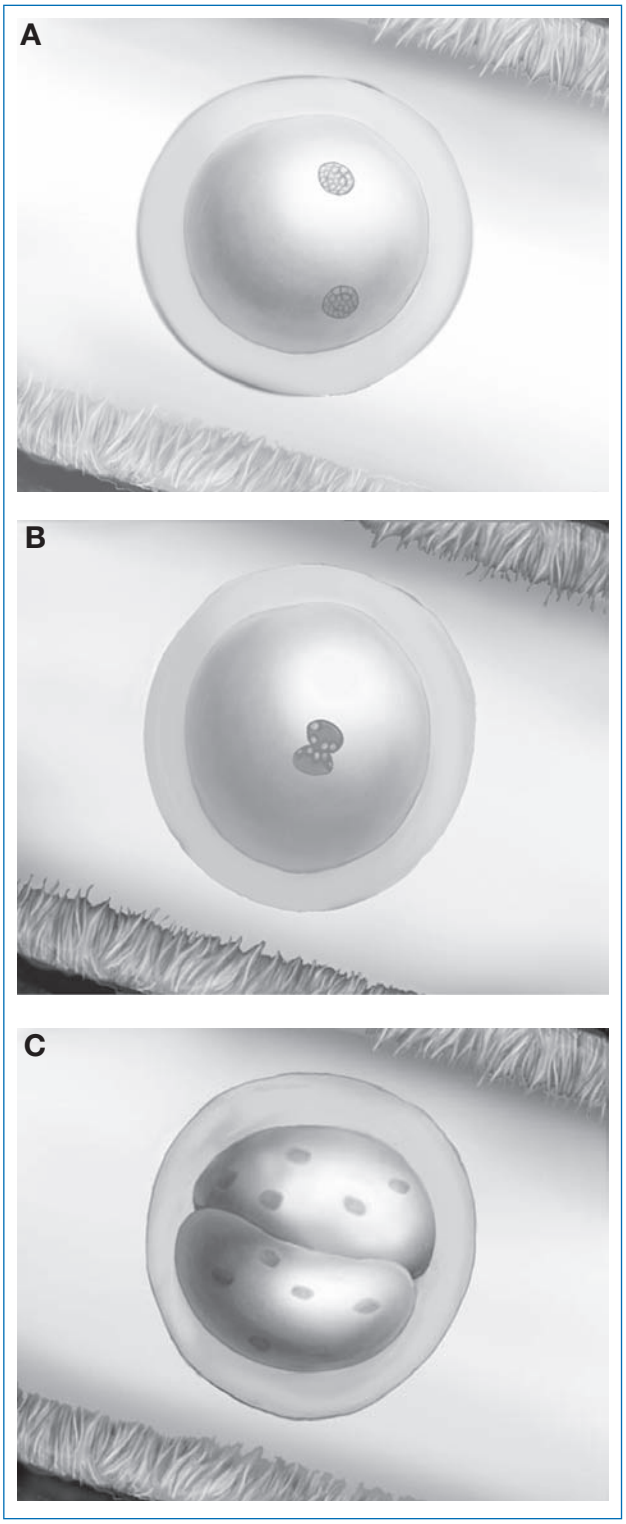

FIGURE 1.2 Stages of cell division: cleavage. (A) Zygote. (B) Zygote undergoing first cleavage. (C) Two-cell blastomere state.

Formation of the Trilaminar Embryonic Disk: The Third Week of Development

The third week of development is marked by rapid growth, the formation of the primitive streak, and the differentiation of the three germ layers, from which all fetal tissue and organs are derived (Moore et al., 2015; Sadler, 2015; Figure 1.4).

Gastrulation. Gastrulation is the process through which the bilaminar disk develops into a trilaminar embryonic disk.

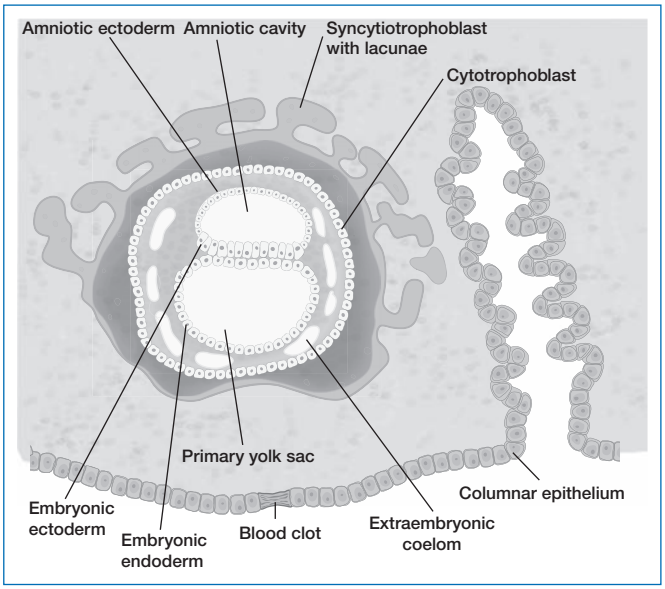

FIGURE 1.3 Cross section of a blastocyst at 11 days. Two germ layers are present. The trophoblast has differentiated into the syncytiotrophoblast and the cytotrophoblast.

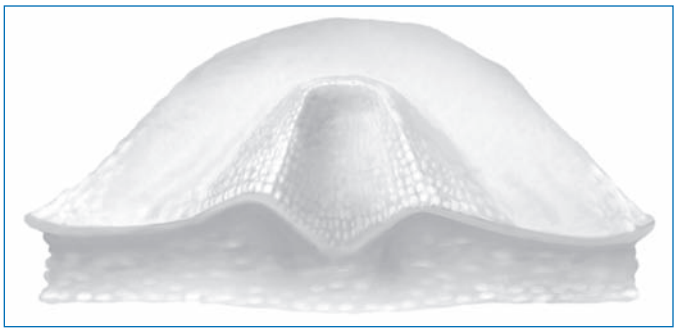

FIGURE 1.4 Formation of the trilaminar embryonic disk: gastrulation. During gastrulation, the bilaminar embryonic disk changes to a trilaminar embryonic disk, consisting of the epiblast (ectoderm), hypoblast (endoderm), and mesoblast (mesoderm).

Gastrulation is the most important event of early fetal formation; it affects all of the rest of embryologic development. During the third week, epiblast cells separate from their original location and migrate inward, forming the mesoblast, which spreads cranially and laterally to form a layer between the ectoderm and the endoderm called the intraembryonic mesoderm. Other mesoblastic cells invade the endoderm, displacing the endodermal cells laterally, forming a new layer, the embryonic ectoderm. Thus, the hypoblastic ectoderm produces the embryonic ectoderm, embryonic mesoderm, and the majority of the embryonic endoderm. These three germ layers are the source of the tissue and organs of the embryo (Moore et al., 2015; Sadler, 2015).

Primitive Streak. Over days 14 and 15, a groove and thickening of the ectoderm (epiblast), called the primitive streak, appears caudally in the center of the dorsum of the embryonic disk. The primitive streak results from the migration of ectodermal cells toward the midline in the posterior portion of the embryonic disk. The primitive groove develops in the primitive streak. When the primitive streak begins to produce mesoblastic cells that become intraembryonic mesoderm, the epiblast is referred to as the embryonic ectoderm and the hypoblast is referred to as the embryonic mesoderm (Moore et al., 2015; Sadler, 2015).

Notochordal Process. Cells from the primitive knot migrate cranially and form the midline cellular notochordal process. This process grows cranially between the ectoderm and the endoderm until it reaches the prochordal plate, which is attached to the overlying ectoderm, thus forming the oropharyngeal membrane. The cloacal membrane, caudal to the primitive streak, develops into the anus (Moore et al., 2015; Sadler, 2015).

The primitive streak produces mesenchyme (mesoblasts) until the end of the fourth week. The primitive streak does not grow as rapidly as the other cells, making it relatively insignificant in size when compared with the other structures that continue to grow. Persistence of the primitive streak or remnants is the cause of sacrococcygeal teratomas (Moore et al., 2015; Sadler, 2015).

The notochord, a cellular rod that develops from the notochordal process, is the structure around which the vertebral column is formed. It forms the nucleus pulposus of the intervertebral bodies of the spinal column (Figure 1.5; Moore et al., 2015; Sadler, 2015).

Neurulation. Neurulation is the process through which the neural plate, neural folds, and neural tube are formed. The developing notochord stimulates the embryonic ectoderm to thicken, forming the neural plate. The neuroectoderm of the neural plate gives rise to the central nervous system (CNS). The neural plate develops cranial to the primitive knot. As the neural plate elongates, it gets wider and extends cranially to the oropharyngeal membrane. The neural plate invaginates along the central axis to form a neural groove with neural folds on each side. The neural folds move together and fuse, forming the neural tube showing the first indication of brain development (Figure 1.6). The neural tube detaches from the surface ectoderm, and the free edges of the ectoderm fuse, covering the posterior portion of the embryo. With formation of the neural tube, nearby ectodermal cells lying along the crest of each neural fold migrate inward, invading the mesoblast on each side of the neural tube. These irregular, flattened masses are called the neural crest. This structure's cells give rise to the spinal ganglia, the ganglia of the autonomic nervous system, and cranial nerves V, VII, IX, and X. Neural crest cells also form the meningeal covering of the brain and spinal cord and the sheaves that protect nerves. The neural crest cells contribute to the formation of pigment-producing cells, the adrenal medulla, and skeletal and muscular development in the head (Moore et al., 2015; Sadler, 2015).

Development of Somites. Another important event of the third week is the development of somites, which give rise to most of the skeleton and associated musculature and much of the dermis of the skin. During formation of the neural tube, the intraembryonic mesoderm on each side thickens, forming longitudinal columns of paraxial mesoderm. At about 20 days, the paraxial mesoderm begins to divide into paired cuboidal bodies known as somites. In all, 42 to 44 somites develop, in a craniocaudal sequence, although only 38 develop during the "somite" period. These somite pairs can be counted and give an estimate of fetal age before a crown-rump (C-R) measurement is possible (Moore et al., 2015; Sadler, 2015).

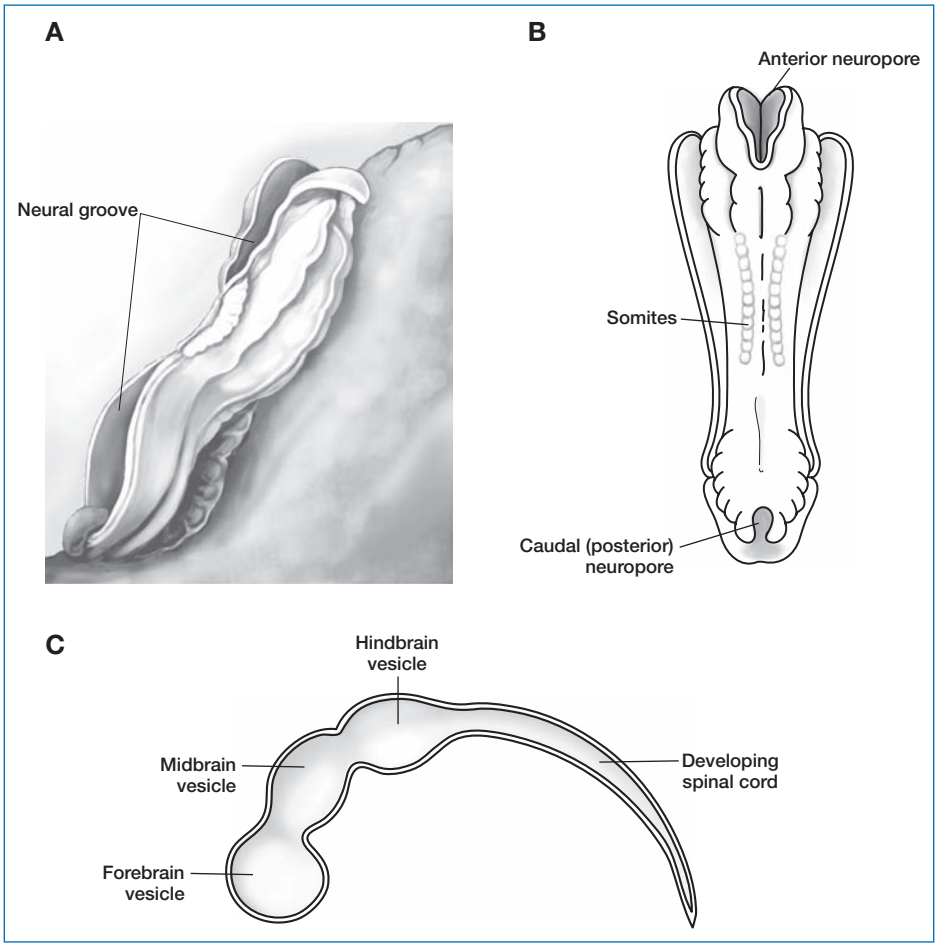

FIGURE 1.6 Formation of the neural tube. (A) Neural groove. (B) Closure of the neural tube almost completed. (C) Dilation of the neural tube forms the forebrain, midbrain, and hindbrain.

Intraembryonic Cavity. Another significant process is the formation of the intraembryonic cavity. This structure first appears as a number of small spaces within the lateral mesoderm and the cardiogenic mesoderm. These spaces combine to form the intraembryonic cavity; it is horseshoe-shaped and lined with flattened epithelial cells that eventually line the peritoneal cavity. The intraembryonic cavity divides the lateral mesoderm into the parietal (somatic) and visceral (splanchnic) layers. It gives rise to the pericardial cavity, the pleural cavity, and the peritoneal cavity (Moore et al., 2015; Sadler, 2015).

PLACENTAL DEVELOPMENT AND FUNCTION

The rudimentary maternal fetal circulation is intact by the fourth week of gestation. Growth of the trophoblast results in numerous primary and secondary chorionic villi, covering the surface of the chorionic sac until about the eighth week of gestation. At about the eighth week, the villi overlying the conceptus (decidua capsularis) degenerate, leaving a smooth area (smooth chorion). The villi underlying the conceptus (decidua basalis) remain and increase in size, producing the chorion frondosum, or fetal side of the placenta. The maternal side of the placenta is made up of the chorion and the chorionic villi. On implantation of the conceptus, maternal capillaries of the decidua basalis rupture, causing maternal blood to circulate through the developing fetal placenta (chorion frondosum). As growth and differentiation progress, extensions from the cytotrophoblast invade the syncytial layer and form a cytotrophoblastic shell, surrounding the conceptus and chorionic villi. This shell is continuous, but has communications between maternal blood vessels in the decidua basalis and the intervillous spaces of the chorion frondosum. The latter is attached to the maternal side of the placenta (decidua basalis) by the cytotrophoblastic shell and anchoring villi. The placenta is mature and completely functional by 16 weeks of development (Figure 1.7). If the corpus luteum begins to regress prior to the 16th week and fails to produce enough progesterone (the hormone responsible for readying the uterine cavity for the pregnancy), the pregnancy is aborted because the placenta is not capable of supporting the pregnancy on its own until about this time (Moore et al., 2015; Sadler, 2015).

Placental Fetal Circulation

A simple ebb-and-flow circulation is present in the embryo, yolk sac, connecting stalk, and chorion by 21 days of gestation. By 28 days, unidirectional circulation is established. Deoxygenated fetal blood leaves the fetus via the umbilical arteries and enters the capillaries in the chorionic villi, where gaseous and nutrient exchanges take place. Oxygenated blood returns to the fetus through the umbilical veins. At first, there are two arteries and two veins, but one vein gradually degenerates, leaving two arteries and one vein. If only one artery is present, a congenital anomaly, especially a renal one, should be suspected (Moore et al., 2015; Sadler, 2015).

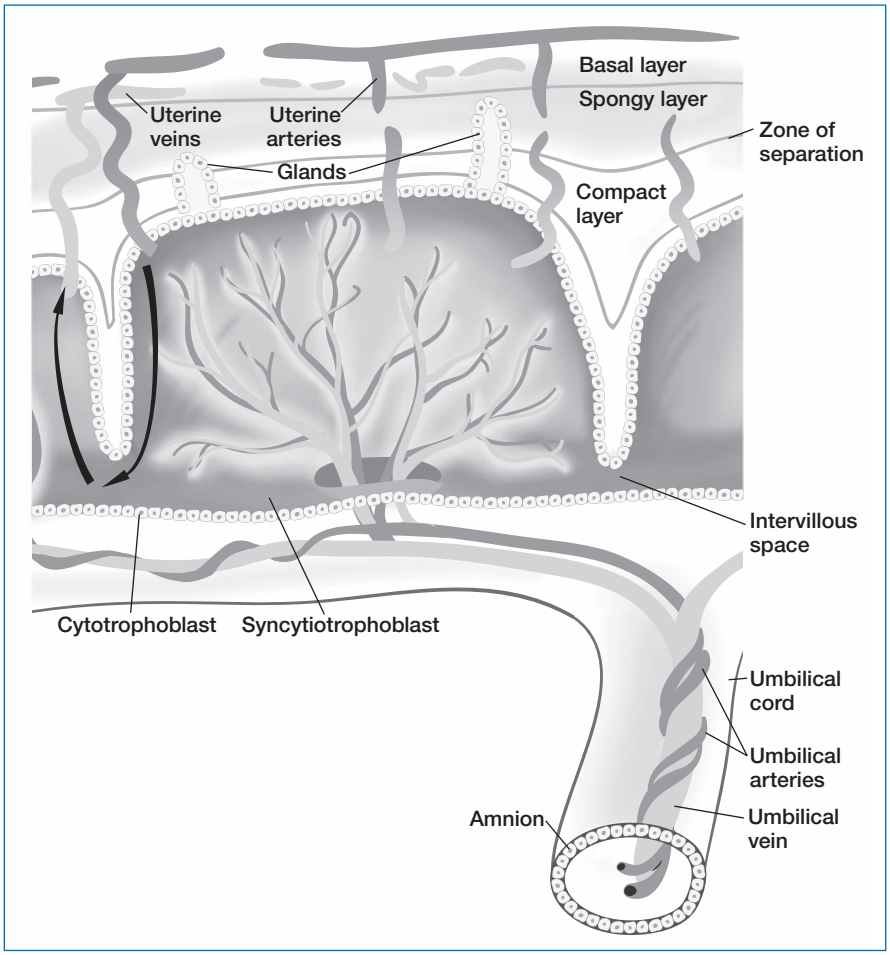

FIGURE 1.7 Formation of the placenta. The fetal and maternal sides of the placenta. Separation of the placenta from the uterus occurs at the site indicated by the gray line labeled zone of separation.

Placental Function

Normal growth and development of the embryo depend on adequate placental function. The placenta is responsible for oxygenation, nutrition, elimination of wastes, production of hormones essential for maintenance of the pregnancy, and transport of substances. In addition, the placenta synthesizes glycogen, cholesterol, and fatty acids, which provide nutrients and energy for early fetal development. Transport across the placental membrane occurs primarily through simple and facilitated diffusion, active transport, and pinocytosis. Oxygen, carbon dioxide, and carbon monoxide cross the placenta through simple diffusion. The fetus depends on a continuous supply of oxygenated blood flowing from the placenta (Moore et al., 2015; Sadler, 2015).

Water and electrolytes cross the placenta freely in both directions. Glucose is converted to glycogen in the placenta as a carbohydrate source for the fetus. Amino acids move readily across the placental membranes for protein synthesis in the fetus. Free fatty acids are transferred across the placenta by pinocytosis. There is limited or no transfer of maternal cholesterol, triglycerides, and phospholipids. Water- and fat-soluble vitamins cross the placenta and are essential for normal development (Moore et al., 2015; Sadler, 2015).

The placenta produces and transports hormones that maintain the pregnancy and promote growth and development of the fetus. Chorionic gonadotropin, a protein hormone produced by the syncytiotrophoblast, is excreted in maternal serum and urine. The presence of human chorionic gonadotropin is used as a test for pregnancy. Human placental lactogen, also a protein hormone produced by the placenta, acts as a fetal growth–promoting hormone by giving the fetus priority for receiving maternal glucose (Moore et al., 2015; Sadler, 2015).

The placenta also produces steroid hormones. Progesterone, produced by the placenta throughout gestation, is responsible for maintaining the pregnancy. Estrogen production by the placenta depends on stimulation by the fetal adrenal cortex and liver. Placental transport of maternal antibodies provides the fetus with passive immunity to certain viruses. IgG antibodies are actively transported across the placental barrier, providing humoral immunity for the fetus. IgA and IgM antibodies do not cross the placental barrier, placing the neonate at risk for neonatal sepsis. However, failure of IgM antibodies to cross the placental membrane explains the lower incidence of a severe hemolytic process in ABO blood type incompatibilities when compared with Rh incompatibilities. The latter result when an Rh-negative mother has an Rh-positive fetus. If the mother is sensitized to the Rh-positive fetal blood cells, the mother produces IgG antibodies. IgG is transferred from the maternal to fetal circulation, and hemolysis of fetal red blood cells occurs (Moore et al., 2015; Sadler, 2015).

The placenta is selective in the transfer of substances across the placenta; however, this selectivity does not screen out all potentially harmful substances. Viral, bacterial, and protozoal organisms can be transferred to the fetus through the placenta. Toxic substances such as drugs and alcohol can also be transferred to the fetus. The effects of these substances depend on the stage of gestation and type and duration of exposure, as well as the interaction of these and other factors, such as nutrition.

EMBRYONIC PERIOD: WEEKS 4 THROUGH 8

The embryonic period lasts from the beginning of gestational week 4 through the end of week 8. Organogenesis, which is the formation of all major organs, occurs during this period. The shape of the embryo changes as the organs develop, taking a more human shape by the end of the eighth week. The major events of the embryonic period are the folding of the embryo and organogenesis.

Folding of the Embryo

In the trilaminar embryonic disk, the growth rate of the central region exceeds that of the periphery so that the slower growing areas fold under the faster growing areas, forming body folds. The head fold appears first as a result of craniocaudal elongation of the notochord and growth of the brain, which projects into the amniotic cavity. The folding downward of the cranial end of the embryo forces the septum transversum (primitive heart), the pericardial cavity, and the oropharyngeal membrane to turn under onto the ventral surface. After the embryo has folded, the mass of mesoderm cranial to the pericardial cavity, the septum transversum, lies caudal to the heart. The septum transversum later develops into a portion of the diaphragm. Part of the yolk sac is incorporated as the foregut, lying between the heart and the brain. The foregut ends blindly at the oropharyngeal membrane, which separates the foregut from the primitive mouth cavity (stomodeum; Moore et al., 2015; Sadler, 2015).

The tail fold occurs after the head fold as a result of craniocaudal growth progression. Growth of the embryo causes the caudal area to project over the cloacal membrane. During the tail folding, part of the yolk sac is incorporated into the embryo as the hindgut. After completion of the head and tail folding, the connecting stalk is attached to the ventral surface of the embryo, forming the umbilical cord. Folding also occurs laterally, producing right and left lateral folds. The lateral body wall on each side folds toward the median plane, causing the embryo to assume a cylindrical shape. During the lateral body folding, a portion of the yolk sac is incorporated as the midgut. The attachment of the midgut to the yolk sac is minimal after this fold develops. After folding, the amnion is attached to the embryo in a narrow area in which the umbilical cord attaches to the ventral surface (Moore et al., 2015; Sadler, 2015).

Organogenesis: Germ Cell Derivatives

The three germ cell layers (ectoderm, mesoderm, and endoderm) give rise to all tissues and organs of the embryo. The germ cells follow specific patterns during the process of organogenesis. The main germ cell derivatives are listed in Box 1.1. The development of each major organ system is discussed separately. The embryonic period is the most critical period of development because of the formation of internal and external structures. The critical periods of development for the organs are also discussed in the section on specific organ development.

Box 1.1

GERM CELL DERIVATIVES

Ectoderm

- CNS (brain, spinal cord)
- Peripheral nervous system
- Sensory epithelia of eye, ear, and nose
- Epidermis and its appendages (hair and nails)
- Mammary glands
- Subcutaneous glands
- Teeth enamel
- Neural crest cells
- Spinal, cranial, and autonomic ganglia cells
- Nerve sheaths of peripheral nervous system
- Pigment cells
- Muscle, connective tissue, and bone of branchial arch origin
- Adrenal medulla
- Meninges

Mesoderm

- Cartilage
- Bone
- Connective tissue
- Striated and smooth muscle
- Heart, blood, and lymph vessels and cells
- Gonads
- Genital ducts
- Pericardial, pleural, and peritoneal lining
- Spleen
- Cortex of adrenal gland

Endoderm

- Epithelial lining of respiratory and gastrointestinal tracts
- Parenchyma of tonsils, thyroid, parathyroid, liver, thymus, and pancreas
- Epithelial lining of bladder and urethra
- Epithelial lining of tympanic cavity, tympanic antrum, and auditory tube

CNS, central nervous system

DEVELOPMENT OF SPECIFIC ORGANS AND STRUCTURES

Nervous System

The origin of the nervous system is the neural plate, which arises as a thickening of the ectodermal tissue about the middle of the third week of gestation. The neural plate further differentiates into the neural tube and the neural crest. The neural tube gives rise to the CNS. The neural crest cells give rise to the peripheral nervous system (Figure 1.8; Moore et al., 2015; Sadler, 2015).

The cranial end of the neural tube forms the three divisions of the brain: the forebrain, the midbrain, and the hindbrain. The

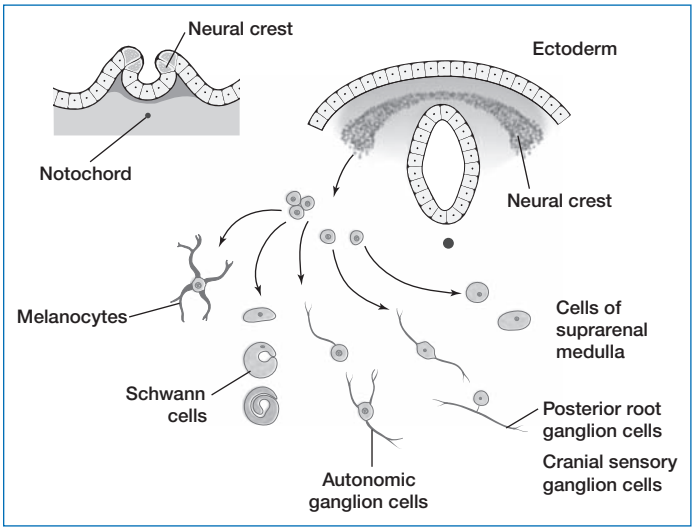

FIGURE 1.8 Differentiation of the nervous system. The cells of the neural crest differentiate into the cells of the ganglia, Schwann cells, and the cells of the suprarenal medulla and melanocytes.

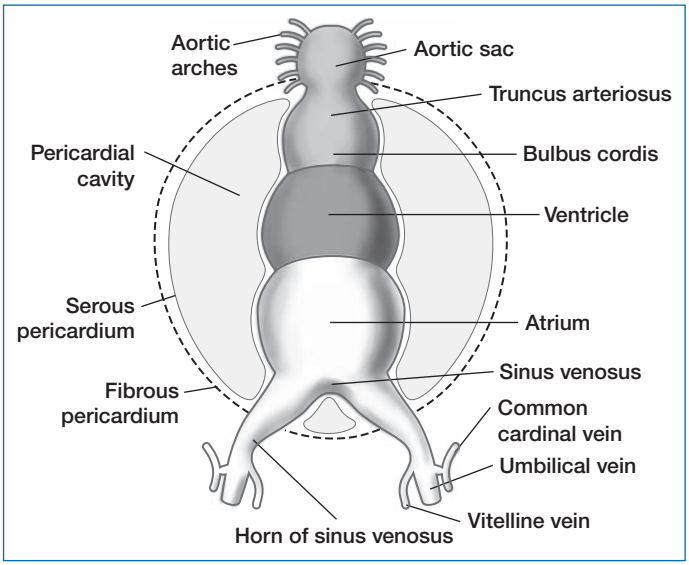

FIGURE 1.9 Formation of the single heart tube. The appearance of the single heart tube inside the pericardial cavity. Note that the atrium and sinus venosus are outside the pericardial cavity.

cerebral hemispheres and diencephalon arise from the forebrain; the pons, cerebellum, and medulla oblongata arise from the hindbrain. The midbrain makes up the adult midbrain (Moore et al., 2015; Sadler, 2015).

The cavity of the neural tube develops into the ventricles of the brain and the central canal of the spinal column. The neuroepithelial cells lining the neural tube give rise to nerves and glial cells of the CNS. The peripheral nervous system consists of the cranial, spinal, and visceral nerves and the ganglia. The somatic and visceral sensory cells of the peripheral nervous system arise from neural crest cells. Cells that form the myelin sheaths of the axons, called Schwann cells, also arise from the neural crest cells (Moore et al., 2015; Sadler, 2015).

Cardiovascular System

The fetal cardiac system appears at about 18 to 19 days of gestation, and circulation is present by about 21 days. The cardiovascular system is the first organ system to function in utero. The heart starts to beat at the beginning of the fourth week. The heart and blood develop from the middle layer (mesoderm) of the trilaminar embryonic disk. Tissue from the lateral mesoderm migrates up the sides of the embryonic disk, forming a horseshoe-shaped structure that arches and meets above the oropharyngeal membrane. With further development, paired heart tubes form, which then fuse into a single heart tube (Figure 1.9). The vessels that make up the vascular system throughout the body develop from mesodermal cells that connect to each other, with the developing heart tube and the placenta. Thus, by the end of the third week of gestation, there is a functional cardiovascular system (Moore et al., 2015; Sadler, 2015).

As the heart tube grows, the folding of the embryonic disk results in the movement of the heart tube into the chest cavity. The heart tube differentiates into three layers: the endocardial layer, which becomes the endothelium; the cardiac jelly, which is a loose tissue layer; and the myoepicardial mantle, which becomes the myocardium and pericardium. The single heart tube is attached at its cephalic end by the aortic arches and at the caudal end by the septum transversum. The attachments limit the length of the heart tube. Continued growth results in dilated areas and bulges, which become specific components of the heart. The atrium, ventricle, and bulbus cordis can be identified first, followed by the sinus venosus and truncus arteriosus. To accommodate continued growth, two separate bends in the heart occur. It first bends to the right to form a U shape, and the next bend results in an S-shaped heart. The bending of the heart is responsible for the typical location of cardiac structures (Figure 1.10; Moore et al., 2015; Sadler, 2015).

Initially, the heart is a single chamber; partitioning of the heart into four chambers occurs from the fourth to sixth weeks of gestation. The changes that cause the partitioning of the heart occur simultaneously. The atrium is separated from the ventricle by endocardial cushions, which are thickened areas of endothelium that develop on the dorsal and ventral walls of the open area between the atrium and ventricle. The endocardial cushions fuse with each other to divide the atrioventricular canals into right and left atrioventricular canals. Partitioning of the atrium occurs through invagination of tissue toward the endocardial cushions, forming the septum primum. As the septum primum grows toward the endocardial cushions, it becomes very thin and perforates, becoming the foramen ovale. The septum primum does not fuse completely with the endocardial cushions; it has a lower portion that lies beside the endocardial cushions. Overlapping of the septum primum and the septum secundum forms a wall if the pressure in both atria is equal. In utero, the pressure on the right side is increased, allowing blood to flow across the foramen ovale from the right side of the heart to the left side (Figure 1.11; Moore et al., 2015; Sadler, 2015).

The ventricle is also partitioned by a membranous and muscular septum. The muscular portion of the septum develops from the fold of the floor of the ventricle. With blood flowing through the atrioventricular canal, ventricular dilation occurs on either side of the fold or ridge, causing it to become a septum. The membranous septum arises from ridges inside the bulbus cordis. These ridges, continuous into the bulbus cordis, form the wall that divides the bulbus cordis into the pulmonary artery and the aorta. The bulbar ridges fuse with the endocardial cushions to form the membranous septum. The membranous and muscular septa fuse to close the intraventricular foramen, resulting in two parallel circuits of blood flow. The pulmonary artery is continuous with the right ventricle, and the aorta is continuous with the left ventricle (Figure 1.12; Moore et al., 2015; Sadler, 2015).

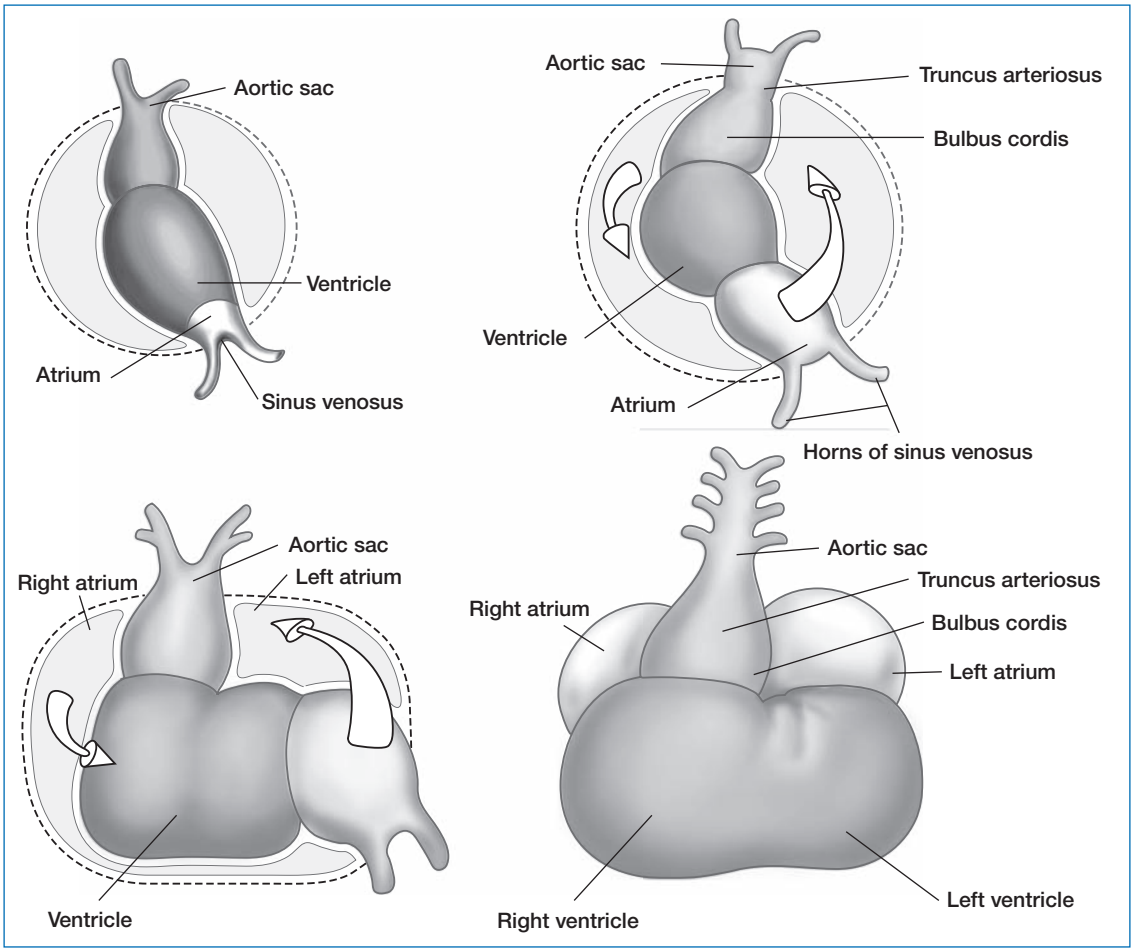

FIGURE 1.10 Bending of the heart tube inside the pericardial cavity. The bending of the heart tube brings the atrium into the pericardial cavity. The sinus venosus is taken into the right atrium and the coronary sinus.

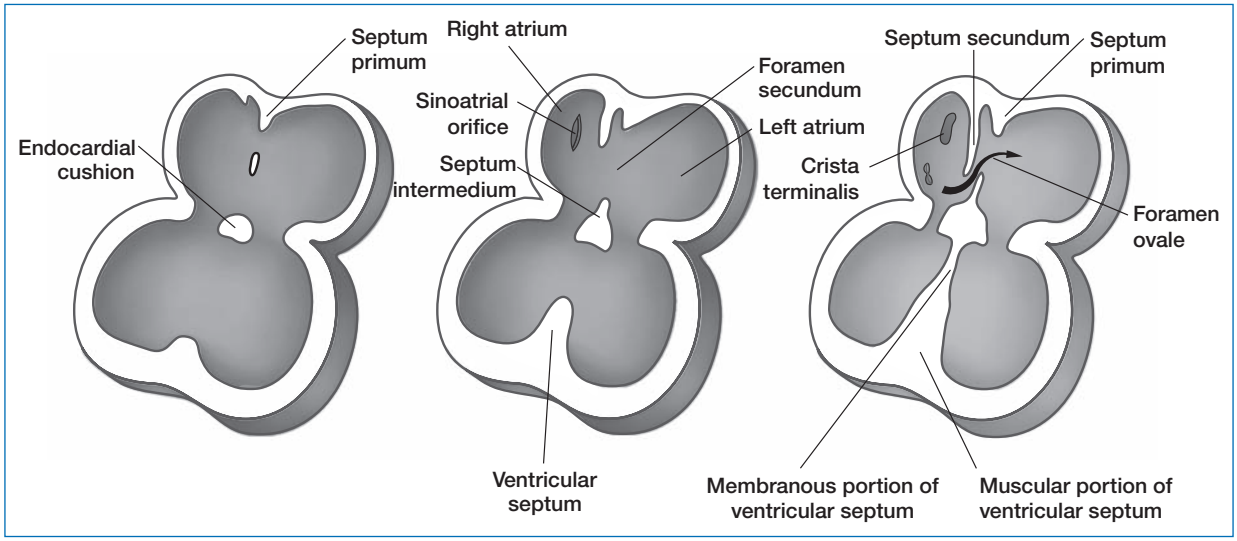

FIGURE 1.11 Partitioning of the atrium. The partitioning of the atrium into the right and left atria through septation.

The blood flowing through the bulbus cordis and truncus arteriosus in a spiral causes the formation of ridges. The ridges fuse to form two separate vessels that twist around each other once. Thus, the pulmonary artery exits the right side of the heart and is in the left upper chest; the aorta exits the left side of the heart and is located close to the sternum (Moore et al., 2015; Sadler, 2015).

The pulmonary veins grow from the lungs to a cardinal vein plexus. Concurrently, a vessel develops from the smooth wall of the left atrium. As the atrium grows, the pulmonary vein is incorporated into the atrial wall. The atrium and its branches give rise to four pulmonary veins that enter the left atrium. These pulmonary vessels, connected to the plexus of the cardinal vein, provide

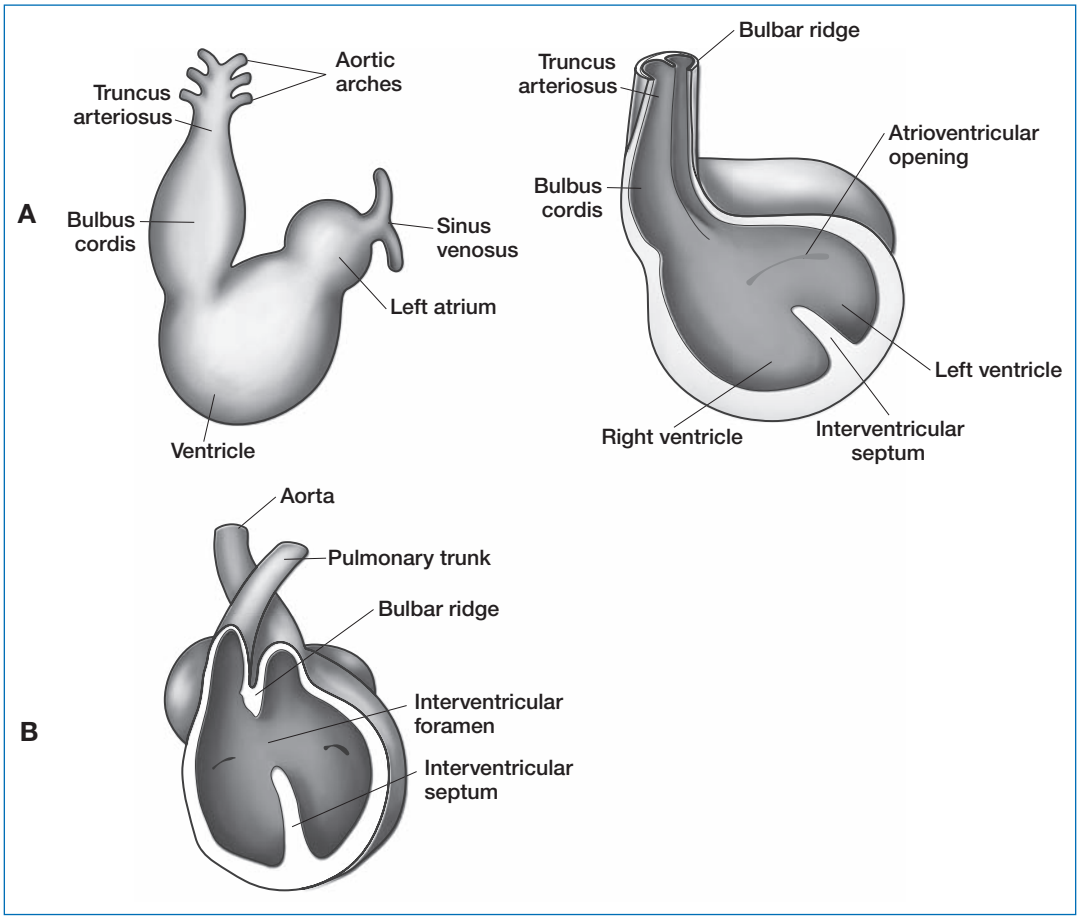

FIGURE 1.12 Partitioning of the ventricles. (A) Five chambers are present in the heart at 5 weeks' gestation. (B) At 6 weeks, the bulbus cordis has been taken into the ventricles and the interventricular septum has partitioned the ventricles into right and left sides.

a continuous circulation from lung to heart. The pulmonary and aortic valves (semilunar valves) develop from dilations within the pulmonary artery and aorta. The ebb-and-flow circulation through these structures causes them to hollow out to form the cusps of the valves. The tricuspid and mitral valves develop from tissue around the atrioventricular canals that thicken and then thin out on the ventricular sides, forming the valves (Figure 1.13; Moore et al., 2015; Sadler, 2015).

Respiratory System

The development of the respiratory system is linked to the development of the face and the digestive system. The respiratory system is composed of the nasal cavities, nasopharynx, oropharynx, larynx, trachea, bronchi, and lungs (Figure 1.14). Development of the lungs occurs in four overlapping stages, which extend from the fifth week of gestation until about 8 years of life. The stages are listed in Table 1.1. At term birth, the normal respiratory system functions immediately. For adequate functioning of the respiratory system, there must be a sufficient number of alveoli, adequate capillary blood flow, and an adequate amount of surfactant produced by the secretory epithelial cells or the type II pneumatocytes. It is the surfactant that prevents alveolar collapse and aids in respiratory gas exchange. Production of surfactant begins around 20 weeks, but does not reach adequate levels until late in gestation. In addition, work to identify the role of epidermal growth factor (EGF) in the development of the fetal respiratory system has determined that EGF indirectly promotes branching morphogenesis of the lung epithelium through a direct effect on the mesenchyme (Moore et al., 2015; Sadler, 2015).

Muscular System

The muscular system develops from mesodermal cells called myoblasts. Striated skeletal muscles are derived from myotomal mesoderm (myotomes) of the somites. The majority of striated skeletal muscle fibers develop in utero. Almost all striated skeletal muscles are formed by 1 year of age. Growth is achieved by an increase in the diameter of the muscle fibers, rather than the growth of new muscle tissue. Smooth muscle fibers arise from the splanchnic mesenchyme surrounding the endoderm of the primitive gut. Smooth muscles lining vessel walls of blood and lymphatic systems arise from somatic mesoderm. As smooth muscle cells differentiate, contractile filaments develop in the cytoplasm, and the external surface is covered by an external lamina. As the smooth muscle fibers develop into sheets or bundles, the muscle cells synthesize and release collagenous, elastic, or reticular fibers (Figure 1.15; Moore et al., 2015; Sadler, 2015).

Cardiac muscle develops from splanchnic mesenchyme from the outside of the endocardial heart tube. Cells from the myoepicardial mantle differentiate into the myocardium. Cardiac muscle fibers develop from differentiation and growth of single cells rather than fusion of cells. Cardiac muscle growth occurs through the formation of new filaments. The Purkinje fibers develop late in

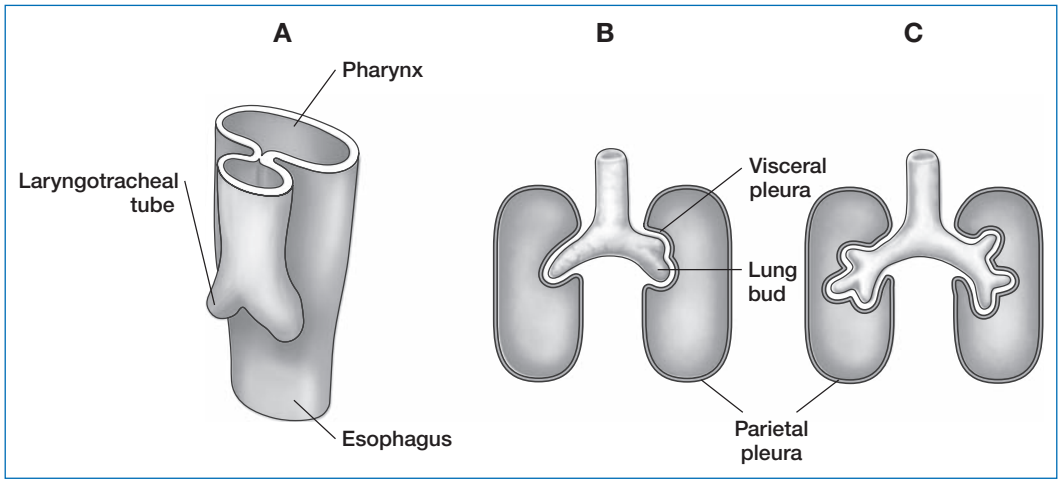

FIGURE 1.14 Development of the pulmonary system. (A) The laryngotracheal groove and tube have formed; the margins of the laryngotracheal groove fuse, forming the laryngotracheal tube. (B) Invagination of the lung buds into the intraembryonic cavity. (C) Division of the lung buds into the right and left mainstem bronchi.

the embryonic period. These fibers are larger and have fewer myofibrils than other cardiac muscle cells. The Purkinje fibers function in the electrical conduction system of the heart (Moore et al., 2015; Sadler, 2015).

Skeletal System

The skeletal system develops from mesenchymal cells. In the long bones, condensed mesenchyme forms hyaline cartilage models of bones. By the end of the embryonic period, ossification centers appear, and these bones ossify by endochondral ossification. Other bones, such as the skull bones, are ossified by membranous ossification in which the mesenchyme cells become osteoblasts (Figure 1.16).

The vertebral column and the ribs arise from the sclerotome compartments of the somites. The spinal column is formed by the fusion of a condensation of the cranial half of one pair of sclerotomes with the caudal half of the next pair of sclerotomes.

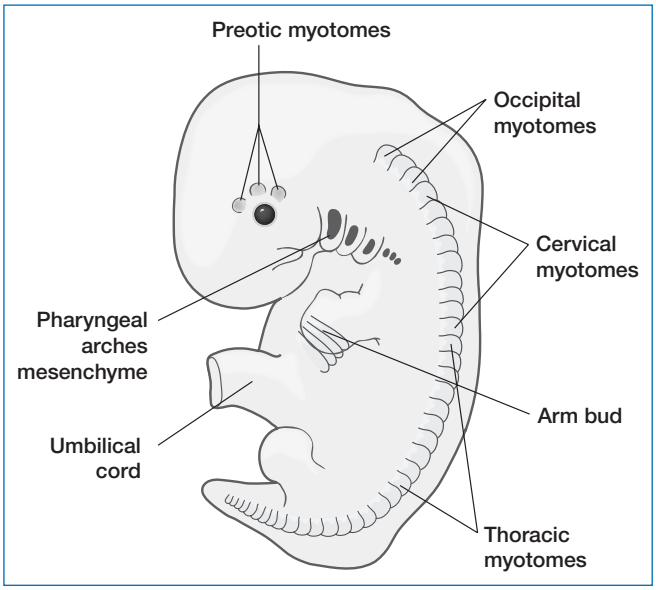

FIGURE 1.15 Origin of the muscles of the head and neck.

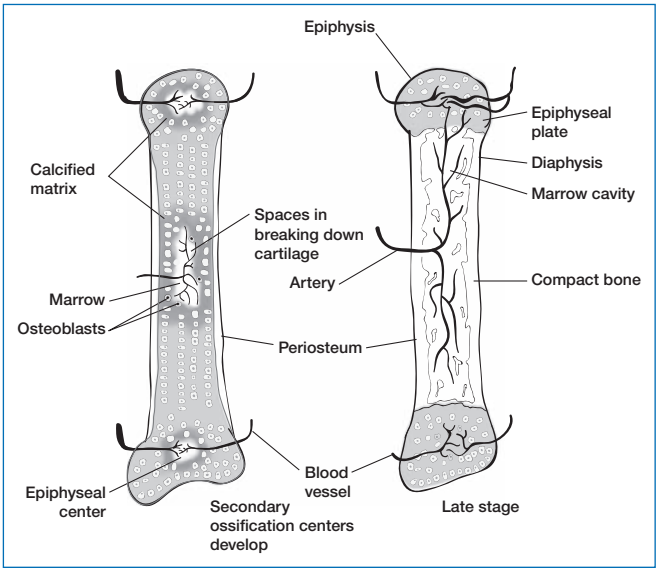

FIGURE 1.16 Endochondral ossification of bones.

TABLE 1.1

STAGES OF LUNG DEVELOPMENT

Stage	Critical Events
Stage 1: Pseudoglandular period: weeks 5–7	Development of the conducting airway
Stage 2: Canalicular period: weeks 13–25	Enlargement of the bronchial lumina and terminal bronchioles Vascularization of lung tissue Development of respiratory bronchioles and alveolar ducts Development of a limited number of primitive alveoli
Stage 3: Terminal sac period: week 24 to birth	Development of primitive pulmonary alveoli from alveolar ducts Increased vascularity Type II pneumatocytes begin to produce surfactant by about 24 weeks
Stage 4: Alveolar period: late fetal period until about 8 years of age	Pulmonary alveoli formed by thinning of terminal air sac lining One-eighth to one-sixth of adult number of alveoli present at term birth Alveoli increase in number until age 8 years

The skull can be divided into the neurocranium and the viscerocranium. The neurocranium forms the protective covering around the brain. The viscerocranium forms the skeleton of the face. The neurocranium is made up of the flat bones that surround the brain and the cartilaginous structure, or chondrocranium, that forms the bones of the base of the skull. The neurocranium (chondrocranium) is made up of a number of separate cartilages, which fuse and ossify by endochondral ossification to form the base of the skull (Moore et al., 2015; Sadler, 2015).

Gastrointestinal System

The gastrointestinal system is primarily derived from the lining of the roof of the yolk sac. The primitive gut, consisting of the foregut, midgut, and hindgut, is formed during the fourth gestational week (Figure 1.17). The structures that arise from the foregut include the pharynx, esophagus, stomach, liver, pancreas, gallbladder, and part of the duodenum. The esophagus and trachea have a common origin, the laryngotracheal diverticulum. A septum, formed by the growing tracheoesophageal folds, divides the cranial part of the foregut into the laryngotracheal tube and the esophagus. Smooth muscle develops from the splanchnic mesenchyme that surrounds the esophagus. The epithelial lining of the esophagus, derived from the endoderm, proliferates, partially obliterating the esophageal lumen. The esophagus undergoes recanalization by the end of the embryonic period (Moore et al., 2015; Sadler, 2015).

The stomach originates as a dilation of the caudal portion of the foregut. The characteristic greater curvature of the stomach develops because the dorsal border grows faster than the ventral border. As the stomach develops further, it rotates in a clockwise direction around the longitudinal axis. The duodenum is derived from the caudal and cranial portions of the foregut and the cranial portion of the midgut. The junction of the foregut and midgut portions of the duodenum is normally distal to the common bile duct (Moore et al., 2015; Sadler, 2015).

The liver, gallbladder, and biliary ducts originate as a bud from the caudal end of the foregut. The liver is formed by growth of the hepatic diverticulum, which grows between the layers of the ventral mesentery, forming two parts. The liver forms from the largest cranial portion. Hepatic cells originate from the hepatic diverticulum. Hematopoietic tissue and Kupffer cells are derived from the splanchnic mesenchyme of the septum transversum. The liver develops rapidly and fills the abdominal cavity. The liver begins

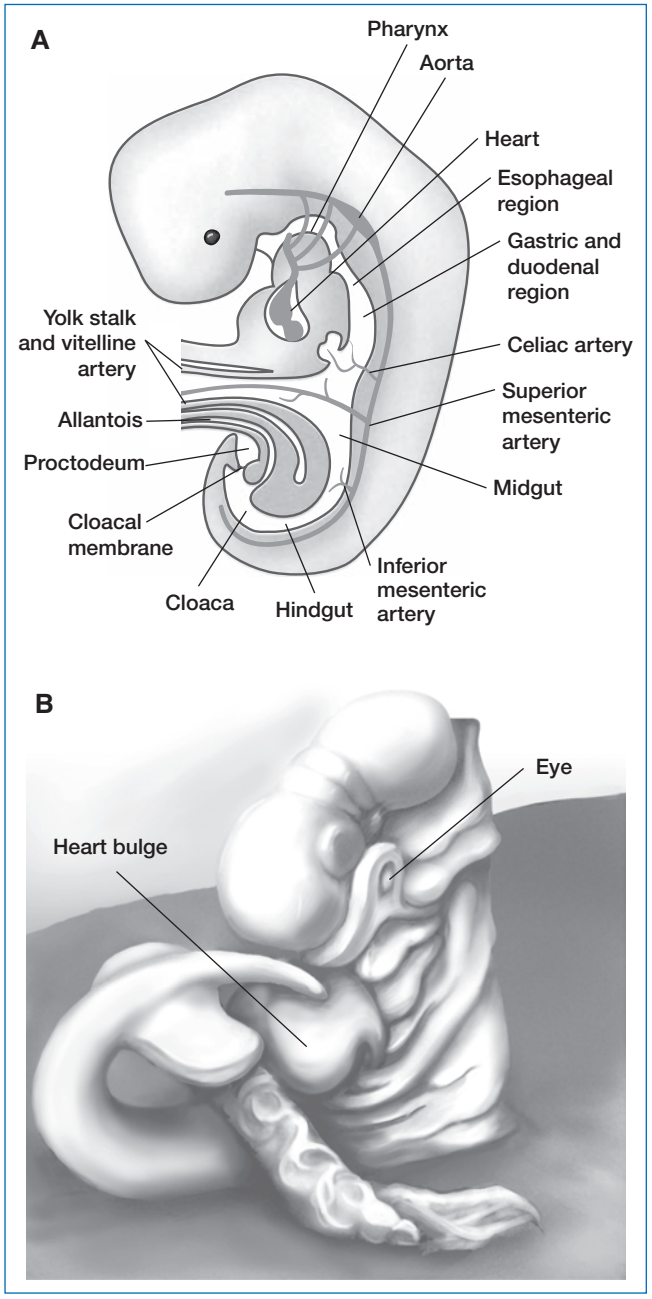

FIGURE 1.17 (A, B) The primitive gut. The early gastrointestinal system presents in an embryo at about 4 weeks' gestation.

its hematopoietic function by the sixth gestational week (Moore et al., 2015; Sadler, 2015).

The smaller portion of the hepatic diverticulum forms the gallbladder. The common bile duct is formed from the stalk connecting the hepatic and cystic ducts to the duodenum. By the 12th week, bile formation begins by the hepatic cells. The pancreas is derived from the pancreatic buds that arise from the caudal part of the foregut. Insulin secretion begins at week 10 (Moore et al., 2015; Sadler, 2015).

The structures that are derived from the midgut include the remainder of the duodenum, the cecum, the appendix, the ascending colon, and the majority of the transverse colon. The intestines undergo extensive growth during the first weeks of development. The liver and kidneys occupy the abdominal cavity, restricting the space available for intestinal growth. The growth of the intestines is accommodated through a migration out of the abdominal cavity via the umbilical cord. A series of rotations occurs before the intestines return to the abdomen. The first rotation is counterclockwise, around the axis of the superior mesenteric artery. At about the 10th week, the intestines return to the abdomen, undergoing further rotation. When the colon returns to the abdomen, the cecal end rotates to the right side, entering the lower right quadrant of the abdomen. The cecum and appendix arise from the cecal diverticulum, a pouch that appears in the fifth week of gestation on the caudal limb of the midgut loop (Figure 1.18; Moore et al., 2015; Sadler, 2015).

The hindgut is that portion of the intestines from the midgut to the cloacal membrane. The latter structure consists of the endoderm of the cloaca and the ectoderm of the anal pit. The cloaca is divided by the urorectal septum. As the septum grows toward the cloacal membrane, folds from the lateral walls of the cloaca grow together, dividing the cloaca into the rectum and upper anal canal dorsally and the urogenital sinus ventrally. By the end of the sixth week, the urorectal septum fuses with the cloacal membrane, forming a dorsal anal membrane and a larger ventral urogenital membrane. At about the end of the seventh gestational week, these two membranes rupture, forming the anal canal (Moore et al., 2015; Sadler, 2015).

Urogenital System

The development of the urinary and genital systems is closely related. The urogenital system develops from the intermediate mesenchyme, which extends along the dorsal body wall of the embryo. During embryonic folding in the horizontal plane, the intermediate mesoderm is moved forward and is no longer connected to the somites. This mesoderm forms the urogenital ridge on each side of the primitive aorta. Both the urinary and genital systems arise from this urogenital ridge. The area from which the urinary system is derived is called the nephrogenic cord. The genital ridge is the area from which the reproductive system is derived (Moore et al., 2015; Sadler, 2015).

There are three stages of development of the kidney: the pronephros, the mesonephros, and the metanephros. The pronephros, a nonfunctional organ, appears in the first month of gestation and then degenerates, contributing only a duct system for the next developmental stage. The mesonephros uses the duct of the pronephros and develops caudally to the pronephros (Figure 1.19). The mesonephros begins to produce urine during development of the metanephros. The mesonephros degenerates by the end of the embryonic period. Remnants of the mesonephros persist as genital ducts in males or vestigial structures in females. The metanephros appears in the fifth week of gestation and becomes the permanent kidney. The metanephros begins to produce urine by about the 11th week of gestation. The number of glomeruli increases until week 32, when the fetal kidney becomes subdivided into lobes. The urinary bladder and the urethra arise from the urogenital sinus and the splanchnic mesenchyme. The caudal portion of the mesonephric ducts is incorporated into the bladder, giving rise to the ureters (Moore et al., 2015; Sadler, 2015).

Although the genetic sex of the embryo is determined at conception, the early development of the genital system is indistinguishable until the seventh week of gestation. In the seventh week, the gonads begin to differentiate. The ovaries and the testes are derived from the coelomic epithelium, the mesenchyme, and the primordial germ cells. Development of female sexual organs occurs in the absence of hormonal stimulation precipitated by the H-Y antigen gene carried on the Y chromosome. If the Y chromosome is present, testes develop; otherwise, ovaries develop (Moore et al., 2015; Sadler, 2015).

FETAL PERIOD: WEEK 9 THROUGH BIRTH

The fetal period begins at the start of week 9 following conception and continues through the duration of pregnancy. It is characterized by further growth and development of the fetus and the organs formed during the embryonic period.

Weeks 9 to 12

At the beginning of this period, the head is large, and the body begins growing faster than the head. The face is broad and characterized by a wide nose and widely spaced eyes. The mouth is formed, and palate formation is complete. Tooth buds appear for the baby teeth. Fingernails are present, and the fetus can curl its fingers to make a fist. The intestines enter the abdomen from the umbilical cord. By the end of the 12th week, blood formation shifts from the liver to the spleen. The fetus can produce urine and excretes it into the amniotic fluid. By the end of the 12th week, the sex of the fetus can be identified by appearance of the external genitalia. By week 12, the fetus weighs 45 g (1.6 oz) and has a C-R length of 8 cm (3.2 inches; Moore et al., 2015).

Weeks 13 to 16

During this time of rapid growth, the fetal head becomes smaller in proportion to the body. The appearance of hair patterning is forming on the head, and *lanugo*, a fine downy hair, is found on the body. Fingerprints are now developed. The fetus can now open its mouth, make a sucking motion, and swallow amniotic fluid. Ossification of the fetal skeleton is active during this time. Reflex response and muscular activity begin. The lower limbs lengthen during this time, and limb movement is more coordinated. In females, the ovaries differentiate and contain primordial follicles. At 16 weeks, the fetal weight is about 200 g (7 oz) and the C-R length is 13.5 cm (5.4 inches; Moore et al., 2015; Sadler, 2015).

Weeks 17 to 20

This marks a period of slower growth. The skin is covered in a fatty, cheese-like substance called *vernix caseosa* that protects it from exposure to amniotic fluid. The limbs are in proportion to the rest of the body and muscles are well developed. Myelination of the spinal cord begins at 20 weeks. Lanugo now covers the body, and brown fat begins to form at the base of the neck, behind the sternum, and around the kidneys. Fetal movement is usually felt by the mother around 18 weeks. The uterus is formed in the female fetus by 18 weeks, and at 20 weeks the testes begin to descend in the male fetus. At 20 weeks, the fetus has a crown to heel (C-H) length of 25 cm (10 inches) and a weight of 435 g (15 oz; Moore et al., 2015; Sadler, 2015).

Weeks 21 to 25

During this period, there is substantial weight gain, but the fetus is thin and has little subcutaneous fat. The skin is wrinkled and translucent red because the capillaries are close to the surface of the skin. The fetus has a grasp, and startle reflex and rapid eye movements begin. Eyebrows and eyelashes are fully formed. Teeth that will become second molars are forming. At 24 weeks, the lungs begin to produce surfactant. IgG levels reach maternal levels. At 24 weeks, the fetus has a C-H length of 28 cm (11.2 inches) and a weight of 780 g (1 lb 11½ oz; Moore et al., 2015; Sadler, 2015).

Weeks 26 to 29

The fetal lungs, pulmonary capillaries, and CNS are more mature, and the fetus is likely to survive if born after 24 to 25 weeks. Blood formation (erythrocyte production) shifts from the spleen to the bone marrow. The CNS is now mature enough to direct breathing movements and control body temperature. There is now enough subcutaneous fat to help maintain body temperature. The eyelids that have been closed since 9 weeks' gestation start to open. In males, the testes descend into the inguinal canal and upper scrotum. At 28 weeks, the fetus has a C-H length of 35 cm (14 inches) and a weight of 1,200 to 1,250 g (2 lb 12 oz; Moore et al., 2015; Sadler, 2015).

Weeks 30 to 34

This period marks a rapid increase in body fat and muscle. Bones are fully developed but are soft and pliable. The lungs are not yet mature but developed enough to provide gas exchange if the fetus were to be born during this period. Surfactant production is not quite at mature levels. The fetus exhibits rhythmic breathing movements as a result of a more mature CNS. The pupillary light reflex is present at 30 weeks. The fetal skin is smooth and pigmented, and the fingernails reach the fingertips. At 32 weeks, the fetus has a C-H length of 38 to 43 cm (15.2–17.2 inches) and weighs 2,000 g (4 lb 7 oz; Moore et al., 2015; Sadler, 2015).

Weeks 35 to 36

Growth of all body systems continues until birth but at a slower rate. The circumference of the head and abdomen is approximately equal by 36 weeks. The fetus starts to look "plump" and the skin is less wrinkled. Lanugo is disappearing. In males, the testes are in the scrotum. In both males and females, breasts are enlarged. At 36 weeks, the fetus has a C-H length of 42 to 48 cm (16.8–17.2 inches) and a weight of 2,500 to 2,750 g (5 lb 8 oz to 6 lb 1 oz; Moore et al., 2015; Sadler, 2015).

Weeks 37 to 40

The fetus is considered *full term* between 38 and 40 weeks. During the last few weeks of gestation, the fat increases in the fetus at a rate of 14 g/day; however, white fat makes up 16% of its total weight. Amniotic fluid decreases to 500 mL or less as the fetal mass fills the uterus. The measurement of the fetal foot is slightly larger than the femur and this is used as an alternate measurement to confirm fetal age. The chest is more prominent but slightly smaller than the diameter of the head. The earlobes are firm, and the skin has a smooth polished appearance. Vernix caseosa is present in the deep folds and creases of the skin. The lungs are well developed and have the ability to exchange gases. The lecithin-sphingomyelin (L/S) ratio is approaching 2:1, indicating lung maturity. At term, the fetus weighs 3,200 g or more and is 48 to 52 cm (19–21 inches) long (Moore et al., 2015; Sadler, 2015).

DEVELOPMENTAL RISKS

The fetus is at less risk for structural defects caused by teratogenic factors than is the embryo; however, there is still a risk for functional impairment of existing structures. This risk is addressed in the section on environmental factors. Changes in specific organs or organ systems during the fetal period are discussed in the section on the development of specific organs (Moore et al., 2015; Sadler, 2015). For a summary of prenatal development, see Box 1.2.

Congenital Defects

Congenital defects or anomalies are structural or anatomic abnormalities present at birth. Congenital defects vary in severity and location, ranging from minor insignificant defects to major organ system defects and are attributed to genetic or chromosomal abnormalities or to maternal or environmental factors. Most congenital defects result from an interaction between genetic and environmental factors, or multifactorial inheritance. Congenital defects caused by single-gene disorders and chromosomal abnormalities are discussed in Chapter 40, Human Genetics and Genomics: Impact on Neonatal Care. The influence of the environment on embryonic development is discussed in this section.

Box 1.2

THREE PERIODS OF FETAL DEVELOPMENT

Embryonic Period

Extends from the fertilization of the ovum

Period 1: Preembryonic Period

Extends from the fertilization of the ovum to the formation of the embryonic disk with three germ layers—weeks 1 to 3.

Period 2: Embryonic Period

Period of rapid growth and differentiation; formation of major organ systems occurs—weeks 4 to 8.

Period 3: Fetal Period

Further growth and development of organ systems—extends from weeks 9 to 40 (term).

Source: Data from Moore, K. L., & Persaud, T. V. N. (2008). *The developing human: Clinically oriented embryology* (8th ed.). Philadelphia, PA: Saunders.

Moore and Persaud (2008) listed six mechanisms that can cause congenital defects: (1) too little growth, (2) too little resorption, (3) too much resorption, (4) resorption in the wrong location, (5) normal growth in an abnormal position, and (6) overgrowth of a tissue or structure. Embryonic organs are most sensitive to noxious agents during a period of rapid cell growth and differentiation. Damage to the primitive streak at about 15 days of gestation could cause severe congenital malformations of the embryo because of its role in the production of intraembryonic mesoderm, from which all connective tissue is formed. Biochemical differentiation occurs before morphologic differentiation, so organs or structures are sensitive to the action of teratogens before they can be identified.

Critical Periods of Human Development

Environmental influences during the first 2 weeks after conception may prevent successful implantation of the blastocyst and cause spontaneous abortion of the embryo. The most sensitive period for the embryo, known as the *critical period*, is the period of organogenesis, during the first 8 weeks of development. Each organ has a critical period during which its development is most likely to be adversely affected by the presence of teratogenic agents; however, some organs such as the brain are sensitive throughout fetal development (Moore et al., 2015).

The terms *congenital anomaly*, *congenital malformation*, and *birth defect* are used synonymously to describe structural abnormalities in an infant; however, according to Moore and Persaud (2008), there are four classifications of congenital anomalies: malformation, disruption, deformation, and dysplasia. A malformation is a structural defect of an organ or larger body region. Usually a malformation is a defect of a morphogenic or developmental field and may result in complex or multiple malformations. A disruption is an interruption of a normal developmental process. This may be caused by a teratogen such as a drug or virus; however, it is not inherited. A deformation is an alteration in form or shape that results from mechanical forces in otherwise healthy tissue. Dysplasia is abnormal development of tissue and may affect several organs.

Birth defects are a leading cause of infant death, accounting for more than 20% of all infant deaths. The generally reported incidence of congenital defects is about 2% to 3%. The actual incidence is higher because some defects are not apparent at birth. Close to 12% of birth defects are not discovered until after the newborn period. The incidence of all defects (including both minor and major defects) is approximately 14% (Lewis, 2009; Moore et al., 2015; Sadler, 2015).

Environmental Factors

Environmental factors cause 7% to 10% of congenital anomalies. During the critical period, or the first 8 weeks, when cell division, cell differentiation, and morphogenesis take place, the fetal structures are most sensitive to environmental agents known as *teratogens*. Each organ or structure has its own critical period in which exposure to teratogens can cause malformations of functional disturbances in varying severity depending on the timing and the teratogen. Teratogens are agents such as chemicals, viruses, radiation, drugs, maternal disease, and other environmental factors that cause birth defects (Lewis, 2009; Moore et al., 2015).

Infectious Agents

Several viral agents including rubella, cytomegalovirus (CMV), herpes simplex virus (HSV), and HIV have been positively identified as teratogenic to the developing fetus. Rubella (German measles) is a viral infection spread through the air or by close contact. The virus can cross the placenta, and during the first trimester can cause cataracts, permanent hearing loss, cardiac malformations (especially patent ductus arteriosus and pulmonary stenosis), and congenital rubella syndrome in the fetus. If exposed in the second or third trimester, the fetus can develop learning disabilities or speech and hearing problems. Prevention is the goal; however, women should be tested to determine if the rubella antibody is present; if not, they should be vaccinated as long as they are not pregnant and will avoid pregnancy for at least 6 months.

CMV is a virus belonging to the herpes family. It is transmitted by direct contact of body fluids including urine, saliva, blood, semen, and breast milk. Approximately 30% to 50% of women have never been infected with CMV, and infected women have no symptoms (Sadler, 2015). One in 200 infants is CMV infected, but only one in five will become ill (Centers for Disease Control and Prevention [CDC], n.d.-a). If exposed in early gestation, the embryo will likely spontaneously abort. A small number of infants who are infected will have microcephaly, meningoencephalitis, hearing and vision loss, mental retardation, and/or seizures (CDC, n.d.-a).

HSV is one of the most common sexually transmitted infections among adult women and is transmitted across broken skin and mucous membrane by direct exposure to the virus. If a woman has a primary outbreak during late pregnancy, there is a 30% to 50% risk of transmission to the fetus. Infection to the fetus is transmitted during birth 85% of the time. An infected fetus has a mortality rate of 50%. Infants who survive may have significant neurologic defects, blindness, and seizures (Moore et al., 2015; Sadler, 2015).

HIV is the virus that causes AIDS. HIV is transmitted through body fluids—blood, semen, genital fluids, and human milk—and can cross the placenta in pregnancy. Almost all pediatric cases of HIV are acquired in utero or through breastfeeding. Women who are treated in pregnancy with an antiretroviral medication reduce the risk of transmission to 2% (Peterson, 2019). Anomalies associated with HIV are microcephaly, growth factor, and craniofacial features.

Toxoplasmosis is caused by a protozoan, *Toxoplasma gondii*, and when exposed in utero can cause hydrocephalus, cerebral calcification, microphthalmia, and ocular defects in the fetus. *T. gondii* can be contracted from raw or undercooked meat, by handling feces of infected cats, or from the soil. The risk and severity depend on the timing of the exposure in pregnancy (Moore et al., 2015; Sadler, 2015).

Untreated primary maternal infections of *Treponema pallidum*, the spirochete that causes syphilis, can result in serious congenital anomalies or stillborn infants. Congenital syphilis is classified as early or late. Early congenital syphilis is defined as in the first 3 months of life and may cause vesiculobullous lesions, rash, lymphadenopathy, hepatosplenomegaly, and a mucopurulent nasal discharge known as "snuffles." Late congenital syphilis occurs around or after age 2 and includes symptoms such as gummatous ulcers on the nose, septum, and palate, bossing of frontal and parietal bones, optic atrophy leading to blindness, interstitial keratitis, and sensorineural deafness. Treatment must be as early as possible to prevent complications and transmission of the infection to the fetus (Moore et al., 2015).

Zika virus is a growing public health problem. When a fetus is exposed to Zika, resultant malformations may occur. The most common effects are microcephaly, macular scarring and retinal changes, contractures, clubfoot, arthrogryposis, and hypertonia (CDC, n.d.-c). For more information on Zika, please see Chapter 26, Emerging Infections.

Other viral agents have been implicated as causes of congenital malformations. Such malformations have been reported following

maternal infection with mumps, varicella, echovirus, coxsackie virus, and influenza virus. The incidence of congenital malformations following these infections is unknown, but is suspected to be low (Sadler, 2015). (For further information on viral agents, see Chapter 11, Immune System).

Drugs/Medications

Drug safety is a primary concern during pregnancy, especially in women with pregestational disease. Safety of a medication cannot be tested on pregnant women for obvious ethical reasons as it could expose a fetus to possible teratogens.

Few drugs are known to be teratogenic; however, no drug can be considered completely safe. The U. S. Food and Drug Administration (FDA) as of June 2015 established three labels for prescription drugs used in pregnancy or preconception. They are 8.1 Pregnancy (including during labor); 8.2 Lactation; and 8.3 Females and Males of Reproductive Potential (FDA, 2014). Over-the-counter medications are not included in this labeling nomenclature (FDA, 2014). The FDA established a pregnancy exposure registry to maintain up-to-date information on the medication along with a risk summary (FDA, 2014).

Drugs that are known teratogens that can cause birth defects include antibiotics streptomycin and tetracycline; antineoplastic agents; anticoagulants, anticonvulsants; hormones such as adrenocorticoids and diethylstilbestrol (DES); antithyroid drugs; psychotropics; anti-anxiety agents such as diazepam; and retinoic acid (a metabolite of vitamin A).

Hormonal agents are also implicated in the incidence of congenital defects. Androgenic agents (progestins) may cause masculinization of female fetuses. DES, a synthetic estrogen used to prevent abortion in the 1940s and 1950s, has been found to cause an increased incidence of vaginal and cervical cancer in female children exposed to the drug in utero. There are also associated abnormalities of the reproductive system, often causing reproductive dysfunction (Moore et al., 2015; Sadler, 2015).

Amphetamines are associated with oral clefts and heart defects. Salicylates (aspirin), a commonly used medication during pregnancy, may be harmful to the fetus if taken in large amounts or may lead to bleeding problems. Isotretinoin, a drug used to treat acne, causes craniofacial abnormalities, cleft palate, thymic aplasia defects, and neural tube defects (Sadler, 2015).

Opioids, often prescribed for pain relief, if used in pregnancy can result in a premature birth, intrauterine growth restriction (IUGR), and the infant may experience withdrawal, referred to as neonatal abstinence syndrome (NAS; March of Dimes, n.d.). NAS secondary to in utero opioid exposure increased fivefold in the United States from 2000 to 2012, and has continued to rise with recent rates reported as high as 20 per 1,000 live births (Milliren et al., 2018). For more information on NAS, please see Chapter 30, Neonatal Abstinence Syndrome.

Illicit Drugs

Social or recreational drugs are highly suspected of contributing to congenital defects and the risk of spontaneous abortion. Drugs such as lysergic acid diethylamide (LSD) have been associated with limb abnormalities and CNS abnormalities. Other drugs that may be teratogenic include phencyclidine and marijuana. "Crack" cocaine has been associated with preterm birth (PTB), low birth weight (LBW), premature rupture of membranes (PROMs), placental abruption, and sudden infant death syndrome (SIDS; Gouin, Murphy, & Shah 2011). The tendency of drug abusers to use multiple drugs, combined with poor nutritional habits and lack of prenatal care, makes it difficult to establish the effects of the drugs individually.

Marijuana. Cannabis (marijuana, hashish, or sensimilla, all products of the *Cannabis sativa* or *Cannabis indica* plant) is the most commonly used psychoactive substance in the United States with an estimated 1 in 5 adults aged 18 to 25 years reporting use in the past month in 2015 (Center for Behavioral Health). Recent estimates of the prevalence of cannabis use among pregnant women in the United States range between 3% and 16%, and the National Survey on Drug Use and Health suggests that cannabis use among pregnant women in the United States has increased as much as 62% between 2002 and 2014 (Brown et al., 2017).

As yet, no teratogenic effects of marijuana have been reported; yet, research on the teratogenicity of marijuana is difficult since it remains illegal in many states. Co-use of other substances is common among prenatal and postpartum marijuana users.

Evidence is inconclusive as to its effect on premature birth or low birth weight; however, there is evidence to suggest a potential impact on fetal brain development (National Institute on Drug Abuse, 2018). Ko et al. (2018) found that prenatal marijuana use was not independently associated with lower average birthweight or gestational age; however, postpartum marijuana use was associated with depressive symptoms and shorter breastfeeding duration. Growing evidence suggests prenatal cannabis exposure has a detrimental impact on offspring neurocognitive function starting in the toddler years (Wu, Jew, & Lu, 2011). More research is needed especially as marijuana becomes legal in many states.

Alcohol. The term *fetal alcohol syndrome* (FAS) is used to describe the cluster of defects characteristic of maternal ingestion of alcohol. A major factor in the development of FAS is timing, amount, and frequency of alcohol consumption during pregnancy. Infants with FAS may exhibit craniofacial abnormalities, microcephaly, limb deformities, smooth philtrum, thin upper lip, small palpebral fissures, and short nose. They may have visual impairment. They may exhibit cognitive impairment; impaired fine motor skills; developmental disabilities; attention deficit disorder; and seizure disorder as well as alcohol-related birth defects (ARBD) such as heart and kidney defects, malformations of the bone, and hearing (CDC, n.d.-b). Fetal alcohol spectrum disorder (FASD) is a modern term that describes the range of permanent effects of alcohol use in pregnancy. This cluster of conditions is preventable if pregnant women do not consume alcohol (CDC, n.d.-b). There is no known safe level of alcohol consumption during pregnancy, and even low levels of prenatal alcohol exposure have been found to cause adverse fetal effects, and not just in the brain (Sarman, 2018)

Tobacco. The dangers of smoking cigarettes in pregnancy have been well documented. Use of tobacco during pregnancy can lead to PTB, LBW, PROMs, placenta previa, placental abruption, or stillbirth. The fetus can suffer from growth restriction because of the vasoconstrictive properties of nicotine, which decreases oxygenated blood to the fetus. Damage to fetal lung and brain tissue is also possible (CDC, n.d.-f). Katoka et al. (2018) demonstrated that newborn weight decreased as the category of number of cigarettes per day increased, with a significant reduction at the 6 to 10 cigarettes. Based on the study results and the principle of harm reduction, if a pregnant woman is unable to quit smoking, she should be encouraged to reduce consumption to less than six cigarettes per day.

E-Cigarettes. Electronic nicotine delivery systems (ENDS), a comparatively new phenomenon, are gaining in popularity, especially among adolescent nonsmokers, and are frequently perceived as being safer than regular cigarettes (Dutra & Glantz, 2014; Grana, Benowitz, & Glantz, 2014). Because ENDS emissions have been found to have lower levels and overall numbers of toxins compared with tobacco cigarettes, they are

commonly marketed as safer alternatives without regard to the intrinsic adverse effects of nicotine (Grana et al., 2014). If pregnant women perceive ENDS as safer than tobacco cigarettes, there is potential for unrealized harm because current tobacco-smoking pregnant women may use ENDS to decrease the amount of tobacco cigarettes smoked during pregnancy (England, Tong, Klobitz, Kish-Doto, & Southwell, 2016; Wigginton, Gartner, & Rowlands, 2017). This perceived harm reduction strategy could result in continued nicotine exposure and associated complications, as well as currently undetermined additional maternal–fetal risks (Bhandari et al., 2018). The variety of flavorings offered may also put the fetus at risk for damage to the lungs and brain (CDC, n.d.-d). Another potential ENDS-associated issue important to expecting mothers is the possibility of unintentional ingestion of ENDS liquids by young children at home (American Association of Poison Control Centers, n.d.). In addition to the perception of lower health risks, the relative lesser cost of e-cigarettes compared with tobacco cigarettes could encourage their use. As such, for women who already smoke and are facing financial hardship during pregnancy, e-cigarettes may seem like a rational solution.

Ionizing Radiation. There is no established "safe" level for radiation. Large amounts of exposure during pregnancy can be detrimental to the fetus; however, this is a rare occurrence. The severity of radiation-induced defects depends on the duration and timing of exposure. Radiation exposure during the first trimester of pregnancy most likely will result in loss of the embryo. High levels of radiation can cause microcephaly, microphthalmia, growth restriction, skeletal and visceral abnormalities, retinal changes, cataracts, and cleft palate. There is no evidence that the small amount of radiation required for modern radiographic studies is harmful; however, caution is used to minimize the exposure to the fetus because of the potential for cumulative effects of radiation exposure throughout the life span (Groen, Bae, & Lim, 2012). Low-dose ionizing radiation (LDIR) is known to promote oxidative stress; however, these levels may not be large enough to result in genomic mutations. There is emerging evidence that oxidative stress causes epigenetic modifications, which can result in permanent cellular transformations without altering the underlying DNA nucleotide sequence. Intrauterine fetal development is highly susceptible to oxidative stress-induced epigenetic programing when exposed to LDIR during pregnancy (Tharmalingam, Sreetharan, Kulesza, Boreham, & Tai, 2017).

Heavy Metals. **Heavy metals such as lead (Pb), cadmium (Cd), cobalt, manganese (Mn), and mercury (Hg) during** pregnancy **put the developing fetal brain at risk (CDC, n.d.-e). More specifically,** high maternal second trimester blood levels of Pb and Mn during **pregnancy** are associated with neural tube defects (NTDs) in the newborn (Özel et al., 2018). Ingestion of predatory fish such as shark, swordfish, king mackerel, and tilefish while pregnant may damage the developing fetal brain and CNS (Mayo Clinic, 2016).

Bisphenol-A. Bisphenol-A (BPA) is an organic compound used to make polycarbonate plastic, epoxy resins, and dental sealants. BPA can be found in plastic baby bottles, plastic lining in canned foods, and polycarbonate plastic containers. The chemical structure of BPA is similar to estrogen and may have the same effect on the body. High levels of BPA found in blood have been associated with recurrent miscarriages, preeclampsia, IUGR, and PTB. Fetal exposure to BPA may result in the development of diabetes or heart disease when the child is older (Endocrine Society, 2015).

Maternal Disease

Pregestational maternal disease can be teratogenic to a fetus. Women with poorly controlled pregestational diabetes have a three to four times higher risk of having a fetus with a birth defect than women in the general population. Anomalies typically occur between weeks 5 and 8 and can include brain anomalies, skeletal defects, developmental abnormalities, and congenital heart defects.

Thyroid deficiency during the last two trimesters of pregnancy and first months after birth can result in mental retardation or other neurologic deficits in the neonate. Hypothyroidism or hyperthyroidism during pregnancy can have an adverse effect on fetal growth and result in neonatal hypothyroidism or hyperthyroidism.

Women with phenylalanine hydroxylase deficiency (phenylketonuria [PKU]) and hyperphenylalaninemia are at risk of having a fetus with congenital anomalies if the phenylalanine levels are elevated in pregnancy. High maternal levels of phenylalanine during pregnancy can result in microcephaly, delayed speech, mental retardation, neurologic damage, congenital heart defects, facial anomalies, microcephaly, and delayed development (Mayo Clinic, 2018).

Other

Another teratogenic factor is hyperthermia caused by maternal use of hot tubs or saunas or by maternal febrile illness during pregnancy. Hyperthermia can increase the incidence of embryonic resorption and malformations. The type and severity of congenital defect depend on the amount of temperature elevation, duration of the exposure, and stage of embryonic development. If the mother is exposed during the critical period (the first 8 weeks) when the CNS is particularly vulnerable to hyperthermia, congenital defects of the CNS may occur (Tobah, 2019).

Good nutrition has long been considered essential for proper growth and development of the fetus. Dietary habits have a profound effect on pregnancy outcomes. However, with the exception of folic acid, in which there is evidence that deficiencies are causally related to defects of the neural tube, there is little known about the role of micronutrients on fetal development. Supplementation of vitamins and minerals must occur within the appropriate critical period of development to be effective. Finally, advanced paternal age has recently been associated with an increased risk of complex disorders such as autism, schizophrenia, autism spectrum disorder, and achondroplasia (Castle, 2018).

SUMMARY

This chapter has provided an overview of embryologic and fetal development, outlined the critical periods of development, and described the more common congenital defects. Knowledge of embryologic and fetal development is essential as a foundation for understanding the role of environment, genetics, physical, or other factors that may have an impact upon anatomy, physiology, or pathophysiology of the organism. The future health of the individual in large part depends on numerous events that take place during gestation. As knowledge of genetics, development, and human pathophysiology improves, better healthcare technologies may emerge that can significantly reduce morbidity and mortality and improve quality of life.

CASE STUDY

A 19-year-old female at approximately 19 weeks of gestation presents to the high-risk clinic by referral from her primary

obstetrician. She had a morphology scan at her doctor's office at 18 weeks with intracranial calcifications noted as well as probably hyperechogenic bowel. She and her husband had moved to North Carolina from a small town in Mississippi. They had married immediately after graduation from high school and he had joined the Army. They had neither family in the area nor any other social support systems. Her primary obstetrician had forwarded prenatal records that described a 24- to 48-hour viral illness between 16 and 17 weeks with a fever of 102°F and flu-like symptoms including myalgia and malaise. Detailed ultrasounds demonstrated numerous intracranial calcifications, microcephaly, pleural effusions, and decreased amniotic fluid. The perinatologist discussed with the couple the probability that she had been exposed to and developed CMV, which was passed on to the fetus. The couple refused amniocentesis following a prolonged discussion with family members in Mississippi because they had decided to continue with the pregnancy regardless of the outcome. The infant was born at 37 weeks and was diagnosed with blindness, deafness, and is likely to have severe mental disabilities.

- How would you explain the CMV infection?
- How would you explain the potential outcomes for the baby as well as the extent of care that would be required for optimal developmental outcome?
- How would you prepare the parents for the care of an infant with multiple serious disabilities?

■ **CMV.** When a woman is infected with CMV for the first time during pregnancy (primary infection), the risk that her baby will get infected is as high as 50%. Primary maternal CMV infections occur in 0.15% to 2.0% of all pregnancies. Infants born with CMV are at risk for long-term disabilities such as mental retardation, learning disabilities, epilepsy, cerebral palsy, hearing impairment or deafness, and visual impairment or blindness. Congenital CMV infection is transmitted to the fetus by maternal viremia and placental infection. Maternal immunoglobulin G (IgG) transports the virus across the placental syncytiotrophoblast. In a primary infection in which the placenta becomes infected with CMV, the ability to provide nutrients and oxygen to the fetus is impaired. The placenta becomes enlarged, and tissue damage occurs due to viral placentitis and revascularization. Many symptoms in the newborn are due to the infection of the placenta rather than the direct effect of the virus on the fetus. A primary CMV infection in the first trimester is associated with the worst outcomes. A maternal infection that occurs prior to conception is unlikely to pass to the fetus.

Although the majority (85%–90%) of congenital infections are asymptomatic, 5% to 20% of infants born to mothers with primary CMV infection are overtly symptomatic. Only 10% to 15% of these babies will show symptoms of infection at birth. Symptoms may include petechia, jaundice, hepatosplenomegaly, microcephaly, IUGR, chorioretinitis, thrombocytopenia, and anemia. Babies born with CMV are also at risk for long-term effects such as sensorineural hearing loss, vision problems, and psychomotor development delay. CMV-infected children have a mortality rate of about 5%, and severe neurologic morbidity occurs in 50% to 60% of survivors. Asymptomatic infants are also at risk of developing long-term neurodevelopmental morbidity, but the risk is much lower than in symptomatic neonates.

Diagnosis is made by viral culture of amniotic fluid and by ultrasound examination. Amniocentesis is essential for prenatal diagnosis and CMV isolation from amniotic fluid is the gold standard for prenatal diagnosis. A high viral load in the amniotic fluid may indicate a poor outcome; however, it may also be related to gestational age at the time of sampling. Once a fetal infection has been diagnosed, the fetus should be closely monitored by ultrasound. Abnormal ultrasound findings include abnormalities in amniotic fluid such as polyhydramnios or oligohydramnios, IUGR, hydrocephaly or microcephaly, intracranial calcifications, cerebral ventriculomegaly or atrophy, hyperechogenic bowel, pseudomeconium ileus, hepatosplenomegaly, ascites or hydrops, and/or necrotic, cystic, or calcified lesions in the brain or liver. Some babies that have been infected with CMV during pregnancy will show signs of problems on ultrasound; however, the absence of sonographic findings does not guarantee a normal outcome. Some fetuses with CMV will not show any signs of infection on ultrasound. Once a fetus is diagnosed with a CMV infection, ultrasounds should be done every 2 to 4 weeks to watch for signs that may predict the outcome. Routine serologic testing is not recommended and should be used only when a pregnant woman develops a flu-like illness or if a CMV infection is suspected following an ultrasound.

Currently, there is no effective therapy for CMV infection, and women can be offered the option of pregnancy termination once a fetal infection is detected by ultrasound or amniocentesis and once a fetus is determined or suspected to be affected. Research on the use of CMV-specific hyperimmune globulin in pregnant women with a primary infection has been reported to improve outcomes; however, further studies are needed. There is also some evidence that ganciclovir treatment of babies with symptoms of congenital CMV may be beneficial for prevention or amelioration of hearing loss.

There are currently no vaccines for CMV and no clinical trials of new vaccines. Prevention of congenital CMV infection by practicing good personal hygiene is crucial. Pregnant women should avoid intimate contact with saliva and urine from young children and use good handwashing after changing diapers and wiping secretions. At least one-third of women in the United States have direct contact with children less than 3 years old. Children and staff who care for children in day-care centers are especially likely to be infected; therefore, pregnant women who have children in day-care settings are especially vulnerable. One should assume that all children under age 3 have CMV in their urine and saliva. Other recommendations include not sharing cups, plates, or toothbrushes, not kissing children on or near the mouth, and not sharing towels or washcloths with a young child.

CHAPTER 2

Prenatal, Intrapartal, and Postpartal Risk Factors

Dolores R. Dzubaty

INTRODUCTION

Women who discover they are pregnant expect to experience an uneventful pregnancy and delivery of a healthy term newborn. Unfortunately, full-term delivery of a healthy newborn is not always the outcome. Women, and their partners, are exposed to a myriad of physical, environmental, psychological, genetic, and behavioral factors that influence pregnancy and the outcome. Even in instances when women have access to excellent prenatal care, there may be unknowing exposure to factors that are detrimental to a fetus. The result may be a pregnancy that is completed preterm and an infant affected by the complications of prematurity, low birth weight (LBW), or possibly congenital disorders. Such outcomes account for increases in neonatal morbidity and mortality. Preterm birth (PTB) and the resultant health complications can affect the newborn throughout the life span. Maternal factors that resulted in poor pregnancy outcomes can also continue to have detrimental effects on the newborn.

Perinatal providers assess and identify patient risk factors that may result in poor pregnancy outcomes. Ideally, education can be provided prenatally so that patients enter the pregnancy in a state of good health, minimizing exposure to known teratogens, and knowledgeable about lifestyle changes that may need to occur. Identification of risk factors and development of education for all women is a global, national, and local concern. Many organizations have contributed to the body of knowledge utilized by healthcare practitioners caring for women before, during, and after pregnancy. This chapter presents information on the risk factors contributing to complications in pregnancy and possible changes that can increase healthy outcomes. The perspective considered will be global as well as national in recognition of the multiple cultures nurses are exposed to in practice.

GLOBAL

Among the eight United Nations Millennium Development Goals (MDG), representatives addressed the needs of all nations in achieving the eradication of poverty, reduction in child mortality, and improvement in maternal health by 2015 (Howson, Kinney, & Lawn, 2012). In October 2015, the United Nations General Assembly adopted the document "Transforming Our World: 2030 Agenda for Sustainable Development" (United Nations [UN], 2015). Within this document, the General Assembly recognized the success and lack of progress toward attainment of the MDG. The Assembly then acknowledged:

> progress has been uneven, particularly in Africa, least developed countries, landlocked developing countries and small island developing States, and some of the Millennium Development Goals remain off-track, in particular those related to maternal, newborn and child health and to reproductive health. We recommit ourselves to the full realization of all the Millennium Development Goals, including the off-track Millennium Development Goals, in particular by providing focused and scaled-up assistance to least developed countries and other countries in special situations, in line with relevant support programmes. The new Agenda builds on the Millennium Development Goals and seeks to complete what they did not achieve, particularly in reaching the most vulnerable. (p. 5)

The Resolution stating the 17 new Sustainable Development Goals (SDG) set forth went into effect January 1, 2016 (UN, 2015, p. 14). The assembly recognized in this document that different nations would have dissimilar challenges in meeting the goals set forth. Implementation of action to reach the SDG and targets would occur on national levels. However, as previously stated, the commitment to maternal, newborn, and child health remains imbedded in these new goals.

NATIONAL

At the national level, member nations have committed to the 2030 Agenda (UN, 2015) and adopted policy, procedure, and support of efforts to improve and sustain the conditions of their own populations. In low-resource countries, there are challenges of infrastructure deficiencies. Fewer healthcare facilities, farther distances to travel to obtain care, and lack of transportation means to obtain care all adversely affect pregnancy outcomes. Cultural practices that are not recognized to support healthy outcomes may still be prevalent in some regions of countries that also have modern services available. The result is disparity in healthcare based on geographic location, adherence to cultural beliefs, and socioeconomic status.

Disparity in healthcare can also be found in more developed countries based on the same factors of geographic location, socioeconomic status, and personal belief system. Healthcare provider

groups such as the Association of Women's Health, Obstetric, and Neonatal Nursing (AWHONN, 2016a) and the Royal College of Nurse Midwives (n.d.) have developed standards of care and educational offerings for nurses and midwives. The purpose is to ensure the delivery of care at all levels to support healthy pregnancy outcomes, reduce prematurity, and provide consistent care. The International Confederation of Midwives (2017) seeks to educate, empower, and provide care to women on a global level. Despite all of the efforts put forth by these groups, healthcare disparity and poor perinatal outcomes persist. The American Academy of Nursing (AAN) Expert Panel on Maternal Infant Health reported that maternal death rates in the United States are rising in African American women but data are not collected consistently across the United States to determine etiologies (Amankwaa et al., 2018).

PERINATAL OUTCOMES INDICATORS

As healthcare delivery differs between countries, common indicators must be chosen to be able to compare improvement or worsening of prenatal outcomes. PTB rate, LBW, and neonatal and infant mortality are three indicators that can be compared.

Preterm Birth

In the United States, PTB and LBW accounted for 25.9% of neonatal deaths and 18% of infant deaths in 2013 according to a report by the March of Dimes (MOD, 2016). The PTB rate as well as the rate of LBW increased in 2016 as reported by the Centers for Disease Control and Prevention (CDC), despite a decrease in the fertility rate. PTB rate, delivery at less than 37 weeks, for all races was 9.85% (Martin, Hamilton, Osterman, Driscoll, & Drake, 2018).

PTBs range from 5% to 18% worldwide with the majority of those births occurring between 32 and 37 weeks of pregnancy gestation (Howson et al., 2012). Approximately 15 million babies are *Born Too Soon*, as their document is titled, and more than a million infants die due to complications of prematurity (Howson et al., 2012). The majority of PTBs occur in 10 countries from sub-Saharan Africa, South Asia, and the United States. European countries have the lowest rates of PTBs. The outcomes for premature infants born in low-income countries are not as favorable as for those born in high-income countries. Many preterm infant survivors are left with hearing, vision, or intellectual problems that last a lifetime (Howson et al., 2012).

The definition of PTB distinguishes level of prematurity by weeks of gestational age. In the *Born Too Soon* (Howson et al., 2012) document, the subcategories are defined as moderate to late preterm being 32 to 37 weeks, very preterm as 28 to 32 weeks, and extremely preterm as less than 28 weeks' gestation at birth. Survival rates of infants born at less than 28 weeks are very low. The determination of gestational age to classify a neonate in any subcategory in developed countries is made by a combination of early ultrasound and mother's menstrual history (Howson et al., 2012). When ultrasound is not available or only ultrasound but not menstrual history is used, the determination of gestational age may not be as accurate and result in statistical differences when studying outcomes of PTB. In clinical practice, assigning an infant to the wrong subcategory of prematurity may result following a different standard of care. The New Ballard neonatal assessment tool was introduced in 1991 to include a more accurate gestational age physical assessment of the very preterm newborn and can be used in low-resource settings (Thompson, Levi, Bly, Ha, & Keirns, 2014). In addition to the New Ballard, practitioners have also used the Dubowitz score to assign a gestational age based on neurological and physiological examination (Dubowitz, Dubowitz, & Goldberg, 1970). Variations in results can occur but both methods can be easily taught to healthcare providers and require little in the way of resources (Anne Lee et al., 2017). Therefore, both assessments can be used in low-income, low-resource settings.

There is no one singular cause of preterm labor. For some women, preterm labor is the result of a combination of physical, psychological, and environmental factors (Yamamoto & Premji, 2017). Genetic factors can play a part in preterm labor (Smid et al., 2017) as well as prior history of spontaneous early labor (Hughes et al., 2017). Prior elective or spontaneous abortions have been identified as a risk factor for preterm labor in subsequent pregnancies (McCaffrey, 2017). Premature birth may also result from early induction of labor due to maternal conditions that are detrimental to mother or fetus or both. Many probable causes of preterm labor have been identified, although the occurrence of preterm labor is not always predictable. There are occasions when the interplay of multiple factors may result in preterm labor. A screening tool measuring the possible risk factors a woman may have would be ideal. An evaluation using such a tool could include items such as fetal fibronectin testing, observation of shortened cervical length by ultrasound, prior pregnancy history, presence of infection or inflammatory conditions, and known environmental exposures, all of which may be helpful in identifying women at risk for premature labor. Unfortunately, such a perfect screening tool does not exist. Historically, some women with several risk factors may not deliver prematurely.

Screening tools, ultrasounds, and other testing can only be effective if women make use of available prenatal care. Lack of insurance, lack of transportation, and lack of knowledge are some of the reasons women do not obtain prenatal care (Swartz, Hainmueller, Lawrence, & Rodriquez, 2017). In some countries and cultures, the need for early prenatal care and multiple visits are not viewed as necessary. The inability to form a meaningful relationship with a healthcare provider while garnering social and psychological support from friends and family may result in non-utilization of healthcare systems viewed as unreceptive to meeting the pregnant woman's needs (Nypaver & Shambley-Ebron, 2016). If a woman has had a pregnancy delivered at term without difficulties, she may decide that frequent visits with a care provider are necessary during a subsequent pregnancy, even if that pregnancy occurs within only months of the previous delivery. Lack of availability of appropriate healthcare facilities or trained care providers can also contribute to rates of PTBs, infant mortality, and increased need for preterm infant care (Susuman, Chialepeh, Bado, & Lailulo, 2016).

Preterm infants require specialized care to survive. There is great variation in the methods and effectiveness of care delivered to preterm infants between high- and low-income countries. Disparities in care available and delivered can also be found within geographic areas of the same country. Neonatal intensive care units (NICUs) have been found to be both underutilized and overutilized resulting in higher healthcare costs (Harrison, Wasserman, & Goodman, 2018). The cost of providing neonatal intensive care for vulnerable preterm infants adds a huge financial burden to the healthcare system. As gestational age decreases, the overall costs of care increase. Care costs more for extremely preterm infants who require more diagnostic or medical procedures, medications, longer hospital stays, and long-term care (Stephens, Lain, Roberts, Bowen, & Nassar, 2016). The Institute of Medicine (Berhman & Butler, 2007) estimates that the care of infants born at less than 28 weeks' gestation costs as much as 20 times that of infants born at 32 to 37 weeks' gestation. Preterm infants are also more at risk for hospital readmission within 6 weeks of birth, adding more to the financial burden (Soilly, Lejeune, Quantin, Bejean, & Gouyon, 2014). There are additional societal costs of prematurity which are seldom contemplated, such as early intervention services,

special education, and disability services for infants who survive with residual problems and loss of productivity by parents and caregivers (Berhman & Butler, 2007). The reality is that not all countries have the infrastructure or finances to aggressively treat all preterm infants. Some cultures are more accepting of infant death than others and do not expect all infants to survive regardless of the cost. However, there are some initial interventions that can be performed in any setting which can increase the chances of survival for many premature infants, even in low-resource nations.

Birth Weight

Birth weight is one of the most important determinants of the infant's future health (Howson et al., 2012). LBW is defined as an initial birth weight of less than 2,500 g and is further categorized as either very low birth weight (VLBW) or extremely low birth weight (ELBW). VLBW is defined as an initial birth weight of less than 1,500 g, and ELBW is defined as a birth weight of less than 1,000 g. Ideally birth weight should be measured within the first hour of birth before significant postnatal losses occur. In some cases, when the infant is in distress, the birth weight might be estimated until an accurate weight can be determined. The incidence of LBW in the United States was reported at 8.17% in 2016 (Martin et al., 2018). LBW infants are at higher risk for neonatal and postnatal morbidity and mortality. Being born LBW has implications for health as an adult and has been linked to cardiac and metabolic disorders later in adult life (Morrison et al., 2016). While survival for ELBW infants has improved with advances in neonatal care, the risk for neurodevelopmental impairment has increased (Schieve et al., 2016). As many as 50% of children born extremely preterm or at ELBW have residual effects of prematurity with cognitive, academic, or psychological problems when they are of school age and beyond (Schieve et al., 2016).

The macrosomic or large for gestational age (LGA) fetus also has risks. Pregnancy risk factors for being LGA include maternal obesity, maternal age older than 35, maternal diabetes, prolonged pregnancy longer than 41 weeks, abnormally tall or short maternal stature, and male fetus. LGA is defined as greater than 90th percentile for weight adjusted for gender and gestational weeks at delivery. Potential complications for the mother include prolonged labor with increased risk for cephalopelvic disproportion (CPD) and need for cesarean section. During vaginal delivery, the LGA infant is at great risk for injury such as stillbirth, brachial plexus injury as the result of shoulder dystocia, fracture of the clavicle, the need for ventilatory support, and mortality (Chauhan et al., 2017). In the period immediately following delivery, the macrosomic infant is at risk for hypoglycemia, polycythemia, and hyperbilirubinemia. Successful resolution of these conditions, if they occur, does not appear to have long-term effects on infant development (Khambalia, Algert, Bowen, Collie, & Roberts, 2017).

Determination of gestational age can be estimated prior to delivery or upon examination of the newborn. Additional physical measurements are obtained to determine if the infant weight and size are appropriate for the gestational age obtained. Gestational age can be based upon maternal history in combination with ultrasound when available, or physical assessment. After birth, the neonate's weight, frontal occipital head circumference, and length at birth are plotted on a graph to evaluate appropriateness of growth based on gestational age. The infant is categorized as appropriate for gestational age (AGA) if birth weight falls between the 10th and 90th percentile for his or her gestational age; small for gestational age (SGA) if birth weight falls into the lower 10th percentile for weight based upon gestational age; or LGA if birth weight is greater than 90th percentile for weight based upon gestational age, or more than 4,000 g. at any gestational age (Barth & American College of Obstetricians and Gynecologists, 2016). Identification of infants who are SGA or LGA helps assure they receive proper monitoring of blood glucose and early feedings if indicated.

Before birth, an estimated fetal weight (EFW) can be determined via ultrasound. Many fetuses who are classified as SGA (i.e., EFW below 10% for growth) might, in reality, be healthy and genetically small (Kiserud et al., 2018). Additional fetuses may be intrinsically small secondary to a chromosomal or environmental condition such as trisomy 18, fetal alcohol syndrome (FAS), or infection, such as cytomegalovirus. The remaining fetuses may have increased perinatal risk and have fetal growth restriction (FGR; Gordijn, Beune, & Ganzevoort, 2018)

FGR can be caused by maternal, fetal, or placental problems. Maternal causes include conditions such as preeclampsia; smoking or taking certain drugs can result in progressive uteroplacental insufficiency and limit the normal delivery of oxygen and nutrients to the fetus. Inadequate maternal nutrition, low prepregnancy weight, low weight gain in pregnancy, or inadequate prenatal care are other maternal causes of FGR. In developed countries where bariatric surgery is available, malabsorptive surgery has been associated with FGR (Chevrot et al., 2016). Fetal conditions that can contribute to FGR include fetal genetic factors, congenital infection, intrauterine crowding from multiple pregnancy, Rh isoimmunization, or twin-to-twin transfusion. Abnormal placental pathophysiology resulting in poor perfusion through the placenta, abnormal cord insertion, placental infarcts, or implantation issues such as placenta previa or abruptio placenta are also causes of FGR (Burton & Jauniaux, 2018; Kingdon, Audette, Hobson, Windrim, & Morgen, 2018). Severe uteroplacental insufficiency restricts blood flow to the fetus and affects fetal growth and oxygenation. To spare function of vital organs, the fetus enters a brain-sparing mode which accounts for changes in fetal growth. Oxygen and nutrients are prioritized to the brain, heart, adrenals, and placenta with vasoconstriction resulting in less circulation of oxygen to the kidneys, lungs, muscles, bone marrow, and gastrointestinal tract (Figueras et al., 2018).

Fetuses with FGR must be identified and closely monitored with nonstress testing, biophysical profiles, amniotic fluid volume estimates, contraction stress tests, and Doppler studies of maternal and umbilical vessels when available. Infants may be subject to preterm delivery and FGR due to altered placental implantation and function (Silver, 2015). **Emergency Alert: Preterm delivery is indicated if signs of fetal stress or distress are present.** After birth, infants with FGR often have problems with low blood glucose or thermoregulation due to a lack of subcutaneous fat. They also are at increased risk for necrotizing enterocolitis, thrombocytopenia, and renal failure because during fetal development, blood is shunted away from the gastrointestinal and renal system to the brain, heart, and other vital organs as a protective mechanism. Preterm delivery and FGR infants are at greater risk for necrotizing enterocolitis, retinopathy of prematurity, and increased incidence of neonatal jaundice (Platt, 2014). Prematurity and LBW when occurring together have also been identified as having an impact on neurodevelopment resulting in developmental disabilities and cognitive impairments (Howe, Sheu, Hsu, Wang, & Wang, 2016; Schieve et al., 2016). **Emergency Alert: Infants with low birth weight have also been found to be more at risk to develop a metabolic syndrome with insulin resistance, hypertension, hypercholesterolemia, and heart disease** (Mzayek et al., 2016; Pocobelli, Dublin, Enquobahrie, & Mueller, 2016).

Infant Mortality Rate

Neonatal deaths during the first 28 days of life accounted for 46% of deaths of children under age 5 in 2016, representing an increase from

41% in 2000 (United Nations Children's Fund [UNICEF], 2017). International disparities exist with some countries below or meeting the SDG for 2030 whereas others are still well above the goal. PTB complications are responsible for the majority of neonatal deaths worldwide (UNICEF, 2017). The world infant mortality rate (IMR) is estimated at an average of 19 deaths per 1,000 live births (UNICEF, 2017). Infants from low- or middle-income countries represent a higher percentage of neonatal deaths than infants from industrialized nations. PTB complications and intrapartum events represent the causes of 59% of neonatal deaths (UNICEF, 2017). Reducing neonatal deaths across all nations will have a major impact on progress toward achieving the United Nations SDG 3, which aims to "Ensure healthy lives and promote well-being for all at all ages" (UN, 2015). Because of a high percentage of PTBs, the United States ranked sixth internationally in the top 10 countries accounting for 60% of PTBs, lagging behind many European countries (Howson et al., 2012). PTBs and the resulting complications contribute to higher neonatal mortality. Neonatal mortality rates have declined in the United States but remain higher than comparable countries (Gonzales & Sawyer, 2017). Differences in interpretation of what constitutes fetal viability can account for some differences in how neonatal deaths are reported. Neonatal mortality in the United States was reported to be 3.93%, whereas infant mortality, that which occurs between 28 days and 1 year, was reported at 1.97% in 2015 (Murphy Xu, Kochanek, Curtin, & Arias, 2017). The majority of those deaths are attributed to prematurity followed by underlying perinatal causes responsible for birth defects, sepsis, cord or placental complications, maternal complications, and respiratory distress (MOD, 2016).

IMRs differ in the United States by race, ethnicity, and geographic region. The highest IMR was reported in infants born to non-Hispanic Black (NHB) mothers (11.73 deaths per 1,000 live births) compared with infants born to non-Hispanic White (NHW) mothers (4.82 per 1,000 live births; Murphy et al., 2017). Based on 2016 birth data in the United States, NHB mothers had a higher rate of delivering infants of LBW (<2,500 g) compared with infants of NHW mothers (Martin et al., 2018). Ethnic disparities are also evidently related to neonatal mortality during the first 28 days of life. Comparison rates for NHB and NHW infants for the three leading causes of neonatal death show that infants demonstrate disparities exist. Infants of NHB mothers had the highest rate of neonatal deaths related to congenital malformations, prematurity or LBW, and being affected by maternal complications of pregnancy compared with infants of NHW mothers (Murphy et al., 2017).

The birth complications of congenital malformations, prematurity, and LBW place newborns in danger of not surviving birth. Those infants who do survive frequently require care which may not be available in lower income countries, resulting in eventual mortality. Infants who are born in countries where neonatal care is more advanced may survive but will face a lifetime of future treatments and care for complications resulting from the original condition at birth.

Epidemiologic Paradox

Birth outcomes, such as risk for preterm labor, cannot always be predicted by the presence of maternal risk or sociodemographic factors (Yamamoto & Premji, 2017). For example, Mexican women who immigrate to the United States have demographic and socioeconomic factors such as high rates of teen pregnancy, less education, and higher rates of no prenatal care or late prenatal care in the third trimester that put them at high risk for poor perinatal outcomes. However, Asian Indian women who immigrate to the United States have demographic and socioeconomic risk factors similar to White women that put them at low risk. Asian Indian women have higher education levels with more college graduates, less teenaged pregnancy, and are more likely to initiate prenatal care in the first trimester. However, an "epidemiologic paradox" occurs, and outcomes do not occur as predicted. Black women have the highest incidence of LBW, SGA, and fetal and neonatal deaths in the United States (Purisch & Gyamfi-Bannerman, 2017). Foreign-born Mexican women with demographic and socioeconomic risk factors comparable to Black women have better than expected perinatal outcomes, including less LBW and less neonatal deaths (Murphy et al., 2017). In comparison, Asian women in the United States initiate prenatal care later, have lower incidences of preterm delivery, and have higher incidences of LBW and VLBW than White women (Murphy et al., 2017). This "epidemiologic paradox" suggests that there might be other factors that give foreign-born women either a perinatal advantage or disadvantage such as environmental factors, diet or lifestyle factors, or genetic factors (Mehta-Lee, Palma, Bernstein, Lounsbury, & Schlecht, 2017; Rood & Buhimschi, 2017).

MATERNAL RISK FACTORS

Evaluation of maternal risk factors can help anticipate many of the neonates who will be at increased risk for problems at birth. There is no way to accurately predict every neonate who will be at risk since a cause-and-effect relationship between high-risk maternal characteristics or behaviors and poor outcomes is not always clearly defined. For example, there have been cases of identical twins where one twin was born healthy and the other one required admission to the NICU. Although both babies had similar genetic makeup, gestational age, and exposure to the same in utero environment, only one of them had problems.

One of the most essential ways to decrease problems of prematurity, LBW, and perinatal death is to promote optimal pregnancy health. The ideal state is for all women considering pregnancy to seek preconceptual counseling. During the preconceptual visit, the woman can learn about risk factors that could potentially cause birth defects or problems with pregnancy. Risk factors may be either modifiable or nonmodifiable. Examples of modifiable risk factors that can be changed include diet, smoking, alcohol use, and substance use or abuse. Nonmodifiable risk factors are intrinsic factors that can't be changed such as maternal age, ethnicity, genetic inheritance, or preexisting health problems. Risk factors usually do not occur in isolation. The presence of one risk factor may lead to other risk factors, causing an additive effect. For example, a pregnant woman who lacks financial resources might also have a poor obstetric history, an inadequate nutritional intake, increased stress, and nicotine addiction. Some maternal risk factors can be modified through patient education, counseling, lifestyle changes, and support. The purpose of preconceptual care is to help the woman who is contemplating pregnancy get into optimal physical condition for childbearing prior to conception. Unfortunately, preconceptual counseling is not the norm. Therefore, all women of childbearing age must be encouraged to live healthy lifestyles and to seek early prenatal care in the first trimester of pregnancy. Even the first trimester of pregnancy is not too late to implement interventions or modify lifestyle risk factors that will maximize positive pregnancy outcomes.

Maternal risk factors consist of demographic, behavioral, and psychosocial factors, as well as maternal medical conditions and pregnancy-related conditions. Demographic risk factors include ethnicity, age, socioeconomic status, occupation, and environmental or work-related exposures. Psychosocial risk factors include

social, behavioral, stress-related, or maternal psychological conditions. Medical risk factors for prematurity that are unalterable can vary by population and can include previous obstetric events (i.e., previous history of infertility or pregnancy loss) or pregnancy-related conditions that only happen during pregnancy such as multiple gestation, pregnancy-induced hypertension (PIH), or gestational diabetes. Modifiable risk factors include low prepregnancy weight, low or high body mass index (BMI), and behavioral risk factors the mother has either prior to or during pregnancy. Examples of behavioral risk factors that can possibly be harmful to the fetus include inadequate dietary intake, smoking, or substance abuse (drugs or alcohol).

A complete maternal history done at the first prenatal visit will help identify important demographic and medical risk factors that might influence the outcomes of the pregnancy. A variety of demographic factors are related to neonatal outcomes. The presence of risk factors should serve as a warning. Many women with identifiable high-risk factors will give birth to healthy infants without problems. The potential influence of demographic risk factors of age, ethnicity, obstetric history, and the health-compromising behaviors (HCBs) of nutrition, smoking, alcohol, and drug use upon pregnancy will be further discussed.

Maternal Age

Maternal age is considered to be a risk factor for poor perinatal outcomes at either end of the childbearing age spectrum. The maternal childbearing age range has widened over the past decade partially due to advances in assisted reproductive technology (ART) that have made it possible for women to achieve pregnancy, even into the fifth or sixth decade of life, if desired. Worldwide, the maternal age at the time of the birth of the first child ranges from a mean of 18.1 in less developed populations to a mean of 28.5 years in more industrialized nations (Central Intelligence Agency, n.d.).

There is conflicting evidence that adolescent pregnancy increases the risk of adverse outcomes. Some adverse outcomes could be due to societal socioeconomic conditions. Younger adolescent mothers (15.9 years of age or younger) have demonstrated increased risk for complications of anemia, preterm delivery, postpartum hemorrhage, and preeclampsia. Older adolescents (16–19.9 years of age) have presented a higher risk for needing blood transfusions in addition to increased risk for anemia and preterm delivery (Kawakita et al., 2016). Adolescent mothers younger than age 20 are considered to be especially high risk because they are biologically immature and have not had the chance to complete their own physical growth and reproductive development (Brosens et al., 2017). Reproductive immaturity can increase risks of a fetal loss, PTB, or infant death.

In 2016, the U.S. teen birth rates for ages 15 to 19 years declined dramatically to a rate of 20.3 births per 1,000 births, representing a decline of 9% since 2015 (Martin et al., 2018). Even so, the United States has one of the highest teen birth rates worldwide compared with other developed nations. Numbers of teen and adolescent births globally are difficult to estimate, but rates are higher in countries where child marriage is allowed. Child marriage rates are declining in many countries due to the efforts of numerous stakeholders—for example, The Programme introduced by the United Nations Population Fund (UNFPA) and UNICEF (UNFPA-UNICEF, 2017). The Programme is intended to increase educational levels of the female population and teach necessary life skills and decision-making principles. In countries where there has been success, the age of first birth has increased and girls completing the Programme are planning fewer children and a limited number are using birth control (UNFPA-UNICEF, 2017). In the United States, the rate of unmarried teen births has dropped to 18.5 births per 1,000 deliveries (Martin et al., 2018). However, there are many countries where unmarried teen pregnancy rates are high. Teen mothers and their infants have increased perinatal risks including higher risk of dying during childbirth compared with 20-year-old women. Infants of teen mothers have an increased risk of dying within the first year of life (WHO, 2018a). There are also lifelong disadvantages for younger teen mothers who have less years of formal education. Education is known to be a factor related to promotion of positive pregnancy behaviors. Pregnant adolescents who are less educated most likely will not use contraception, may not recognize danger signs in pregnancy that something is wrong, or may not even seek prenatal care. In the United States, many programs directed at preventing teen pregnancy focus on education in general and are specifically related to attitudes, prevention, and community support (Bhuiya et al., 2017; Galloway, Duffy, Dixon, & Fuller, 2017). Unmarried teen mothers require financial support for the pregnancy from parents or social agencies. Many teen mothers find it difficult to remain in school while pregnant or return to school full-time following delivery. The parenting role is difficult without financial support or help with day care from their parents (Kumar, Raher, Ware, & Phipps, 2017). Dropping out of school during pregnancy can make it difficult to return and complete their education, limiting employment opportunities in the future. Some teen girls drop out of school or leave home due to poor family relationships even before getting pregnant. Globally, the acceptance of adolescent pregnancy by families and communities differs sometimes, resulting in fear of stigmatization, family shame, and additional stress (Aziato et al., 2016). Preexisting maternal disadvantages, not young maternal age, are more likely to account for negative outcomes of teen parenting for mothers and infants (McHugh, Kvernland, & Palusci, 2017). A need has been identified for improved parenting information for teens, as well as improved medical knowledge and continued healthcare access (Dumas, Terrell, & Gustafson, 2018). Teen mothers are also more likely to have a repeat teen pregnancy. In 2016, about 17% of teen births in the United States were the mother's second, third, or fourth child (U.S. Department of Health and Human Services, n.d.).

Advanced maternal age refers to women who are older than 35 at the estimated date of delivery. Women may have problems conceiving secondary to infertility, or some women may choose to delay childbearing voluntarily while pursuing educational or professional goals. A recent trend has been an increase in the number of women in the advanced maternal age group who are having babies. Advances in reproductive science, such as oocyte donation, have made it possible for women who are postmenopausal in their 50s or 60s to conceive. The birth rate for women ages 40 to 44 was 11.4 births per 1,000 women and the birth rate for women ages 45 to 49 increased in 2016 to 0.9 births per 1,000 women (Martin et al., 2018). Advanced maternal age poses increased risks for decreased fertility, chromosomal abnormalities in the infant, spontaneous abortion, and preterm delivery (Frederiksen et al., 2018; Waldenström, Cnattingius, Vixner, & Norman, 2017; Wesselink et al., 2017). Late fetal and early perinatal death rates are higher for pregnant women 40 and older than for any other age groups. Pregnant women older than 40 have a higher rate of spontaneous abortion than pregnant women between the ages of 20 and 24 (Frederiksen et al., 2018). Women older than 35 are at increased risk for perinatal mortality; however, the increased risk appears to be related to previous obstetric and medical comorbidities more than age (Morris, Totterdell, Bin, Ford, & Roberts, 2018). Although fertility tends to decline with advanced maternal age, women between the ages of 35 and 39 actually have an

increased risk of conceiving twins without the assistance of fertility treatments. Women over age 40 having twins are at less risk to have a preterm infant than 15- to 17-year olds at each gestational age (i.e., <32, <34, and <37 weeks; McLennon et al., 2017). Older women also are more likely to have multifetal pregnancies due to use of assistive reproductive technologies, which could account for increased maternal morbidity (Moaddab et al., 2017; Witteveen, Van Den Akkar, Zwart, Bloemenkamp, & Van Roosmalen, 2016). Current guidelines suggest practitioners screen for maternal genetic disorders and medical disorders and avoid multifetal implantation while attempting single gestation pregnancies (Sumners, Echer, & Hearns-Stokes, 2016).

Older pregnant women are at an increased risk for medical problems associated with aging such as cardiac disease and chronic hypertension (Morris et al., 2018). The rates of medical complications including diabetes, cardiac disease, and hypertension in pregnant women increase as maternal age advances. Diabetes increases their risk for delivery of a macrosomic infant. Pregnancy over 48 years of age can also contribute to increased risks of gestational hypertension, gestational diabetes, and placenta previa (Fitzpatrick, Tuffnell, Kurinczuk, & Knight, 2016). Fitzpatrick et al. (2016) also found that women of advanced maternal age usually planned the pregnancy, expected and participated in more prenatal visits, and took part in more prenatal assessment testing.

Advanced maternal age creates genetic risks because as the woman gets older, the genetic material contained within her ova ages. The prevailing theory is that all females are born with all of the oocytes they will ever have, which contain the genetic material that she will pass on to her progeny. According to maternal aging theory, as the woman ages, her oocytes and the genetic material contained within also age. Aging genetic material is more likely to have errors during cell division and migration during meiosis that can result in aneuploidy (an abnormal number of chromosomes), lower implantation rates, decreased fertility, or increased risk of spontaneous abortion (Moaddab et al., 2017; Wesselink et al., 2017). Chromosomal disorders increase with advanced maternal age. Although chromosomal disorders can occur at any maternal age, there is an increased risk after age 35. **Quality & Safety: Advances in screening tests now allow practitioners the advantage of offering testing appropriate to the low- or high-risk status of a patient** (Dashe, 2016).

PATERNAL FACTORS

Paternal age does not appear to be an independent factor in adverse pregnancy outcomes such as disparities in fetal growth or genetic disorders (Hurley & DeFranco, 2017). However, the use of ART increased as paternal age increased. The use of ART has been associated with nonchromosomal birth defects, LBW, and placental complications (Luke, 2017). Increases in childhood cancers have been observed with advanced ages of both mother and father, with increased risk for non-Hodgkin lymphoma influenced by paternal age only (Wang et al., 2017). Paternal socioeconomic position has been associated as a factor with LBW in infants of African American women when controlled for maternal factors (Collins, Rankin, & David, 2016). Advanced paternal age should also be considered when evaluating prenatal risks, as it has been associated with rare congenital anomalies in offspring due to dominant mutations such as neural tube defects (Prasoona et al., 2016). **Quality & Safety: A careful assessment of the family history of both parents will help alert the healthcare provider to potential risks.**

Paternal environmental or occupational exposure to certain chemicals can lead to developmental outcomes including altered growth, structural or functional abnormalities, or death. Some effects may be expressed across the lifetime of the child (Yen et al., 2016). High levels of paternal occupational exposure to lead have been linked to LBW (Craft-Blacksheare, 2017). Paternal exposure to occupational and environmental toxins may continue throughout the child's lifetime.

LIFE COURSE DETERMINANTS OF BIRTH OUTCOMES AND WEATHERING

The life course theory (LCT) is an approach that is being used to explain health, disease, and health disparities across populations and over time. Rather than focusing on ethnic or genetic differences or an individual's choices to explain health disparities, the LCT focuses on social, economic, and environmental factors as key determinants that help shape health or disease in communities and populations. The LCT acknowledges the importance of intergenerational preprogramming (i.e., maternal preconceptual health) and prenatal preprogramming (i.e., the in utero environment) in influencing fetal and child health. While health can be impacted at any time, there are critical and sensitive periods when events can have a maximal impact on lifetime health such as during fetal development, early childhood, or adolescence. The goal would be to promote interventions during these sensitive times to maximize health (UN, 2015).

Applying the LCT perspective to preterm delivery would propose that reproductive and birth outcomes are the product of circumstances and events that occur not only during pregnancy but throughout the life of the mother, beginning either before or at the time when she was conceived. The LCT perspective acknowledges the possibility that early-life experiences can shape health across an entire lifetime and could potentially influence the health of future generations (Yingwattanakul & Moschis, 2017). According to the LCT perspective, it is not enough to assess the woman's experiences during the immediate preconceptual and prenatal period to determine risks for poor outcomes. Assessment of major events during her entire life course and the effects of material deprivation, social disadvantage, discrimination, and marginalization must be explored (Nist, 2017). The health consequences of poverty and race-based discrimination and the health effects of chronic stress from having inadequate resources to meet demands must also be considered. For example, exposure to poor nutrition as a child, or even as a developing fetus, could impact a woman's pregnancy outcomes. The life course perspective aligns with the developmental origins of health and disease approach, which posits the important role of the fetal in utero environment in development of structure and functions of organs of the body. For example, a lack of folic acid during development can lead to neural tube defects; exposure to tobacco can lead to LBW or short gestation; and exposure to maternal antidepressants may cause PTB and increased risk of neonatal morbidity (Eke, Saccone, & Berghella, 2016; Nörby et al., 2016; Trinidad & Wick, 2017). Components of a perinatal life course risk assessment tool are not yet developed; however, this area of study offers intriguing promise to unravel some possible explanations for healthcare disparities.

PSYCHOLOGICAL STRESS IN PREGNANCY

Maternal mental health and psychological stress are increasingly being studied as possible sources of adverse perinatal outcomes. Stress is an interaction between the person and environment in which there is a perceived discrepancy between the demands of the environment and the individual's resources (i.e., psychological,

social, or biological) for dealing with it. During pregnancy, women may experience many types of stressors. Chronic life stressors include stress about finances, work situations, difficult relationships, health concerns of self or other family members, or other factors. Acute stressors during pregnancy include situational crisis or natural disasters. There is a growing body of evidence related to the effects of acute and chronic maternal stress during pregnancy on gestational length and birth weight (Nkansah-Amankra, 2018). Other evidence points to associations between preconceptual stress and accumulated life stress on birth outcomes.

Acute and chronic stressors can occur due to life events such as the death or serious illness of a loved one, previous traumatic event, or any social or economic stressors. Rosenberg, Li, and Seng (2017) suggested the use of the concept of allostatic load in nursing research. Stress in either the acute or chronic form affects pregnancy outcomes. When the body experiences stress, there is a physiological reaction. Chronic stress results in physiological dysfunction over time that impairs the immune response and produces metabolic and cardiovascular changes that produce illness. Increased stress during pregnancy can result in normal stress reactions causing increased physiological response, which is harmful to the pregnancy. A woman may be entering her pregnancy unknowingly in a poor physiological state at risk for hypertension and diabetes due to these changes. Maternal exposure to severe life events, such as death or serious illness in close relatives, witnessing or experiencing physical violence as a child or adult, or having experienced an adverse birth outcome previously, can place the woman at risk for adverse pregnancy outcomes (Margerison-Zilko, Strutz, & Holzman, 2017; Shaw et al., 2017). Labor and delivery may trigger a response in women who suffer from posttraumatic stress disorder (PTSD) resulting from prior adverse pregnancy outcome or sexual assault. Healthcare providers should evaluate all patients who exhibit signs of depression in pregnancy to rule out PTSD so the patient receives the proper psychologic support (Geller & Stasko, 2017). PTSD has been identified in women who have had a diversity of acute traumatic events in their life. The diagnosis and effect on pregnancy outcomes can be found in all countries, ethnic groups, and socioeconomic levels. Intimate partner violence has been identified as a chronic stressor and as a cause of PTSD in women, which can have a negative impact on pregnancy and result in LBW and preterm delivery (Karakurt, Patel, Whiting, & Koyutürk, 2017).

Pregnancy-related anxiety is a form of anxiety specific to pregnant women and includes worries about the health and well-being of the baby, impending labor and birth, hospital and healthcare experiences and one's own health and survival, and about parenting and the maternal role. Pregnancy-specific stress includes: (a) fear of pain; (b) pregnancy-related concerns about the health of the baby, labor, and delivery or body size and body image; (c) pregnancy-specific support and giving birth; and (d) pregnancy-related symptoms and attitudes toward whether the current pregnancy was intended or wanted (Westerneng et al., 2017). Pregnancy-specific anxiety can result in detrimental health behaviors such as smoking and dieting to avoid excessive weight gain (Westerneng et al., 2017).

Major stressors such as life events, major catastrophes, chronic strain, neighborhood stress, and multiple stressors may contribute to PTB, gestational age, or gestational length. The exact mechanism by which maternal stress causes preterm labor is not fully understood, but it is thought to occur by one of two mechanisms. Corticotropin-releasing hormone released as a by-product of maternal stress could stimulate neuroendocrine pathways within the maternal–fetal–placental unit that trigger labor; or maternal stress could cause increased maternal and fetal susceptibility to inflammation and infection, triggering labor through an immune-inflammatory pathway (Rosenberg et al., 2017; Sultana et al., 2017). These interactions between neuroendocrine, immune, and behavioral processes may be tempered by maternal resilience resources (ego strength, personality, social, coping, cultural values, and worldview). Hardiness, resilience, and social support might act as stress buffers in some women, lessening the impact of stress (Scoglio et al., 2018).

Not all women are affected in the same way by stress, which could account for difficulty with prediction of outcomes. Critical periods may occur during pregnancy where there is altered vulnerability to the effects of prenatal stress. The cumulative effects of lifetime exposure to acute stress and experiences of chronic day-to-day stress increase the risk of stress-related disease during pregnancy and may help explain some ethnic disparities in birth outcomes (Margerison-Zilko et al., 2017). Just as it is difficult to predict the outcomes related to stress, it is imperative to assess for the methods pregnant women may use to cope with stress prenatally.

Smoking has been cited by many as a method to deal with stress. Tobacco use often rises in periods of increased stress. Many women attempt to reduce or quit smoking prior to conception or during pregnancy once they are made aware of the dangers of perinatal complications (Damron, 2017). Exposure to second-hand smoke also carries the risk of lower birth weight and PTB in addition to making it difficult for the mother to quit herself. Unfortunately, women of lower socioeconomic status are more likely to persist with smoking in pregnancy and also have higher rates of comorbidities of hypertension and diabetes (Martin et al., 2018). Alcohol use has also been identified as a stress reduction strategy by some individuals. The use of alcohol in pregnancy can have the outcome of SGA and postnatal growth restriction (Carter et al., 2016). As there is no accurate method of determining how much alcohol is too much nor if the timing of drinking changes the outcome of FAS disorder, it is best to advise no use of alcohol during pregnancy (Wilhoit, Scott, & Simecka, 2017). Alternative stress reduction measures can be advised by care providers to improve pregnancy outcomes.

Physical activity such as walking can reduce the incidence of gestational hypertension and diabetes (Garland, 2017). Care providers may need to dispel the common myths about activity increasing the risk of miscarriage and make an individual assessment of the suitability of the activity for patients. In identifying a safe area for the patient to walk prenatally, the provider has also informed the patient of a possible safe area to bring the infant. Yoga is another intervention that some women may already practice and has been found to be useful in the treatment of anxiety and depression in the general population (Butterfield, Schultz, Rasmussen, & Proeve, 2017). Many of the moves and poses can be adapted for pregnancy. In addition to alternatives, providers can offer smoking cessation programs and support to mothers as quitting at any time during pregnancy will improve neonatal outcomes (Wallace, Aland, Blatt, Moore, & DeFranco, 2017). The success of any intervention will depend on the appropriateness for the individual client.

OBSTETRIC FACTORS

Obstetric history is a good indicator of the presence of maternal risk factors. Women with previous obstetric complications are more at risk for problems with the current pregnancy. Previous obstetric history of infertility, stillbirth, preterm infant, infant with growth restriction or congenital anomalies/genetic problems, complications during pregnancy or birth, or other poor outcomes are

clues that indicate that the pregnancy must be closely monitored. Prepregnancy health status is another factor associated with the risk of preterm delivery. Women who are in poor physical condition prior to conception (i.e., underweight, having poor prepregnancy physical function, chronic hypertension, or smoking before pregnancy) have an increased risk for preterm delivery (Purisch & Gyamfi-Bannerman, 2017). Important obstetric factors that can compound pregnancy risk are the adequacy of prenatal care, the number of previous pregnancies, interpregnancy level, the use of ART, and postterm pregnancy (Frederiksen et al., 2018; Malacova et al., 2017; Howson et al., 2012).

PRENATAL CARE

Prenatal care that begins in the first trimester of pregnancy and continues until birth helps promote good birth outcomes. Most women seek prenatal care during the first trimester of pregnancy. Only about 6.2% of U.S. women start prenatal care during the last trimester or have no prenatal care, with higher rates of late or no prenatal care seen in NHB and Hispanic women compared with NHW women (Martin et al., 2018). WHO has set a worldwide goal for a minimum of eight focused antenatal care visits during pregnancy (WHO, 2016a). Worldwide, only half of women had four prenatal visits as previously recommended (UNICEF, 2018). Inadequate prenatal care increases the risk for LBW, PTB, and perinatal death (Hug, Sharrow, & You, 2017; Swartz et al., 2017). Increased death rates are seen in infants of women who did not have prenatal care, which might be associated with lack of access to care providers or lack of use of pediatric medical care resulting in untreated complications of pregnancy or neonatal infection (Murphy et al., 2017).

The decision to seek prenatal care is influenced by the woman's attitudes toward pregnancy, cultural preference, or lifestyle factors. For some women, access to prenatal care is limited due to financial constraints or geographic availability of a trained practitioner. Having six prenatal visits prior to delivery was considered a protective factor against LBW and prematurity. Current recommendations by WHO (2016a) encourage group antenatal care contact as well as private contacts as a means of encouraging pregnant women to engage in antenatal care, improve satisfaction, and decrease adverse pregnancy outcomes.

Providing care to the mother at delivery by a skilled birth attendant could also improve outcomes through early recognition of problems during labor and intervention. Worldwide, there are many countries where a majority of women deliver at home with or without the assistance of a trained practitioner. Countries with the highest rates of unattended births also have the highest rates of infant mortality (Hug et al., 2017). The United Nations SDG 3 (2015) seeks to provide universal access for all women to reproductive care including access to prenatal care and family planning information.

PARITY

Parity or number of previous deliveries has been considered another risk factor for preterm delivery, LBW infant, and abnormal placental implantation. Parity is difficult to disassociate from age as women with higher parity are usually older. Eugene and Abedinego (2017), in an age-matched case–control study, found adverse pregnancy outcomes appeared to be related to maternal age, education level, and socioeconomic status rather than grand multiparity. In general, primiparous women older than 35 years of age and multiparous teens younger than 18 years of age have an increased risk for PTB at any gestational length; however, there are some racial differences. Both primiparous and multiparous Black and Hispanic women have an increased risk for very PTB starting at a younger age (25 years). Primiparous teenagers tend to have the highest risk of having an extremely PTB (EPTB). The incidence of EPTB is higher in older primiparous Black and Hispanic women compared with teenagers. On the other hand, in White women EPTB risk is highest at either end of the age spectrum for both teenagers and older primiparas. However, for all races, the risks for any type of PTB increase as women are older than 40 years of age (MOD, 2016).

INTERPREGNANCY LEVEL

Interpregnancy level is defined as the amount of time between delivery of a baby and the subsequent conception of another child. Short interpregnancy level of less than 6 months increases the risk for maternal complications, including third-trimester bleeding, prelabor rupture of membranes (PROM), puerperal endometritis, anemia, and maternal death. Women with longer interpregnancy levels have the highest risk for preeclampsia, eclampsia, and gestational diabetes, again probably related to older maternal age. The risk for prematurity is increased when the interpregnancy level is less than 18 months and should be considered when providing postpartum care (Stuebe, Auguste, & Gulati, 2018). Programs developed to educate all women regarding family planning and appropriate birth intervals can help prevent the adverse outcomes of shortened interpregnancy level (Cross-Barnet et al., 2018).

ASSISTED REPRODUCTIVE TECHNOLOGY

ART is any procedure or medical treatment used to assist a woman to achieve pregnancy. ART is an option for many couples who have a history of infertility. ART methods include the use of medications to stimulate ovulation and release of eggs, or procedures where eggs and sperm are removed and mixed outside of the body to achieve fertilization. Some techniques require that the fertilized egg remain outside the body for a few days before being implanted back into the woman's body. In some cases, the eggs, sperm, or embryos might be frozen for later use or manipulated with instrumentation during the earliest stages of cell formation.

According to the CDC, about 1.7% of U.S. pregnancies are conceived using ART (CDC, n.d.-b). ART increases the risk for multiple pregnancy, prematurity, and LBW. Previously, many types of ART procedures resulted in high rates of multiple gestation pregnancies to describe triplet and greater gestation since couples may choose to have multiple embryos implanted to maximize their chances for success. More recent statistics in the United States demonstrate a higher rate of singletons and very few triplets (CDC, n.d.-a). The risk of prematurity increases with twins and higher order multiples. The identified risks involved with multiple gestation pregnancy prompted the American College of Obstetricians and Gynecologists (ACOG) to advise that providers limit the number of embryos transferred, use low-dose ovarian stimulation protocols, and educate clients regarding the risks inherent in higher order multiple gestation (Sumners et al., 2016). Multiple gestation pregnancy naturally increases risks for preterm labor (PTL), cesarean delivery, and LBW and provides one explanation for the increase in number of LBW and preterm infants over the past few years. However, the risk for prematurity and LBW exists for even singleton pregnancies conceived with ART (Luke, 2017). The Massachusetts Outcomes Study of Assisted Reproductive Technology provided data that demonstrates subfertile women with singleton pregnancies were at increased risk for developing gestational

hypertension, gestational diabetes, and delivering preterm (Luke, Gopal, Cabral, Stern, & Diop, 2017). The risk was present regardless of whether the client used ART to achieve pregnancy. Clients conceiving using in vitro fertilization (IVF) had the additional increased risk of fetal malpresentation, placenta previa, placental abruption, and delivery by cesarean section.

Couples who electively conceive through ART with a large number of embryos may have to make tough ethical decisions, including options for selective reduction later in the pregnancy, in order to protect the health of compromised fetuses. The risk for prematurity and LBW increases as the numbers of fetuses increase, increasing risks of poor outcomes for the infants. The decision to maintain a pregnancy with a large number of fetuses can be economically and emotionally catastrophic for the family. Outcomes for the babies who survive depend in part upon the number of fetuses and gestational age at delivery. Maternal care provider organizations have suggested limits on the numbers of embryos that can be implanted during ART procedures to help address some of these issues (Sumners et al., 2016). Continued research to improve ART techniques to assure success of singleton pregnancies will do much to impact outcomes of ART pregnancies.

POSTTERM PREGNANCY

Postterm pregnancy is defined as a pregnancy that continues past 42 weeks (294 days) or 14 days past the estimated due date (ACOG, n.d.). The cause of postterm pregnancy is not known, but it occurs more often with male fetuses and may have a genetic basis. Some cases of postterm pregnancy can be attributed to inaccurate dates used to calculate the estimated date of confinement. Ultrasound dating of pregnancy is considered to be accurate if done during the first trimester; however, ultrasound dating of pregnancy has a margin of error.

Postterm infants are more likely to have macrosomia, with increased risks for prolonged labor or CPD with increased risk for cesarean section, or shoulder dystocia with increased risks of possible musculoskeletal injury (i.e., fractured clavicle or brachial plexus injury). Postmaturity also predisposes to uteroplacental insufficiency, resulting in intrapartum asphyxia and meconium aspiration (N. Walker & Gan, 2017). These infants are more at risk for cord compression due to oligohydramnios and presence of meconium-stained amniotic fluid (Karahanoglu et al., 2016). Postterm pregnancy has also been related to lower umbilical artery pH levels and more frequent NICU admissions (Karahanoglu et al., 2016). The risk for cesarean section and associated complications also increases as pregnancy progresses beyond full-term (N. Walker & Gan, 2017). ACOG recommends close surveillance of postterm pregnancies between 41 and 42 weeks due to increased risks of complications as gestational age advances. Postterm fetuses should be evaluated by nonstress testing or biophysical profiles. Cervical ripening and induction of labor at 41 weeks is an alternative approach for management of postterm pregnancies when combined with appropriate fetal assessments (Dekker, 2016).

UNFAVORABLE HEALTHCARE BEHAVIORS

Personal habits such as smoking, illicit drug use, or alcohol use can compromise overall maternal health during pregnancy and can negatively influence fetal well-being. Prepregnancy maternal health status and poor health behaviors can play a role in PTL risk. Babies born to mothers who smoke, drink alcohol, or take drugs weigh less than babies of mothers who do not smoke, drink, or take drugs (Martin et al., 2018). Inadequate nutrition, over-the-counter or prescribed drug consumption, and environmental factors may create other HCBs and increase risks during pregnancy.

Smoking

Smoking is a major predictor of LBW, possibly due to impaired oxygen delivery (hypoxia) and nutrient delivery from the mother to fetus (Slemming, Bello, Saloojee, & Richter, 2016). Infants of mothers who smoke have an increased risk of premature rupture of membranes, intolerance of labor, and NICU admission (Wallace et al., 2017). Risk of adverse outcomes decreases with smoking cessation. Recent popularity of nicotine delivery systems such as e-cigarettes results in delivering the same neurotoxic effects as tobacco smoking. Unfortunately, some pregnant women have the perception that using e-cigarettes is less harmful than regular cigarettes and can be used to help in smoking cessation (Bhandari et al., 2018). Women who smoke are more likely to use alcohol or illicit drugs during pregnancy than those who do not smoke. In an analysis of national data, Kurti et al. (2017) identified a correlation with cigarette smoking, e-cigarette use, and use of illicit drugs. The effect of smoking on pregnancy outcomes is also dose dependent with heavy smokers more likely to have infants who are born extremely preterm (Dahlin, Gunnerbeck, Wikström, Cnattingius, & Edstedt Bonamy, 2016). Smoking rate in the United States during pregnancy has been estimated to be 7.2% with ethnic variations. More NHW women (10.5%) smoke during pregnancy as compared with NHB women (6.0%) and Hispanic women (1.8%; Martin et al., 2018).

Substance Use or Abuse

Substance use and abuse is a concern for childbearing women of all ages. Marijuana smoking has been associated with increased neonatal neurological morbidity and neonatal infection morbidity independent of confounding factors (Metz et al., 2017). Subjects of this study (Metz et al., 2017) also reported cigarette smoking and illicit drug use. Women under the influence of mind-altering substances are more likely to make poor choices and have an increased risk of engaging in unprotected sex resulting in an unplanned pregnancy. Additional studies have identified marijuana when used alone or combined with cigarette smoking to be significant in increased risk of PTB and LBW (Chabarria et al., 2016; Leemaqz et al., 2016). The effect of marijuana on pregnancy outcomes will become more apparent as more states legalize medicinal and recreational use.

Maternal alcohol ingestion during pregnancy can result in fetal alcohol spectrum disorders (FASD). The incidence of FASD may be related to both environmental exposure and genetic susceptibility. Alcohol is believed to have a direct teratogenic effect that limits fetal growth and brain growth. The fetal effects of drinking are most pronounced if the fetus is exposed during the first trimester of pregnancy. The minimum amount of alcohol that is harmful to the fetal brain is not known. It is known that binge drinking (ingestion of more than five drinks at one occasion) leads to higher levels of blood alcohol. Binge drinking is a special concern in early pregnancy when the fetal brain is developing and women may not yet realize that they are even pregnant (D. S. Walker, Edwards, & Herrington, 2016). In addition to being SGA, the neonate exposed to alcohol prenatally may have problems with sucking, which results in feeding problems (Wilhoit et al., 2017). Neonates who have been exposed to alcohol at any time prenatally can develop symptoms of FASD. Neonates who are SGA at birth may have continued postnatal growth restriction (Carter et al., 2016). Healthcare providers need to accurately assess women prenatally for alcohol use to be more prepared for possible adverse outcomes.

Research has identified the combined use of alcohol, smoking, and illicit drug use in multiple populations of pregnant women (Cohen, Osorio, & Page, 2017; Myers et al., 2018).

Illicit drug use in pregnant women is inclusive of misuse or abuse of prescription drugs and use of illegal substances. Illegal drug use crosses all socioeconomic sectors with the prevailing drug of choice initially being what is available and affordable. The use of crack cocaine has been more prevalent among more marginalized populations. Neonates of mothers who use crack cocaine are at higher risk of FGR and placental abruption (Butler, Rehm, & Fisher, 2017). As noted by Cohen et al. (2017), most drug use occurs in combination with other harmful substances. Pregnant women using illicit drugs also tend to enter prenatal care later in their pregnancy. Research that focuses on smoking, alcohol, and illicit drug use often relies on self-report by subjects, which may lead to some inaccuracy in findings (Morean et al., 2018). However, it is clear that the result of polypharmacy habits of the mother can result in PTB, LBW, and possible neonatal abstinence syndrome in the neonate (Kozhimannil, Graves, Levy, & Patrick, 2017; Zhao, McCauley, & Sheeran, 2017). Opioid use, both prescribed and illicit, has increased in the United States and resulted in multiple methods of treatment for mother and infant. There are challenges to treating the mother for addiction during pregnancy without having detrimental effects on the neonate (McCarthy, Leamon, Finnegan, & Fassbender, 2017). Treatment options for the neonate presenting with neonatal abstinence syndrome also vary based on the severity of symptoms and provider preference (Kraft, Stover, & Davis, 2016). See Chapter 30, Neonatal Abstinence Syndrome, for more information.

Nutrition

Adequate nutrition prior to conception and during pregnancy is important for maternal and fetal health. The pregnant woman needs to consume enough calories and nutrients to meet her own physiological needs as well as those of the developing fetus. Nutritional risks to consider include inadequate or excessive weight gain, medical conditions that complicate pregnancy such as hyperemesis gravidarum, dental conditions that compromise the ability to take in food, or inadequate resources to access food. Lack of adequate nutrients prior to or during early pregnancy can lead to birth defects. The importance for all women of childbearing age (between 15 and 45) to consume at least 400 mcg of folic acid daily to help prevent neural tube defects has been well established. The World Health Organization continues to recommend supplemental folic acid daily beginning prenatally if possible (WHO, 2016a).

Another important nutritional consideration is prevention of maternal anemia during pregnancy. Anemia is a serious problem affecting about half of pregnant women worldwide. It is more prevalent in nonindustrialized nations due to poor nutrition, iron-deficient diets, presence of parasitic disease, and incidence of HIV/AIDS. Women who are anemic are less likely to withstand blood loss during delivery and have increased risks of perinatal death, LBW, stillbirths, and prematurity. Promoting adequate nutrition prior to pregnancy is a key to improving outcomes of pregnancy. WHO (2016a) recommendations in nonindustrialized nations encourage the intervention of 120 mg of elemental iron and 2.8 mg of folic acid weekly to prevent anemia if daily dosing is not acceptable. Unfortunately, not all women take the recommended supplements due to a cultural belief that anemia is normal and expected in pregnancy (Onyeneko et al., 2016).

Inadequate nutrition may be another risk factor for prematurity, LBW, or pregnancy loss, especially in teenaged pregnancy or for women at risk for not eating due to food insufficiency or conditions such as anorexia nervosa or depression. Many teenaged girls do not eat an adequate diet, even when they may not be pregnant. They may not consume adequate trace elements or antioxidant micronutrients in their diet (i.e., selenium, copper, zinc, manganese, and vitamins C and E) during pregnancy, which are essential in the promotion of adequate placental development, prevention of FGR, and prevention of fetal mortality and morbidity (Micali, Stemann-Larsen, Strandberg-Larsen, & Nybo Anderson, 2016). Young mothers who do not consume enough nutrients to maintain their own growth, as measured by gains in BMI or height, are more at risk to have LBW infants compared to older mothers. Both high and low maternal BMI have been associated with poor pregnancy outcomes for both mother and neonate. Obesity rates have been steadily increasing in industrialized nations with the result of decreased fertility, increased miscarriage when pregnancy is achieved, and increased risk of preeclampsia (Broughton & Moley, 2017; Kim et al., 2016). In response to the risks of poor pregnancy outcomes while obese, many women of childbearing age have chosen bariatric surgery for weight reduction prior to conception. While undergoing this procedure has decreased risk of complications associated with obesity, there is the increased possibility of complications related to poor nutritional intake due to malabsorption of micronutrients needed to support healthy pregnancy and normal fetal growth (Carreau, Nadeau, Marceau, Marceau, & Weisnagel, 2017; Chevrot et al., 2016; Jans et al., 2015).

Conditions in many countries contribute to chronic undernutrition throughout the life span resulting in poor pregnancy outcomes. Girls are more at risk for nutritional deprivation in some countries due to girl gender bias. Chronic undernutrition can delay menarche in young girls. In some cultures, especially rural, underdeveloped populations, early adolescent marriage and pregnancy are permissible. In a study conducted in India where many pregnant women experience chronic undernutrition, adolescent girls less than age 18 with low BMI of less than 18.5 kg/m^2 were found to be at increased risk for pregnancy wastage and prematurity compared with those older than 18 with low BMI. Additionally, prematurity rates were significantly higher in girls who married prior to age 18 compared with those who married after age 18. Pregnancy wastage was six times higher in mothers who conceived at less than 15.25 years compared with those who conceived after 17.25 years. Adolescent pregnancy outcomes often include maternal anemia and preterm delivery (Kawakita et al., 2016). Food insecurity not only can increase risk for a LBW infant but can increase risks of birth defects. Food insecurity can also lead to changes in maternal mental health, including depression, anxiety, and low self-esteem (Pellowski et al., 2017). Interventions that can help improve nutritional status of pregnant women in food-insecure locations are also aimed at increasing infant birth weight, which can markedly decrease infant mortality. Effective interventions include maternal supplementation with iron folate and micronutrients, calcium supplementation, iodized salt, reduction in indoor pollution and tobacco usage, intermittent preventative treatment for malaria, and use of insecticide-treated mosquito nets (Cox et al., 2018; Wallace et al., 2017; WHO, 2016b).

Even in high- to moderate-income nations, some pregnant women living on low incomes do not get adequate nutrition. In the United States, nutritional support during pregnancy along with nutritional education, and participation in programs such as the Special Supplemental Nutrition Program for Women, Infants, and Children (SNAP), have been demonstrated to increase the mean birth weight and reduce the odds for LBW for infants of low-income women on Medicaid. The use of foodbanks is increasing in middle and higher income countries as food insecurity

increases in rural as well as urban areas as families face the challenges of meeting multiple monetary and social needs (Chang, Kim, & Chatterjee, 2017; Loopstra, 2018). Unfortunately, the use of the SNAP program and foodbanks as a nutrition resource has not improved the nutritional intake of pregnant women as expected due to the availability of primarily processed foods with low nutritional value. Availability of fresh fruits and vegetables is costly and still limited, especially in more urban areas (Mulik & Haynes-Maslow, 2017; Spees, Clark, Hooha, Watowicz, & Taylor, 2017). One result of the lack of available nutrient-rich food is continued maternal obesity among participants of the SNAP program (Sanjeevi, Freeland-Graves, & Hersh, 2018).

Maternal foodborne illness or ingestion of toxic substances during pregnancy can be harmful to the fetus. *Listeria monocytogenes,* even though rare, is a special concern in pregnancy since pregnant women have a 10 times greater risk of becoming infected (CDC, n.d.-c). Women who ingest food contaminated with *Listeria* do not usually feel ill; however, the fetus can be significantly affected. Eating food contaminated by microorganisms like *Listeria* or substances like heavy metals can cause abortion, stillbirth, preterm delivery, neonatal infections, fetal brain or kidney problems, or even maternal death. While *Listeria* is found in many foods, teaching pregnant women simple basic precautions such as handwashing when preparing food, avoiding cross-contamination of meat dishes or other prepared foods, and avoiding nonpasteurized milk may help prevent infection (McNeill, Sisson, & Jarrett, 2017).

Pica is an interesting dietary practice seen during pregnancy in almost every culture. Substances like starch, ice, clay, or dirt are ingested as a craving in an attempt to possibly increase iron or calcium intake. The harmfulness of pica in pregnancy is dependent on the substance and amount ingested by the pregnant woman. Women who practice pica tend to have lower hemoglobin and hematocrit levels and be more underweight at the start of their pregnancy (Epler, Pierce, & Rappaport, 2017). One concern if the mother eats dirt or paint chips is that it could possibly be contaminated with lead or heavy metals which could be harmful, cause anemia, or result in lead poisoning. Contamination of soil and water increases the risk of elevated lead levels in women, which can then result in increases in spontaneous abortion, fetal deaths, or infants with LBW (Hanna-Attisha, LaChance, Sadler, & Schnepp, 2016; Tian, 2017).

The influence of cultural dietary practices as potential risk factors can't be ignored and must be assessed. Asian women who ingest betel nuts, which contain arecoline, are at higher risk for spontaneous abortion, LBW, and PTB, placental changes, and neonatal withdrawal (Berger et al., 2016). Some populations continue to use lead-glazed ceramic ware and traditional folk remedies that are lead-based even after immigration into the United States (Welton, Rodriguez-Lainz, Loza, Brodine, & Fraga, 2016). The healthcare practitioner must become familiar with the food and complementary medicine cultural practices of local ethnic groups, as they may affect pregnancy outcomes.

Over-the-Counter and Complementary Drugs

Drugs taken during pregnancy can have harmful effects on the fetus whether they are controlled substances or over-the-counter medications. Despite warnings that pregnant women should not take any medications without consulting with their healthcare provider, many pregnant women take over-the-counter or nonprescribed medications during pregnancy, including complementary therapies they might not consider to be harmful. Findings of a study by Haas et al. (2018) on the prevalence of medication use by nulliparous pregnant women reported that 97.1% of women used one or more medication during their pregnancy. About 95.7% said they used at least one prescription or over-the-counter medication in the first trimester of pregnancy. Prescribed antidepressants and asthma medications are among the most commonly prescribed used during pregnancy. Many women regularly take over-the-counter drugs such as cold remedies, aspirin, nonsteroidal anti-inflammatory drugs, or herbal teas. Some women might take medications that could be harmful to the fetus before they know that they are pregnant. Even vitamins and dietary supplements taken in excessive dosages can be harmful to the fetus. Pregnant women with preexisting medical problems such as asthma, arthritis, heart problems, diabetes, or epilepsy who have to continue to take their prescribed medications during pregnancy should check with their healthcare provider to determine if the prescribed medication will need to be changed to one that is less harmful to the fetus. Communication between patient and provider is essential as some women stop taking their prescribed medications when they cannot access information stating there is no risk to the fetus (Lynch et al., 2017; Sinclair, Lagan, Dolk, & McCullough, 2018).

Healthcare providers must be cognizant of Food and Drug Administration (FDA) pregnancy categories and drugs that must be used with caution or that are contraindicated in pregnancy. Thalidomide was withdrawn from the market in the 1960s after it was linked to fetal limb shortening birth defects when it was used during pregnancy. Currently, thalidomide is being used to treat chronic multifocal osteomyelitis and chronic granulomatous disease (Martin-Nalda et al., 2016). Both are rare conditions but can occur in women of childbearing age. Thalidomide analog medications have been developed, which have lesser teratogenic effects and are used to treat psoriasis (Rosenberg & Meyerle, 2017). There are stringent educational requirements, warnings about risks in pregnancy, and mandatory contraception for both men and women who use thalidomide. It is possible that pregnancy could occur despite these measures.

Environmental Influences

Every individual is conceived with a unique genetic makeup called a genotype. The phenotype, or the person's ultimate physiological and psychological makeup, is determined during the postconceptual period until after birth. The expression of the genetic inheritance (i.e., actual physiological and psychological makeup of the person) is the result of complex gene–gene interactions and environmental influences upon genes that occur at the molecular level. Exposure by the mother to environmental toxicants either before or during pregnancy can precipitate gene–environment interactions that can alter these molecular interactions, especially if the exposure to the harmful substance occurs at critical periods of fetal development. Two critical periods when gene–environmental interactions can be most harmful are during organogenesis (when fetal organs are being formed) and during the fetal period when there is rapid growth of all systems. Spina bifida is an example of a gene–environment interaction. At conception, a fertilized egg might inherit the genes to have an intact neural tube. Neural tube defects occur when there is a lack of adequate folic acid at a critical stage of development while in utero. Exposure to teratogens, substances that are known to cause birth defects, during these times can result in birth defects or other adverse outcomes. Two pregnant women could be exposed to the same toxicants at the same point during pregnancy and could have infants with different outcomes. For example, two infants could inherit the genetic trait for sickle cell disease, yet when they are born they could have different expressions of the disease based upon other complex molecular interactions that happen within genes, which could be influenced by

the environment. It is now recognized that these factors continue to influence functional and developmental outcomes throughout the person's life (Singh, Miaskowski, Dhruva, Flowers, & Kober, 2018). The study of epigenetics is an evolving science that looks at factors such as genetic inheritance, imprinting, or nutritional factors that are hypothesized to mediate genetic interactions at the molecular level and that may one day provide more insight into these complex processes.

Environmental hazards are found in air, water, and food. Environmental changes have increased health risks related to increases in air pollution, water contamination, and the impact of extreme weather events (Nicholas & Breaky, 2017). Maternal exposure to air pollutants during weeks 16 to 18 of pregnancy has been associated with decreased fetal birth weight (Warren, Son, Pereira, Leaderer, & Bell, 2018). Exposure to increased particulate matter in the air during natural geologic events, such as dust storms and volcanic eruptions, has been associated with increases in PTB and LBW (Altindag, Baek, & Mocan, 2017; Balsa, Caffera, & Bloomfield, 2016). Poor or socially disadvantaged women, especially women of color, are more often exposed to environmental hazards because they tend to live in older sections of towns or work in areas with high exposure. Their homes are usually older, increasing the risk for lead paint exposure. Poor parts of towns are often located close to factories where pregnant women are exposed to incinerator emissions or other sources of air pollution. Air pollution exposure in the third trimester has been associated with preterm labor (Li, Guo, & Williams, 2016). Fine particulate air pollution such as that produced by passive exposure to cigarette smoke, organic pollutants, and motor vehicles can have detrimental effects on pregnancy outcome and early childhood health concerns related to lung development and fetal size (Janssen et al., 2017; Korten, Ramsey, & Latzin, 2017). Urban populations with intensified motor vehicle traffic are areas where prenatal and perinatal exposure to air pollution have informed findings of increased asthma and eczema in children (C. Lee et al., 2017; Alison Lee et al., 2018).

Suburban and rural populations are more likely to be exposed to agricultural pesticides or chemicals as they are more likely to garden and do yardwork. Another population at risk for pesticide and chemical exposure are those who work on farms or as migrant workers. Both maternal and paternal exposure to environmental toxins can be contributors to fetal risk and result in alterations in neurodevelopment and IQ (Gunier, Bradman, Harley, Kogut, & Eskenazi, 2017; Liu et al., 2016; Sagiv et al., 2018). The disadvantaged might be more likely to reside on or near land that once served as a hazardous waste dumpsite (Anetor, 2016). Birth outcomes can also be affected by the occurrence of natural or man-made disasters such as hurricanes, severe ice storms, earthquakes, chemical spills, or terrorism. The occurrence of a disaster can alter availability of safe food and water, or adequate prenatal care, which may increase risks for PTB. Increased maternal stress could cause mothers to use substances such as alcohol or tobacco for stress management. There have been some studies linking certain disasters with outcomes such as increased rates of spontaneous abortion, congenital anomalies, decreased fetal growth, and changes in maternal mental health status, although disasters do not seem to cause PTB.

Emerging Risk Factors

Sleep problems during pregnancy have been linked to an increased risk for FGR or LBW and assisted delivery (Plancoulaine et al., 2017). Preterm delivery was more common among women receiving the least amount of sleep prior to pregnancy who obtained lessening hours of sleep as pregnancy progressed. Sleep-disordered breathing is a term applied to multiple types of sleep disturbances. This term can mean anything from snoring to obstructive sleep apnea. Obstructive sleep apnea in pregnancy may be the consequence of comorbidities of pregnancy such as obesity, smoking, and race. Maternal obstructive sleep apnea is associated with increased frequency of preterm, SGA infants who require NICU admission (Felder, Baer, Rand, Jelliffe-Pawlowski, & Prather, 2017; Louis, 2018).

MATERNAL MEDICAL AND OBSTETRIC CONDITIONS

Diabetes, hypertension, and bleeding disorders are some of the most common maternal complications of pregnancy. These complications can lead to preterm delivery, perinatal death, or can influence fetal morbidity. WHO (2018c) has identified severe bleeding after childbirth, infections after childbirth, and hypertension as three of the major causes of maternal mortality worldwide. Recommendations for antenatal care include assessment for anemia, asymptomatic bacteriuria, and intimate partner violence (WHO, 2016b). The risk of maternal complications of pregnancy increases with advanced maternal age (AWHONN, n.d.; Fitzpatrick et al., 2016).

Diabetes

Women with known pregestational diabetes should seek preconceptual care prior to getting pregnant. The preconceptual visit should include a complete physical examination with evaluation of blood glucose levels, cardiovascular and renal health, gastrointestinal system, an eye examination to check for diabetic retinopathy, and evaluation of the presence of neuropathy. A team approach with a diabetes nurse educator and dietician can teach the woman how to implement the dietary and lifestyle changes needed for a healthy pregnancy. Oral hypoglycemic medication may be continued in pregnancy with monitoring of maternal glucose levels. Metformin can be used safely in the preconceptual period and during pregnancy for type 2 diabetics (Romero et al., 2017). Metformin in combination with glyburide during pregnancy reduced the need for insulin (Nachum et al., 2017). Ideally, the woman with diabetes should maintain euglycemia for several months prior to pregnancy, as hyperglycemia in early pregnancy has been associated with increased risk for pregnancy loss and serious congenital defects (Waters et al., 2016). During pregnancy, regulation of blood glucose is sometimes difficult since pregnancy creates a state of insulin resistance and insulin needs change with each trimester. Glycosylated hemoglobin (HbA1c) levels should be maintained to as close to normal range as possible during pregnancy, especially during the period of fetal organogenesis.

Adoption of the International Association of Diabetes and Pregnancy Study Groups (IADPSG) criteria has resulted in increasing the identification of gestational diabetes (Trujillo et al., 2015). Worldwide prevalence of gestational diabetes mellitus (GDM) is difficult to establish. Currently, research is being undertaken utilizing the IADPSG and WHO (2013) criteria to better assess and intervene with diverse populations (Hagiwara et al., 2018; Tan et al., 2017; Wong, Lin, & Russell, 2017). In the United States, there are ethnic variations in the prevalence of GDM, with Asian, Hispanic, and Native American women having higher rates than NHB and NHW women. Identification and treatment of women with gestational diabetes is the key to promoting positive neonatal outcomes. The most important principle of diabetes management for all pregnant women with diabetes is to maintain tight glycemic control. Poor glycemic control increases the risks for birth defects (i.e., cardiovascular, musculoskeletal, and central nervous system

anomalies), hypoglycemia, respiratory complications, and shoulder dystocia (Babović, Arandjelović, Plešinac, Kontic-Vučenić, & Radunović, 2018; Barquiel et al., 2016; Khambalia et al., 2017; Yamamoto, Kallas-Koeman, Butalia, Lodha, & Donovan, 2017).

Currently, pregnant women in the United States are screened for gestational diabetes following review of patient history, presence of clinical risk factors, and administration of a 50-g 1-hour oral glucose tolerance test (OGTT). If positive, a second step 100-g 3-hour OGTT follows. The American Diabetes Association (ADA) recommends a 75-g OGTT at 24 to 28 weeks with blood glucose measurement when fasting, and at 1 and 2 hours after blood glucose administration. The diagnosis of gestational diabetes is based upon results of the blood glucose screening which exceed predetermined laboratory values for the test. Current WHO (2013) recommendations follow the IADPSG guidelines.

Diabetes during pregnancy is frequently accompanied by maternal vascular changes that can compromise uteroplacental circulation; therefore, fetal nonstress testing is recommended in the last trimester. If early delivery is indicated, amniocentesis can be done to determine fetal lung maturity; however, results of the lecithin sphingomyelin (L/S) ratio are often inaccurate for infants of mothers with diabetes. Infants of diabetic mothers generally have macrosomia. These large babies have increased risks for birth injuries due to shoulder dystocia, including fractured clavicles or nerve palsies. Large infants are more likely to be delivered by cesarean section. Infants of diabetic mothers should be closely monitored for hypoglycemia in the immediate postbirth period and until feeding is well established.

Hypertension in Pregnancy

Approximately 6% to 8% of pregnancies are complicated by hypertensive disorders. The four identified categories of hypertension in pregnancy are: chronic hypertension, gestational hypertension, preeclampsia, and preeclampsia superimposed on chronic hypertension (Folk, 2018). Chronic hypertension exists when there is a history of hypertension prior to the pregnancy, or it can also be diagnosed during pregnancy for the first time. Some women with preexisting hypertension develop superimposed preeclampsia during their pregnancy (Nzelu, Dumitrascu-Biris, Nicolaides, & Kametas, 2018). Women with chronic hypertension who develop superimposed preeclampsia are at increased risk for fetal complications (Folk, 2018; Nzelu et al., 2018). Gestational hypertension is diagnosed during pregnancy and usually disappears within 12 weeks after delivery. Preeclampsia is a pregnancy-specific disease that usually occurs after 20 weeks of pregnancy. It is characterized by hypertension, thrombocytopenia, and signs of renal impairment (Nzelu et al., 2018). As the condition progressively worsens, maternal laboratory work indicates elevations in liver enzymes and low platelets. HELLP (hemolysis, elevated liver enzyme levels, and low platelet levels) syndrome occurs in about 20% of pregnancies complicated by preeclampsia. It is characterized by hemolysis, elevated liver enzymes, and low platelets. Approximately half of women with *HELLP* syndrome are preterm.

Hypertension in pregnancy causes vasoconstriction with subsequent poor maternal circulatory and placental perfusion. Decreased uteroplacental circulation compromises the fetus; therefore, it is more likely to be growth restricted, SGA, or at increased risk for stillbirth (Heider, 2017). Women with gestational hypertension are also at increased risk for abruptio placenta. Delivery is the definitive treatment and is generally recommended if the fetus is 34 weeks' gestation or more; however, it might not be appropriate if the fetus is immature (Sievert et al., 2017). Early delivery will be based upon stability of the mother and outcomes of fetal testing. A serious risk for the preeclamptic mother is the possibility of eclamptic seizures due to cerebral edema and central nervous system excitability or progression to the HELLP syndrome. Seizures increase the risk for a placental abruption. Therefore, if the mother's condition worsens, early delivery will be elected; however, the ability of the fetus to survive must be considered (Kuper, Sievert, Biggio, Tita, & Harper, 2017). Corticosteroid administration is advised and may be beneficial if the fetus is between 24 and 34 weeks of gestational age and if the mother has never had them (Travers et al., 2018). Patients with preeclampsia tend to have infants with lower gestational ages at delivery and lower birth weights than do patients with gestational hypertension alone (Kuper et al., 2017; Sievert et al., 2017). Women with severe gestational hypertension (defined as blood pressure >160/110) without proteinuria can quickly develop severe complications of preeclampsia such as thrombocytopenia and pulmonary edema effecting neonatal outcomes (Folk, 2018). The earlier that hypertensive disease occurs in pregnancy, the more likely it is that complications will develop reinforcing the need for early and consistent prenatal care (Sonek et al., 2018).

If preeclampsia worsens, the pregnant woman is admitted to the hospital for stabilization and delivery. If the woman has a seizure, oxygen should be provided during and immediately following the seizure and the fetus should be monitored for signs of distress. Magnesium sulfate is the drug of choice to prevent central nervous system excitability from cerebral edema. Infants rarely have harmful effects from in utero exposure to magnesium sulfate prior to delivery but should be monitored for signs of respiratory depression or hypotonia after birth.

Ethnic differences in the progression of hypertensive disorders in pregnancy have been noted. African American women were hospitalized earlier in the pregnancy for treatment of gestational hypertension. Their babies had lower gestational age and birth weight. African American women also had a higher incidence of abruptio placenta, stillbirths, and neonatal deaths than other ethnic groups despite starting prenatal care in the first trimester (Hoyert & Gregory, 2016; Martin et al., 2018).

Prelabor Rupture of Membranes

PROM is a cause of preterm delivery and can occur at any time during a pregnancy. Following rupture of membranes, the fetus is at increased risk for problems related to oligohydramnios, cord compression, chorioamnionitis, and abruptio placenta. Women with PROM may report that they are leaking fluid from the vagina or may have experienced a gush of fluid. Sterile speculum examination, nitrazine testing, and microscopic examination of fluid for ferning are methods to evaluate if membranes have ruptured. The decision of whether to deliver or to use expectant management must weigh the advantage of postponing delivery until gestational age increases against the risk for maternal or fetal sepsis. Current ACOG guidelines recommend expectant management when premature prelabor rupture of membranes (PPROM) occurs at less than 34 weeks if no maternal or fetal contraindications are present (Ehsanipoor, 2018). When PPROM occurs between 24 and 34 weeks' gestation, a single course of corticosteroids is recommended. PPROM prior to 32 weeks, which exhibits signs of possible delivery, should be treated with magnesium sulfate for the neuroprotective effect on the neonate. A course of antibiotics may also be considered to prevent infection. Signs of intrauterine infection include fever greater than 100.4°F (38.0°C), uterine tenderness, and maternal or fetal tachycardia. Results of the white blood cell count tests should be used judiciously as an indicator of infection, especially if steroids have been given within the previous 5 to 7 days.

Fetal outcomes after PPROM are related to gestational age at time of membrane rupture and whether the infant is delivered without complications of infection or asphyxia from cord compression or prolapse. Neonates born at 22 weeks' gestation after PPROM have lower survival rates. As gestational age increases from 23 to 32 weeks' gestation, outcomes after PPROM improve. Preterm PROM near term occurs between 32 and 36 weeks' gestation, and infants who are delivered at this time are more likely to survive if they do not have other complications (Stensvold et al., 2017). Sometimes in the absence of other indications, a wait and see approach might be taken where delivery is not expedited. If PROM occurs at earlier gestational ages, the risk for chorioamnionitis increases. At delivery, infants of women with chorioamnionitis tend to be of younger gestational age and to weigh less than infants of women who do not have chorioamnionitis. However, research has demonstrated less risk of neonatal sepsis with increased time interval between PPROM and delivery (Lorthe et al., 2017).

Maternal Infections

Infections are a major risk factor for maternal and fetal health during pregnancy. Women may be infected prior to pregnancy or acquire the infection during pregnancy. Maternal infections can be transmitted to the infant while in utero across the placenta, during the birth process, or even during the postpartum period. Fetal infections can cause congenital anomalies, LBW, respiratory illness after birth, or even death. Infectious agents include protozoal infections, helminthic infections, sexually transmitted infections (STIs), viruses, and bacterial organisms.

Three infectious diseases, HIV/AIDS, tuberculosis (TB), and malaria, are the leading causes of perinatal morbidity and mortality, especially in sub-Saharan Africa and Asia. Interactions between these diseases during pregnancy can increase maternal risk of contracting other infectious diseases or can potentiate the existing diseases, increasing morbidity and mortality. For example, malaria and TB infections can increase the risk of vertical transmission of HIV to the fetus. The presence of maternal HIV infection can decrease maternal immunity, lowering resistance to TB or malaria (Natureeba et al., 2017). TB-infected women are more at risk to contract malaria or HIV. Tragically, many of these deaths could be prevented through use of low-cost interventions to prevent vertical transmission of HIV, intermittent prophylactic therapy, use of insecticide-treated nets for malaria prevention, and infection control practices for TB (Natureeba et al., 2017). The most current WHO (2016b) recommendations for antenatal care include intermittent treatment for malaria prevention in endemic areas and HIV prophylaxis to women at high risk.

Vaccine-preventable infections kill more women and babies in low-income nations because basic immunization practices, such as tetanus or rubella vaccination, may be unavailable to them. Tetanus, a disease that can be easily prevented, still accounts for neonatal deaths in developing nations. Although WHO (2016b) recommendations include immunization, lack of knowledge regarding the disease and neonatal mortality prevent some pregnant women from receiving the vaccine (Shafiq et al., 2017). Tetanus develops in newborns due to unclean cord-handling practices, including instrumentation and use of traditional cord salves that can cause infection. Once infected, the infant loses the ability to suck within a few days of exposure and progresses through stiffness, seizures, and death (WHO, 2018b). Rubella in pregnancy can result in miscarriages, stillbirths, or severe defects in the surviving fetus. Congenital rubella syndrome persists in some countries where vaccination is not available or not a standard of care for pregnant women (Herini et al., 2017). Symptoms may include hearing impairment, congenital cataracts, microcephaly, and congenital heart defects.

An additional infectious, mosquito-borne illness has presented in rural, suburban, and urban areas of several countries. In 2015, the link between Zika virus (ZIKV) contracted during pregnancy and microcephaly was announced by the Ministry of Health in Brazil following examination of data regarding an increase in microcephaly occurrence in that country (De Carvalho, De Carvalho, Fugaça, Dóris, & Biscais, 2016). Human infection with ZIKV had already been seen in other subtropical and tropical islands and countries with the same outcomes. Since the recognition of the ZIKV in pregnancy as teratogenic, the virus has been identified as a cause of additional abnormalities such as brain malformation, eye abnormalities, and some central nervous system disorders (Fitzgerald, Boyle, & Honein, 2018). Unfortunately, many of those infected are asymptomatic or mistake the flu-like symptoms as a minor ailment. Testing is currently recommended for women who travel to known areas where the vector mosquito survives (Eppes et al., 2017); however, the virus can also be transmitted through intercourse and perinatally. Prevention measures advised include topical insect repellent sprays and long clothing (De Carvalho et al., 2016). Prevention of sexually transmitted ZIKV may be more challenging as the carrier would have to be identified and willing to use barrier methods of birth control (Santibañez et al., 2017).

SDG 3 focuses on combatting HIV/AIDS, malaria, TB, and other infectious diseases and on the prevention and treatment before and during pregnancy of infectious and noncommunicable diseases known to increase the risk of PTB (United Nations, 2015). Every pregnant woman must be screened for risk factors for infection. Early identification and treatment of women with infections will improve both maternal and neonatal outcomes.

Abruptio Placenta

Abruptio placenta, or premature separation of the placenta prior to delivery, is a leading cause of stillbirth and neonatal mortality. Placental separation is thought to be due to changes in placental vasculature, thrombosis, and reduced placental perfusion. A genetic basis for abruptio placenta has been speculated as the cause for these changes. Placental separation occurs in several ways. In marginal separation, the edges of the placenta separate and bright red bleeding is present. Occult or hidden abruptio placenta occurs when the edges of the placenta are intact but the central part of the placenta detaches from the uterus, allowing blood loss to accumulate behind the placenta without any outward signs of bleeding. Complete abruptio placenta occurs when the placenta totally detaches, a situation that is incompatible with fetal survival. There is a four to six times higher risk of premature delivery when there is a diagnosis of abruptio placenta. Premature delivery increases the risk for infant mortality. Risk of mortality due to abruptio placenta is higher than when abruptio placenta is not present (Downes, Shenassa, & Grantz, 2017). **Quality & Safety: Infants of mothers with abruptio placenta who survive must be closely monitored for signs of blood loss and shock.**

Risk factors for abruptio placenta include smoking, multiple pregnancy, and maternal age greater than 50. Increased risk in older women could be related to increased rates of chronic hypertensive disorders or aging of the uterine blood vessels. The risk of abruptio placenta increases with multiple pregnancy as the number of fetuses increases from singleton to triplet pregnancies. The risk of perinatal complications such as preterm delivery, intraventricular hemorrhage, and death increases in the presence of abruptio placenta (Chevallier et al., 2017).

POSTPARTUM RISK FACTORS

After birth, the leading causes of infant death are congenital anomalies, complications of prematurity and LBW, SIDS, and perinatal complications (Murphy et al., 2017). Congenital anomalies account for most neonatal deaths in the first month of life. Infants who are LBW are more likely to die from complications of prematurity (respiratory distress, infections, or anemia), maternal complications in pregnancy, or placenta/cord conditions. In addition to these leading causes of death, other risk factors such as maternal smoking or drug usage could affect the health of the neonate or cause injury. Providing information and anticipatory guidance to the parents to increase awareness of some of these factors might be enough to protect the infant and to promote positive outcomes.

Drugs Excreted in Maternal Milk

Maternal medications taken while lactating is a concern as medications may alter the milk supply or cross to the infant though the milk supply. While many medications have been demonstrated to be safe, there are still others that have not been reported in the literature. Psychotropic drugs pose a special concern since there has been an increase in their use. These drugs and their metabolites have long half-lives and are detectable in infant tissues and the developing brain. The long-term consequences of this exposure have not been thoroughly studied. As new drugs are placed on the market, their safety for the infant must be evaluated. Some untoward effects on the infant from use of prescribed maternal drugs include possible immune suppression, neutropenia, skin rash, central nervous system changes including irritability, restlessness, sleepiness, lethargy, or convulsions, and gastrointestinal effects such as feeding problems, vomiting, diarrhea, slow weight gain, blood in stool, jaundice, or dark urine. A comprehensive list of drugs, foods, and environmental agents that are excreted in human milk and that could be potentially harmful to neonates is available from the American Academy of Pediatrics (AAP).

The AAP recommendations include the use of the LactMed app provided by the National Institutes of Health (NIH, n.d.a), as a resource for current toxicology and information on medications of any kind. The app is free and downloadable to multiple devices and can be used by professionals as well as the general public. Medication information is updated monthly. When drugs are prescribed for lactating women, the following factors should be considered. When a medication is absolutely necessary, the baby's pediatrician and mother's physician should consult together to select the most appropriate drug for the mother, with minimal effects upon lactation and minimal transfer to the infant. Select the safest drug when there are several to choose from. Consider measuring the infant's blood concentration of the drug if there are potential risks from the drug for the infant. Advise the nursing mother to take the medication immediately after breastfeeding the infant or after a feeding that will be followed by an expected infant sleep period, to minimize infant drug exposure.

Sudden Unexpected Infant Death Syndrome

Sudden unexpected infant death syndrome (SUIDS) is a leading cause of death in infants in the postneonatal period in the United States as well as in other developed countries. SUIDS is broken down into SIDS, unexplained deaths, and accidental strangulation/suffocation in bed. Programs such as the AAP Back to Sleep campaign urged parents to place their infants on their backs instead of prone for sleeping. This change in recommended practice dramatically lowered infant deaths from SIDS. In the United States, the SIDS death rate declined between 1990 and 2015, from 130.3 to 39.4 per 100,000 live births (CDC, n.d.-d). Despite these advances, disparities in SIDS rates exist. Infants born to Black or American Indian or Alaskan Native mothers have the highest rates of death from SIDS at twice the rate of infants of White mothers. Infants of Hispanic and Asian or Pacific Islander mothers have the lowest rates (CDC, n.d.-d). Maternal risk factors include young, single mothers with a history of prenatal smoking or substance abuse. Infant mortality has decreased in the United States with improvements in prenatal care through Medicaid expansion and public health programs aimed at educating the consumer regarding early delivery, smoking, and safe sleep habits (Bhatt & Beck-Sagué, 2018; Hirai et al., 2018).

Over 70 causes of SIDS have been proposed. SIDS has been blamed on environmental factors such as soft bedding, overheating, entanglement in blankets, immunizations, tobacco smoke exposure, or bed sharing with parents or siblings, especially if a bed partner consumes alcohol (Spinelli, Collins-Priano, Van Den Heuvel, & Byard, 2017). Genetic factors have also been blamed for findings. Possible structural defects in the brain that control cardiac and respiratory function might explain the diminished arousal response in infants with SIDS that precedes death. Cardiac mutations resulting in long QT syndrome have been identified in 5% to 10% of SIDS victims (Moon, 2016). In reality, the cause of SIDS is probably multifactorial. The triple risk theory proposes that multiple complex factors (including genetics, prenatal risk factors, and environmental risk factors) make some babies more vulnerable to environmental triggering events and unable to respond to these events through usual homeostatic mechanisms (Moon, 2016; Spinelli et al., 2017). Preterm or LBW infants are at increased risk for SIDS (Ostfeld, Schwartz-Soicher, Reichman, Teitler, & Hegyi, 2017). Term infants with a history of apnea are also at risk. The peak age at death from SIDS is between 1 and 4 months with the majority of deaths occurring before 6 months of age (NIH, n.d.b). No definitive link between SIDS and immunizations has been established.

Sleeping in the prone position has been highly associated with SIDS and is one reason the Back to Sleep campaign has been so successful in reducing SIDS death rates. The rate of SIDS increases for preterm infants who are placed in the prone position. Many parents of premature infants place their infant to sleep on his or her stomach or side once at home. It is possible that new parents are learning the practice of putting their baby in either the prone position or sidelying position by watching caregivers in the NICU. Neonatal care practices that place preterm infants in the prone or sidelying positions are providing poor role models for parents. Every time parents see their baby in a prone or sidelying position while in the hospital, they are getting reinforcement of a poor practice about how to provide care to their baby at home. Infants become habituated to the prone position for sleeping, especially if they have had a prolonged hospitalization, which makes it more difficult for parents to change the baby's sleeping position to the back-lying position. Nurses need to educate parents and encourage them to share information with their childcare providers about placing the baby on the back to sleep (Dufer & Godfrey, 2017). Neonatal nurses must continue to educate each parent about the risk factors for SIDS and remind parents that the safest place for a baby is in its own crib in the parents' room for the first 6 months.

Child Abuse

Child abuse in infants is sometimes difficult to identify. Parents of an injured infant arrive for emergency treatment and seem severely distraught and worried about their child's injuries. They often

offer reasonable explanations for the injury that must be ruled out with medical tests. The victims, the babies, can't speak for themselves to describe what happened. New parents are subject to many stressors that could trigger child abuse such as lack of sleep, financial strain, and dealing with inconsolable infants. Healthcare providers have a legal and ethical duty to report cases of suspected child abuse to child protective services (Ho, Bettencourt, & Gross, 2017). Two forms of child abuse are discussed further: abusive head trauma (AHT), a subset of shaken baby syndrome (SBS), and Munchausen syndrome by proxy (MSBP).

Abusive Head Trauma/Shaken Baby Syndrome

AHT describes a serious form of head trauma caused by several mechanisms including abusive shaking of an infant causing a whiplash-type injury, blunt trauma, or a combination of both (Miller Ferguson et al., 2017). It is a public health issue and the leading cause of death due to child abuse. When the infant is shaken, the head flops back and forth causing rapid acceleration, deceleration, and/or rotational forces of the brain within the skull, causing stretching, shearing, and tearing of blood vessels of the brain. Several types of injuries occur with AHT/SBS. Intracranial injuries cause direct brain injury and damage to the axons. Shearing forces exerted on the veins that bridge from the dura to the brain cause intracranial bleeding. During shaking, there is a lack of oxygen to the brain that is further compounded by chemical processes that occur within the damaged cells. These injuries lead to swelling of the brain and increased intracranial pressure that further compromises brain oxygenation. Even 1 year after injury, children with AHT may have retinal hemorrhages, seizures, and signs of other injuries. External signs of injury to the face or head may be present as well as injuries or bruising of the long bones, thorax, or abdomen may occur as a result of firmly grasping the infant during the shaking episode (Miller-Ferguson et al., 2017).

AHT/SBS most often results when a parent becomes frustrated with an infant who is crying and inconsolable. Parents who are stressed with the parenting role, parents of premature infants, those who are sleep deprived, or parents who do not have support or help to care for their baby's needs may have low tolerance of infant crying. Poverty and stress are risk factors for abuse. In frustration they may pick up the baby and shake it to try to quiet the baby. Newborns are more susceptible to the forces of shaking and may sustain injury even if not shaken as roughly as an older child. Once parents shake their child and get a response, they might shake the child again over time, causing the infant to be injured repeatedly. Because the intracranial bleeding can be slow initially, the child might not manifest symptoms until 48 to 72 hours after the injury. Children who appear to have mild injury may not be brought to the hospital by parents immediately and be misdiagnosed by healthcare providers (Christian; AAP Committee on Child Abuse and Neglect, & AAP Section on Child Abuse and Neglect, 2015).

When parents seek medical attention for the infant, the history of events that preceded the infant's symptoms is often vague. Signs of AHT/SBS vary based on the extent of the injury and are sometimes subtle such as feeding difficulties, vomiting, lethargy, hypothermia, failure to thrive, and increased somnolence. More life-threatening signs include seizures, bulging fontanelle, apnea, coma, bradycardia, or complete cardiovascular collapse. Outcomes are poor for children who present with coma. Survivors of coma may have severe neuromotor impairment, visual impairment, and developmental delay. They may require shunting for hydrocephalus. Long-term occupational therapy, physical therapy, and speech therapy will be needed to help the children achieve their maximum potential. Approximately 20% of infants might die as a result of the shaking abuse. A small percentage of children will have no outward ill effects from the shaking. The remaining children have long-term sequelae, including ongoing neurological injuries and visual impairment.

New parents need to be taught not to shake their infant at any time. Prior to discharge, time should be spent exploring parents' concerns about taking a newborn home, their sources of support, and their coping strategies under stress. Teach parents about normal infant crying patterns and how to handle their stress or frustration due to prolonged periods of infant crying (Kelly et al., 2017). Referral for stress management techniques, anger management, and provision of a parenting hotline number might help prevent this devastating injury. Hospital-based education programs have been effective in reducing the occurrence of AHT/SBS in the high-risk neonatal populations (Lopez-Bushnell, Torrez, Robertson, Torrez, & Strickler, 2017).

Munchausen Syndrome by Proxy

MSBP is a rare form of child abuse where a parent, usually a mother, fabricates illness in a dependent child in order to draw attention to themselves as the parent of a sick child. Four criteria are required for a diagnosis: (a) a parent or guardian fabricates illness in the child, (b) the child is presented for medical care, (c) the perpetrator denies knowledge of the cause of the child's illness, and (d) the signs and symptoms subside if the child is separated from the perpetrator (Gehlawat, Gehlawat, Singh, & Gupta, 2015). The diagnosis of MSBP includes two diagnoses: one for the child and one for the parent. The parent response might range from fabricating illness of a child, exaggerating symptoms of the sick child, to actually inducing the symptoms in the child such as by attempts to suffocate or poison the child. Some of the most common types of fabrications include gastrointestinal (diarrhea), neurologic (seizures), infections (fevers), dermatologic (strange rashes), and cardiopulmonary (acute life-threatening events). Some children will die as a result of the parent's abuse or ministrations. Unwittingly, physicians or healthcare workers can be drawn into the situation attempting to help the child based upon the parent's descriptions of what is occurring. Healthcare professionals might prescribe unnecessary diagnostic tests or treatments for the child (Yates & Bass, 2017). Healthcare professionals need increased awareness of MSBP and should question cases where children are seen constantly for parental reported conditions not witnessed by anyone else or if siblings of the child have had similar hospitalizations or have died from SIDS or under suspicious circumstances. Cases where children who are not gaining weight begin to gain during hospitalization are also suspect. If the parent is approached and refuses to get psychological help, or if the child has been subjected to a major illness because of the parent, then the child may need to be placed into a protective environment. MSBP has long-term psychological implications for the child, including PTSD, behavioral problems, and depression (Yates & Bass, 2017).

PERINATAL CARE IN DEVELOPING NATIONS

Pregnant women in developing nations have many of the same risk factors for prematurity and LBW as women in the United States. Such as poor prepregnancy physical condition, inadequate spacing between pregnancies, inadequate nutrition, decreased weight gain during pregnancy, maternal anemia, and lack of access for perinatal care. They also have to contend with other risk factors not even seen in the United States such as diseases like malaria and lack of sanitation. Availability of safe clean water is becoming a global

problem. Poverty and lack of education about pregnancy health are sometimes compounded by lack of skilled care providers, lack of transportation to healthcare centers, problems of war, civil unrest, and low status of women (WHO, 2016b).

Decreasing worldwide maternal and neonatal mortality rates is a priority of the United Nations SDGs. Maternal mortality rates have declined 44% between 1990 and 2015 in response to global efforts toward achieving the Millennial Development Goals. Partnership programs have developed in many countries to improve access to birth control and prenatal care. Management of chronic diseases such as HIV and malaria, efforts to assure a skilled attendant at delivery, and use of evidence-based practices are beginning to make a positive difference (UNICEF, 2018). However, the numbers of maternal deaths are still too high; approximately 303,000 mothers died worldwide due to complications of pregnancy and childbirth in 2015. Almost 99% of these deaths occurred in developing countries, with the highest rates in Africa and South Asia (WHO, 2018c).

Globally, the neonatal mortality rate declined more slowly and fell from 37 per 1,000 births in 1990 to 19 per 1,000 births in 2016 (Hug et al., 2017). Neonatal mortality fell by 49% between 1990 and 2016 but still accounts for more than 46% of deaths in children younger than age 5 worldwide, representing an increase. The worldwide average is 19 neonatal deaths per 1,000 live births, ranging from 3 neonatal deaths per 1,000 live births for high-income countries to 27 neonatal deaths per 1,000 live births in low-income countries. Stillbirth rates globally average 19 stillbirths per 1,000 live births, with a range from 3 per 1,000 live births in high-income countries to 29 per 1,000 in low-income countries prior to 2014 (WHO, 2014). Improved prenatal care, having a skilled attendant at delivery, improved use of hygienic practices for clamping and care of the umbilical cord, and concerted efforts to provide basic resuscitation equipment and training in neonatal resuscitation have had good results in some countries, but much work still needs to be done (WHO, 2014).

Many neonates worldwide have died from preventable conditions. Some congenital anomalies could have been prevented with maternal folic acid supplementation. Many newborns die from birth asphyxia, which might have been prevented through use of timely neonatal resuscitation at delivery. Some deaths from prematurity might have been prevented with adequate prenatal care or a system of basic neonatal care for premature infants. Some deaths from infections could have been prevented with use of hygienic practices at birth, patient teaching about cord care, immunizations, maternal screening for communicable disease risks, or treatment for HIV during pregnancy. Keys to making changes include creating funding partnerships, improving infrastructure, professional education, and implementation of culturally appropriate evidence-based care.

Interventions to improve birth outcomes and decrease neonatal loss in developing nations have been instituted through efforts of WHO, UNICEF, USAIDS, and organizations of UN member nations. These perinatal programs can be tailored to meet the specific needs of each country. As stated by Ban Ki-Moon, United Nations Secretary General:

> To meet the Every Woman Every Child Vision and the Global Strategy for Women's, Children's, and Adolescent's health, we need innovative, evidence-based approaches to antenatal care. I welcome these guidelines, which aim to put women at the centre of care, enhancing their experience of pregnancy and ensuring that babies have the best possible start in life. (WHO, 2016a, p. iv)

Antenatal care is implemented on a local level not only for screening for possible problems but also to educate women about how to promote a healthy pregnancy. Optimal timing and spacing of pregnancy is another important part of prenatal care to promote mothers who are in the best physical condition prior to conception. Prevention and control of infection are also important during the prenatal period. Proper medical treatment of women who are infected with STIs or HIV/AIDS during pregnancy will increase the infant's chances of healthy survival.

Antenatal screening alone can't predict or prevent most problems during pregnancy or delivery; therefore, all pregnant women should be considered high risk and must have access to skilled birth attendants and timely emergency obstetric care. Nations with the highest rates of neonatal and maternal mortality are those that have the lowest number of births attended by a skilled birth attendant. In some countries, access to medical care is difficult due to living in remote village locations, a lack of basic transportation, or poor infrastructure, making it difficult to transport women or infants with problems to specialized centers. Sometimes the policies of developing nations interfere with the provision of safe obstetric care. The current WHO (2018d) recommendations for antenatal care stress the differences for expected care with diverse populations.

Basic training and equipment for infant resuscitation at birth will help prevent some of the poor birth outcomes related to birth asphyxia. Many facilities in developing nations are working with antiquated equipment as they attempt to provide care for neonates. Textbooks are often outdated or are not written in the native language of the healthcare provider. The AAP Neonatal Resuscitation Program (NRP) has been demonstrated to be an effective method to provide immediate resuscitative care to neonates. This program has been translated into at least 24 languages and has been taught in over 130 countries through formally organized courses through the AAP or by independent efforts of NRP instructors (AAP, n.d.). The Helping Babies Survive program is a suite of evidence-based infant resuscitation programs designed for settings where human or technology resources are limited. It is not designed to replace NRP but serves as an adjunct for training birth attendants in how to assess and stimulate breathing during the initial Golden Minute of life. Neonatal mortality is lower when the mother has received professional care during the antenatal period and during childbirth.

Postpartum care that includes parent teaching about infant care and family planning services to help prevent close intrapregnancy levels is included in the UN strategies addressing women's and children's health (UN, 2016). Strategies for successful breastfeeding, proper cord care, recognition of signs of illness, and promotion of psychosocial well-being are all skills that parents need to have in order to promote optimal newborn health. Women of childbearing age need to learn the importance of being in optimal physical condition prior to and during pregnancy. Family planning services will help women become empowered to make choices about when to have children and will help prevent unnecessary abortions.

SUMMARY

This chapter has presented an overview of some of the many prenatal, intrapartum, and postpartum risk factors that influence neonatal health, especially in relation to prematurity and LBW. The perinatal nurse must be aware of potential risk factors in order to screen pregnant women and provide counseling and support. The presence of risk factors can raise suspicion that a baby might have problems after delivery; however, many more babies, even in the presence of multiple risk factors, will be born healthy. Anticipation

of neonates at risk helps assure that adequate personnel and equipment are available at birth to manage problems should they occur. Patient education about modifiable risk factors and support for altering detrimental healthcare behaviors can help prevent some adverse neonatal outcomes.

Some inroads have been made to improve maternal and child health internationally. There are still many barriers for many nations, including creation of the infrastructure needed to support the WHO United Nations goals set forth in the SDG (UN, 2015). Recommendations and training of adequate healthcare professionals to provide care will take commitment and monetary resources of multiple nations. Some countries are beginning to see successes in reducing their maternal and infant mortality. A sustained worldwide effort is needed to continue to improve these outcomes.

CASE STUDY

Identification of the Problem. A 29-year-old woman arrives at the clinic reporting she had a positive home pregnancy test in the past week. Her last menstrual period (LMP) was 4 months ago. The nurse practitioner assesses the woman for potential antepartum risk factors during the first prenatal visit.

Assessment, History

- *Menstrual history:* Menarche at age 12. Reports her periods are regular every 30 days with duration of 4 to 5 days. LMP was 4 months ago on March 10.
- *Obstetric history:* G4T3P0A0L3—reports she had three previous pregnancies. The first pregnancy was a term vaginal delivery 12 years ago. The female infant weighed 3,570 g at birth and is in good health today. The second vaginal delivery 6 years later was a term male born at 40w 4d gestation weighing 3,830 g. He is now 5 years old and in good health. The third vaginal delivery was a term male infant at 40w 2d gestation and weighed 3,800 g. The child is now 3 years old and reported to be in good health. Estimated date of confinement is December 17.
- *Past gynecologic history:* Reports she uses no contraception because she does not believe in taking birth control pills. Reports having a history of multiple sexual partners, currently in monogamous relationship. Was treated for unspecified sexually transmitted infection (STI) 2 years ago at a state health department clinic. HIV status is negative. Reports blood type is O+.
- *Past medical history:* Reports she had acute idiopathic pancreatitis as a teenager but avoided any symptoms or "flare-ups" during her previous pregnancies by watching her diet. Reports she had mild hypertension in the last trimester of last pregnancy that was managed with decreasing her work hours.
- *Drug/substance abuse history:* Denies taking any prescription, over-the-counter, homeopathic, or street drugs. Has not taken prenatal vitamins. Smokes 10 to 12 cigarettes a day. Alcohol: consumes two to three beers a week. Denies alcohol use since she found out she was pregnant.
- *Family/social history:* Lives with husband who is father of baby. Denies familial history of genetic problems. Employed part-time as waitstaff in a casual dining restaurant. Reports husband yells at her a lot and gets angry easily. Reports they are getting along great now.

Physical Examination

- *Neurological:* alert, oriented; pupils dilated, equal and reactive to light and accommodation; DTRs 2+ bilaterally without clonus
- *Head and neck:* neck supple, thyroid examination unremarkable; denies headache, blurred vision, flashing lights in eyes, or scotoma
- *Cardiovascular:* heart rate regular without murmur; denies palpitations, chest pain
- *Respiratory:* lungs clear to auscultation; denies history of asthma, TB, or bronchitis; reports chronic smoker's cough; denies thick sputum
- *Abdomen/Gastrointestinal:* gravid abdomen, distended, fundal height 20 cm, uterine fundus at umbilicus; bowel sounds present, active; denies problems with constipation or diarrhea; reports appetite is fair, occasional nausea and vomiting
- *Genitourinary:* denies vaginal spotting or cramping; reports urinary frequency during the day; denies burning with urination
- *Extremities:* No edema noted in pretibial area. DTRs 2+
- *Other:* reports backache when standing for prolonged periods at work; reports breast tenderness, no colostrum noted

Diagnostic Tests

- Blood type: O+
- Hgb: 10.9; Hct: 34%
- HIV test: negative
- Vaginal cultures: negative
- 50 g 1 hour oral glucose test results: 130 mg/dL
- 100 g 3 hour glucose tolerance test (GTT) results:
  - Fasting: 130 mg/dL
  - 1 hour: 190 mg/dL
  - 2 hour: 155 mg/dL
  - 3 hour: 138 mg/dL

Working Nursing Diagnoses

- Increased risk for prematurity due to history of smoking.
- Increased risk for gestational diabetes due to previous pregnancy and medical history
- Increased risk for PIH due to previous history
- Increased risk for infection related to history of STIs
- Increased risk for injury due to anemia
- Increased risk for injury related to potential physical abuse from significant other
- Increased risk to fetus for FAS due to report of maternal drinking
- Increased risk for SGA infant due to maternal smoking
- Increased risk for LGA infant due to previous history

Development of Management Plan

1. Counsel regarding alcohol use in pregnancy, consider outpatient treatment
2. Provide contact information for emergency women's shelter
3. Teach danger signs during pregnancy and symptoms of PTL and when to notify practitioner
4. Encourage smoking cessation and provide resources

5. HIV testing, screen/treat for STIs
6. Obtain GTT at 24 weeks, follow blood glucose closely
7. Dietary counseling for iron, diabetic diet, limiting fats
8. Promote breastfeeding
9. Serial ultrasounds to monitor infant growth

■ **Implementation.** The patient and nurse discussed needed lifestyle modifications during pregnancy and developed a plan to support the patient counsel; refer to support group for smoking cessation. Mother agreed to attend smoking cessation group for pregnant women. Patient agreed to refrain from alcohol usage during pregnancy. HIV testing completed. Completed GTT at 28 weeks and was referred for nutritional counseling for GDM and sources of iron in diet. Daily iron supplementation provided. Fetal growth was monitored with serial ultrasounds. Patient instructed in how to monitor daily fetal kick counts at 34 weeks.

■ **Evaluation of Effectiveness.** Patient attended smoking cessation group and reported that she cut down her smoking while pregnant to two to three cigarettes a day. She also reported she refrained from use of alcohol during remainder of pregnancy and avoided second-hand smoke outside at the workplace. GTT was positive for GDM, but she was able to maintain control of blood glucose with diet and exercise. She also developed mild hypertension and 3+ proteinuria during the last weeks of pregnancy that was managed with bed rest in the last 2 weeks of pregnancy.

■ **Outcome.** Patient had labor induced at 38 weeks' gestation and delivered a 3,860-g girl. Her Apgar scores at 1 and 5 minutes were 8 and 9. Infant had no hypoglycemia after birth. No signs of FAS noted on admission physical examination. The mother decided to use an intrauterine device (IUD) for birth control following this delivery. Mother was discharged breastfeeding the infant and scheduled for follow-up postpartum visit and IUD insertion in 6 weeks.

EVIDENCE-BASED PRACTICE BOX

Adoption of the International Association of Diabetes and Pregnancy Study Groups (IADPSG) criteria has resulted in increasing the identification of gestational diabetes (Trujillo et al., 2015). Worldwide prevalence of gestational diabetes mellitus (GDM) is difficult to establish. Currently, research is being undertaken utilizing the IADPSG and WHO (2013) criteria to better assess and intervene with diverse populations (Hagiwara et al., 2018; Tan et al., 2017; Wong et al., 2017). In the United States, there are ethnic variations in prevalence of GDM, with Asian, Hispanic, and Native American women having higher rates than NHB and NHW women. Identification and treatment of women with gestational diabetes is the key to promoting positive neonatal outcomes.

Currently, pregnant women in the United States are screened for gestational diabetes following review of patient history, presence of clinical risk factors, and administration of a 50-g 1-hour oral glucose tolerance test (OGTT). If positive, a second step 100-g 3-hour OGTT follows. The ADA recommends a 75-g OGTT at 24 to 28 weeks with blood glucose measurement when fasting, and at 1 and 2 hours after blood glucose administration. The diagnosis of gestational diabetes is based upon results of the blood glucose screening which exceed predetermined laboratory values for the test.

Adverse outcomes for mother and infant when affected by GDM include risk for cesarean delivery, birth trauma or injuries, and hypoglycemia. Large for gestational age (LGA) is defined as greater than 90th percentile for weight adjusted for gender and gestational weeks at delivery. Prenatal care which includes maternal assessment for GDM and continued fetal surveillance for fetal size may improve outcomes.

Review of Studies

Diagnostic Recommendations and Criteria

The IADPSG, a collaboration formed in 1998, suggested revision of the methods and timing of prenatal screening for gestational diabetes in women. Kong, Lim, and Thompson (2015) conducted a retrospective analysis of patient records comparing the rate of diagnosis of GDM and maternal/fetal outcomes after implementation of IADPSG methods and criteria versus the Carpenter & Coustan (C&C) used previously. IADPSG recommendations include a fasting blood glucose and glycated hemoglobin (A1C) at the first prenatal appointment for those identified at risk for GDM. A second 75-g OGTT is administered at 24 to 28 weeks' gestation to women who did not previously test positive for possible overt diabetes (IADPSG Consensus Panel, 2010). After analysis, Kong et al. (2015) found that use of the IADPSG recommendations resulted in increased diagnosis of GDM but there was no significant maternal/fetal outcomes in either cohort.

Appropriateness of Recommendations Internationally

WHO currently suggests individual countries decide on the methods and criteria for diagnosing diabetes in pregnant women or GDM (WHO, 2016a). If a woman is considered at risk, a fasting specimen is taken at the first prenatal visit. This is followed by a 75-g OGTT between 24 and 28 weeks' gestation. Hagiwara et al. (2018) performed a retrospective review of records to determine if there was a difference in adverse outcomes in Japanese women diagnosed with early pregnancy versus those with mid-pregnancy diagnosis using the international criteria. Results of the study did not demonstrate any differences in the early and mid-pregnancy diagnostic groups. The study investigators determined that the IADPSG recommendations and criteria were not appropriate for Japanese women as there appeared to be no significant difference in outcomes.

A prospective study completed by Hosseini, Janghorbani, and Aminorroaya (2018) in Iran also found increased levels of patients diagnosed with GDM using the One-step test (IADPSG) guidelines over those identified using the Two-step test currently recommended by the ACOG. Women diagnosed by either method had similar pregnancy outcomes, which included

(*continued*)

EVIDENCE-BASED PRACTICE BOX (*continued*)

infants with macrosomia, development of gestational hypertension, and delivery by cesarean section.

Gestational Diabetes in the United States and Recommendations

There is a significant prevalence of GDM in the United States (Martin et al., 2018) with the highest rates among women of Asian race. Prepregnancy diabetes is highest among non-Hispanic Black women. The ACOG currently recommends a two-step approach to prenatal testing for diabetes in pregnancy and GDM. Women considered at risk include those with a previous history of GDM, medical indications, and obesity. Ideally, the woman with diabetes should maintain euglycemia for several months prior to pregnancy, as hyperglycemia in early pregnancy has been associated with increased risk for pregnancy loss and serious congenital defects (Waters et al., 2016). Current recommendations in the United States include blood sugar testing (50-g, 1-hour GTT) at the first prenatal visit if a woman has any risk factors for GDM. Testing is also done at 24 to 28 weeks by a 100-g, 3-hour OGTT. Follow-up for patients after diagnosis includes dietary consultation with nutrition assessment, blood sugar testing daily or more frequently if needed, weight assessments, and fetal assessment for size. If glycemic control is not achieved with improved nutrition measures, then insulin or oral hypoglycemic medications should be considered. Metformin, an oral hypoglycemic, has been used in pregnancy with some success, although caution is still recommended with administration in early pregnancy (Nachum et al., 2017; Vanlalhruaii et al., 2018). The ACOG considers metformin an option especially among women who may not have the desire or ability to self-administer insulin (Caughey & Turrentine, 2018). Glycemic control is an important step in preventing maternal and fetal/newborn complications.

Adverse Maternal, Fetal/Newborn Outcomes

Fetal macrosomia, newborn weight over 4,000 or 4,500 g, is a possible outcome of poor glycemic control in pregnancy (Barth & American College of Obstetricians and Gynecologists, 2016). LGA are those infants over the 90th percentile for gestational age. Assessment during pregnancy of fetal size by measurement and/or ultrasound is not always accurate but has been used to estimate fetal size. Predicted LGA is not considered a reason for induction of labor but may occur in practice. Maternal complications from delivering an LGA infant include perineal trauma and hemorrhage. Poor glycemic control increases the risks for birth defects (i.e., cardiovascular, musculoskeletal, and central nervous system anomalies), hypoglycemia, respiratory complications, and shoulder dystocia (Babović, Arandjelović, Plešinac, Kontić-Vučinić, & Radunović, 2018; Barquiel et al., 2016; Khambalia, Algert, Bowen, Collie, & Roberts, 2017; Yamamoto, Kallas-Koeman, Butalia, Lodha, & Donovan, 2017).

PARENT VOICES

Ali Dunn

After 3.5 years of infertility and multiple rounds of IVF, finding out I was pregnant was a surprise. Finding out I was expecting twins was shocking, even though I was well aware that the incidence of multiples increases with fertility treatments. Having a high-risk pregnancy due to twins can create additional stress and anxiety. Additional monitoring, appointments with specialists, and careful assessment of the risks involved can take a very natural experience and make it quite medical. Personally, my twin pregnancy started and ended with extreme medical intervention. While it was necessary and lifesaving, it also left me feeling disappointed that my pregnancy experience and birth plans were left unrealized.

Keira Sorrells

Because we did fertility treatments and I was being monitored closely, we knew at our 6-week ultrasound that we were expecting multiples. We were told very quickly that triplets had (at the time) an 85% chance of a successful outcome, meaning little or no NICU time. Our goal was 32 to 34 weeks with the understanding being that they may need a little bit of oxygen, a little help learning how to suck, and a little time to grow. There was very little information shared on the possibility of our babies being born far earlier than 32 weeks. When I was admitted with preeclampsia at 25 weeks, I was totally unprepared, terrified, and sure none of my daughters would survive delivery. I had never seen the inside of the NICU nor had I ever laid eyes on a baby that weighed just 1 lb 4 oz and still had her eyes fused shut. The shock of seeing my three girls as three fetuses outside the womb is something I will not soon forget.

CHAPTER 3

Resuscitation and Stabilization of the Newborn and Infant

Gail A. Bagwell

INTRODUCTION

The vulnerable and sick infant requires the healthcare professional to quickly assess and take action when signs of cardiac or respiratory depression are present. This chapter begins with a discussion of risk factors that predispose the newborn to cardiorespiratory depression followed by a description of the actions to be taken to avoid this depression or to alleviate the symptoms and reverse a downward spiral and concludes with a short discussion on the stabilization of the ill neonate.

CAUSES OF CARDIORESPIRATORY DEPRESSION IN THE NEWBORN

The combined effects of numerous maternal, fetal, and intrauterine factors determine the condition of an infant at birth (some of these factors are listed in Table 3.1). Although some of these factors emerge only during labor and delivery (e.g., cord prolapse), most arise during gestation (e.g., placenta previa) or even before conception (e.g., maternal diabetes). Regardless of the site or time of origin, the influence of each of these problems can manifest as cardiorespiratory depression in the newborn.

To provide effective care, the nurse must be able not only to recognize potential risk factors but also to understand the ways in which they disrupt cardiorespiratory function. Ideally, the healthcare professional determines that cardiorespiratory depression may occur and is thoroughly prepared to intervene. Although many risk factors come into play, the underlying pathogenic processes can be divided into six major categories. The mnemonic TAMMSS can be used as a simple but effective means of remembering these etiologic groups:

T Trauma
A Asphyxia (intrauterine)
M Medication
M Malformation
S Sepsis
S Shock (hypovolemia)

Trauma

Traumatic injury to the central or peripheral nervous system of the newborn is an uncommon occurrence that can result in immediate

TABLE 3.1

CONDITIONS ASSOCIATED WITH ASPHYXIATION OF NEWBORNS

Source of Problem	Conditions
Maternal	Amnionitis; anemia; gestational or insulin-dependent diabetes; gestational hypertension; preeclampsia or eclampsia; chronic maternal hypertension; maternal cardiac, pulmonary, renal, thyroid, neurologic, or genetic disease; maternal deformities; hypotension; infection; polyhydramnios; oligohydramnios; drug therapy such as magnesium sulfate; adrenergic agonists; maternal substance abuse; no prenatal care; mother older than 35 years of age; previous fetal or neonatal death
Uterine	Preterm labor, prolonged labor, premature rupture of membranes, multiple gestation, breech or other abnormal fetal presentation, precipitous delivery, uterine tachysystole with fetal heart rate changes
Placental	Placenta previa, abruption placentae, any second or third trimester bleeding, other significant intrapartum bleeding, placental insufficiency, postterm gestation
Umbilical	Cord prolapse, entanglement, compression, or rupture
Fetal	Category 2 or 3 fetal heart rate patterns, cephalopelvic disproportion, size date discrepancy, macrosomia, prematurity, intrauterine growth retardation, congenital abnormalities, fetal anemia or isoimmunization, erythroblastosis fetalis, intrauterine infection, decreased fetal activity, narcotics administered to the mother within 4 hours of delivery, meconium-stained fluid
Iatrogenic	Mechanical (difficult forceps or vacuum delivery), emergency C-section, drugs–general anesthesia

or delayed respiratory depression. Because the skull is incompletely mineralized and has open sutures, it can undergo considerable distortion without fracture. The underlying membranes and vessels are, however, much less resilient and are easily stretched or torn (subgaleal hemorrhage) if overly compressed, particularly if the pressure is abruptly applied. Similarly, forced traction or torsion of the neck during delivery may damage the spinal cord or the phrenic nerve, with consequent paralysis of the diaphragm or brachial plexus nerve group. An unusually long and difficult delivery, multiple gestation, abnormal presentation (especially breech), cephalopelvic disproportion (secondary to macrosomia or a small or contracted pelvis), shoulder dystocia, or rapid extraction by forceps or vacuum extraction (as may be required for fetal distress) are frequently involved. Despite their generally low birth weight, premature infants also may be at risk because of the unusual compliance of their skulls.

Asphyxia (Intrauterine)

The most common cause of cardiorespiratory depression at birth is fetal hypoxia and asphyxia. Any condition that reduces oxygen delivery to the fetus may be the cause. Such conditions include maternal hypoxia (from hypoventilation and hyperventilation, respiratory or heart disease, anemia, postural hypotension), maternal vascular disease that results in placental insufficiency (from preexisting or pregnancy-induced diabetes, primary or pregnancy-induced hypertension), and accidents involving the umbilical cord (compression, entanglement, or prolapse). Postterm pregnancies also are at risk, perhaps because of placental aging and progressive placental insufficiency. An asphyxia episode occasionally may trigger the passage and aspiration of meconium in utero for term and postterm infants.

Medication

Pharmacologic agents given to the mother during labor and delivery may affect the fetus both directly and indirectly. Indirectly, these agents may cause maternal hypoventilation and hypotension or adversely affect placental perfusion. Hypnotic, analgesic, or anesthetic drugs may depress maternal respirations, resulting in reduced oxygen intake and delivery to the tissues and organs, including the uterus and placenta. Anesthetic agents, because of their effect on the sympathetic nervous system, may also cause peripheral vasodilation, diminished cardiac output, and hypotension with decreased placental perfusion. Narcotic analgesics, which rapidly cross the placenta, may directly depress the neonatal respiratory drive. Oxytocin (Pitocin), on the other hand, may cause uterine hyperstimulation and shorten placental perfusion time. Each of these conditions places the fetus at greater risk of fetal hypoxia and asphyxia. In addition, prescription and nonprescription medications, herbs, and essential oils that the mother may take prior to delivery may also affect the fetus. Many street drugs, especially opiate derivatives, are known to cause infants to deliver prematurely, to be small for gestational age, to have congenital anomalies as well as cause infants to have respiratory depression on delivery.

Malformation

Infants may have any of a vast array of congenital anomalies, but the ones that cause the most problems during the first few minutes of life are those associated with facial or upper airway deformities and conditions that lead to pulmonary hypoplasia. Many of these conditions can be diagnosed through antenatal ultrasonographic examinations and other screening techniques, but suspicion also should be raised if oligohydramnios or polyhydramnios is reported.

Oligohydramnios is seen with prolonged rupture or leakage of membranes and neonates with renal agenesis or dysplasia or urethral obstruction. If fluid is lost or diminished, the developing fetal structures may be compressed, leading to characteristic Potter facies (including micrognathia) or pulmonary hypoplasia. Polyhydramnios is seen in infants with impaired swallowing ability (as in anencephaly, neuromuscular disorders), in those with real or functional obstruction high in the gastrointestinal tract (as with esophageal atresia), and in those with profuse leakage of cerebrospinal fluid (as in neural tube defects), which contributes to the volume of amniotic fluid. Polyhydramnios is also noted with diaphragmatic hernia and hydrops fetalis.

Sepsis

The fetus may acquire bacterial or viral agents from infected amniotic fluid, from maternal blood crossing the placenta, or from direct contact on passage through the birth canal. An infant is especially susceptible to infection if born prematurely (because these infants are relatively immunocompromised) or if born to a mother who had a premature rupture of membranes or a history of infection or chorioamnionitis. If infection is acquired in utero, the lungs tend to be heavily involved, and the alveoli may be filled with exudate. The infant may be apneic at birth, may be slow to establish a spontaneous and regular breathing pattern, or may show frank signs of respiratory distress.

Shock (Hypovolemia)

Most of the blood lost during delivery is from the maternal side of the placenta; therefore, it is of no consequence to the newborn. Blood loss from the fetal side of the placenta as a result of abruptio placenta or placenta previa can, however, lead to acute hypovolemia and cardiovascular collapse. Normally the umbilical cord is unusually strong, but ruptures are possible if cord tension increases suddenly, as in a precipitous delivery, or if the vessels are superficially implanted in the placenta (velamentous insertions). In rare cases acute hypovolemia may occur without frank hemorrhage. With severe cord compression, for example, blood flow to the fetus is impeded. The umbilical arteries, however, are much more resistant to compression and continue to pump blood back to the placenta. In this case, the effects of hypovolemia and asphyxia may be superimposed. Infants with chronic blood loss (as in fetal–maternal hemorrhage or twin-to-twin transfusions) are generally asymptomatic immediately after delivery.

PREPARATION FOR DELIVERY

While the majority of deliveries will result in a healthy neonate where delayed cord clamping can occur and then the infant can go immediately to the mother's chest for skin to skin care, healthcare professionals must always be prepared for a problem to arise. The general consensus is that approximately 10% of all births will require some assistance to begin breathing at birth and only 1% require compressions and medications.

Quality and Safety: The success of resuscitative efforts depends on multiple factors: (a) anticipation of the need, (b) the presence of trained personnel, (c) ready availability of necessary equipment and supplies, and (d) strong communication and teamwork. The most competent personnel and the finest equipment are useless if they are not present in the delivery room. Frantic calls for assistance or a scavenger hunt for equipment

should never occur; they needlessly delay intervention and can compromise the patient's outcome.

The antepartum and intrapartum history of each pregnant woman must be carefully reviewed to identify those at risk of delivering a depressed infant. Especially worrisome is a fetus that clinically demonstrates the effects of asphyxia (i.e., an indeterminate/abnormal fetal heart rate pattern, particularly bradycardia and persistently minimal or loss of fetal heart rate variability; acidosis, as determined by fetal scalp blood sampling; or meconium-stained amniotic fluid).

Personnel

Although most risk factors can be identified at some time during the pregnancy, many may not become apparent until birth. Delivery through meconium-stained amniotic fluid and unexpected diaphragmatic hernia are just two cases in point. Consequently, at least one person competent in neonatal resuscitation should be present at every delivery. In addition, each institution that delivers babies needs to have a plan in place on how to mobilize a full neonatal resuscitation team in an emergency such as the delivery of a depressed newborn (Weiner, 2016; Wyckoff et al., 2015).

When a team is required, the role each member is to play in the resuscitative effort should be predetermined, including the head of the team. The head of the team, who has a complete set of resuscitation skills, will be the one to position the baby, open the airway and intubate the trachea if necessary, and evaluate and direct the resuscitation efforts. A second person will assist with positioning, suctioning, and drying, as well as giving oxygen and positive pressure ventilation (PPV). A third person is responsible for monitoring the heart rate and for initiating chest compressions, if needed. If intravenous (IV) medications are required, two additional individuals are needed, one to catheterize the umbilical vein and administer the drugs and the other to pass equipment and prepare the medications. The person who passes the equipment and prepares the medications may also be responsible for documenting the resuscitation process, but a sixth person is preferable to do this because minute-to-minute notations must be made. The individual delivering the baby is not considered part of this resuscitative team, as his or her main concern is the mother.

Quality and Safety: **All team members should be trained in neonatal resuscitation via an evidence-based program such as the American Academy of Pediatrics (AAP) Neonatal Resuscitation Program (NRP) for high-resource areas or in-patient facilities or Helping Babies Breathe (HBB) for low-resource areas or rural community settings.** Both the programs emphasize the importance of strong communication skills of team members for the team to be effective and provide the highest level of care possible.

Equipment and Supplies

A newly born infant is predisposed to heat loss (particularly evaporative and radiant losses), and, if unprotected, can quickly become cold stressed. The consequences of such stress include hypoxemia, metabolic acidosis, and rapid depletion of glycogen stores with hypoglycemia. All are conditions that may exacerbate asphyxia and thus complicate resuscitation. Clearly, measures to prevent hypothermia must be part of any resuscitative effort. The delivery room should be kept warm, and the radiant bed should be preheated, if possible. Prewarming of linens, towels, and caps or other head coverings is also helpful.

For a premature baby of less than 32 weeks' gestation, the use of a food-grade polyethylene bag or wrap up to the baby's neck, without drying, in addition to a warm cap will reduce convective and evaporative heat loss. The use of the polyethylene bag or wrap will also help maintain the infant's body temperature in the delivery room as well as decrease hypernatremia at 24 to 48 hours of life due to transepidermal water loss. In addition, it has been found that a delivery room of at least 26°C assists with maintaining a premature infant's (<32 weeks' gestation) body temperature in combination with the use of a polyethylene bag or wrap. Because of this finding, all delivery room temperatures should be at least 26°C or 78.8°F when delivering a baby less than 32 weeks' gestation. Other interventions for preventing heat loss in infants less than 32 weeks' gestation are the use of a prewarmed hat and a thermal mattress (Perlman et al., 2015; Weiner, 2016; Wyckoff et al., 2015).

Possible exposure to blood and body fluids is of particular concern in the delivery room. Gloves, gowns, masks, and protective eyewear should be worn in the delivery room as procedures are likely to generate droplets or splashes of blood or other body fluids.

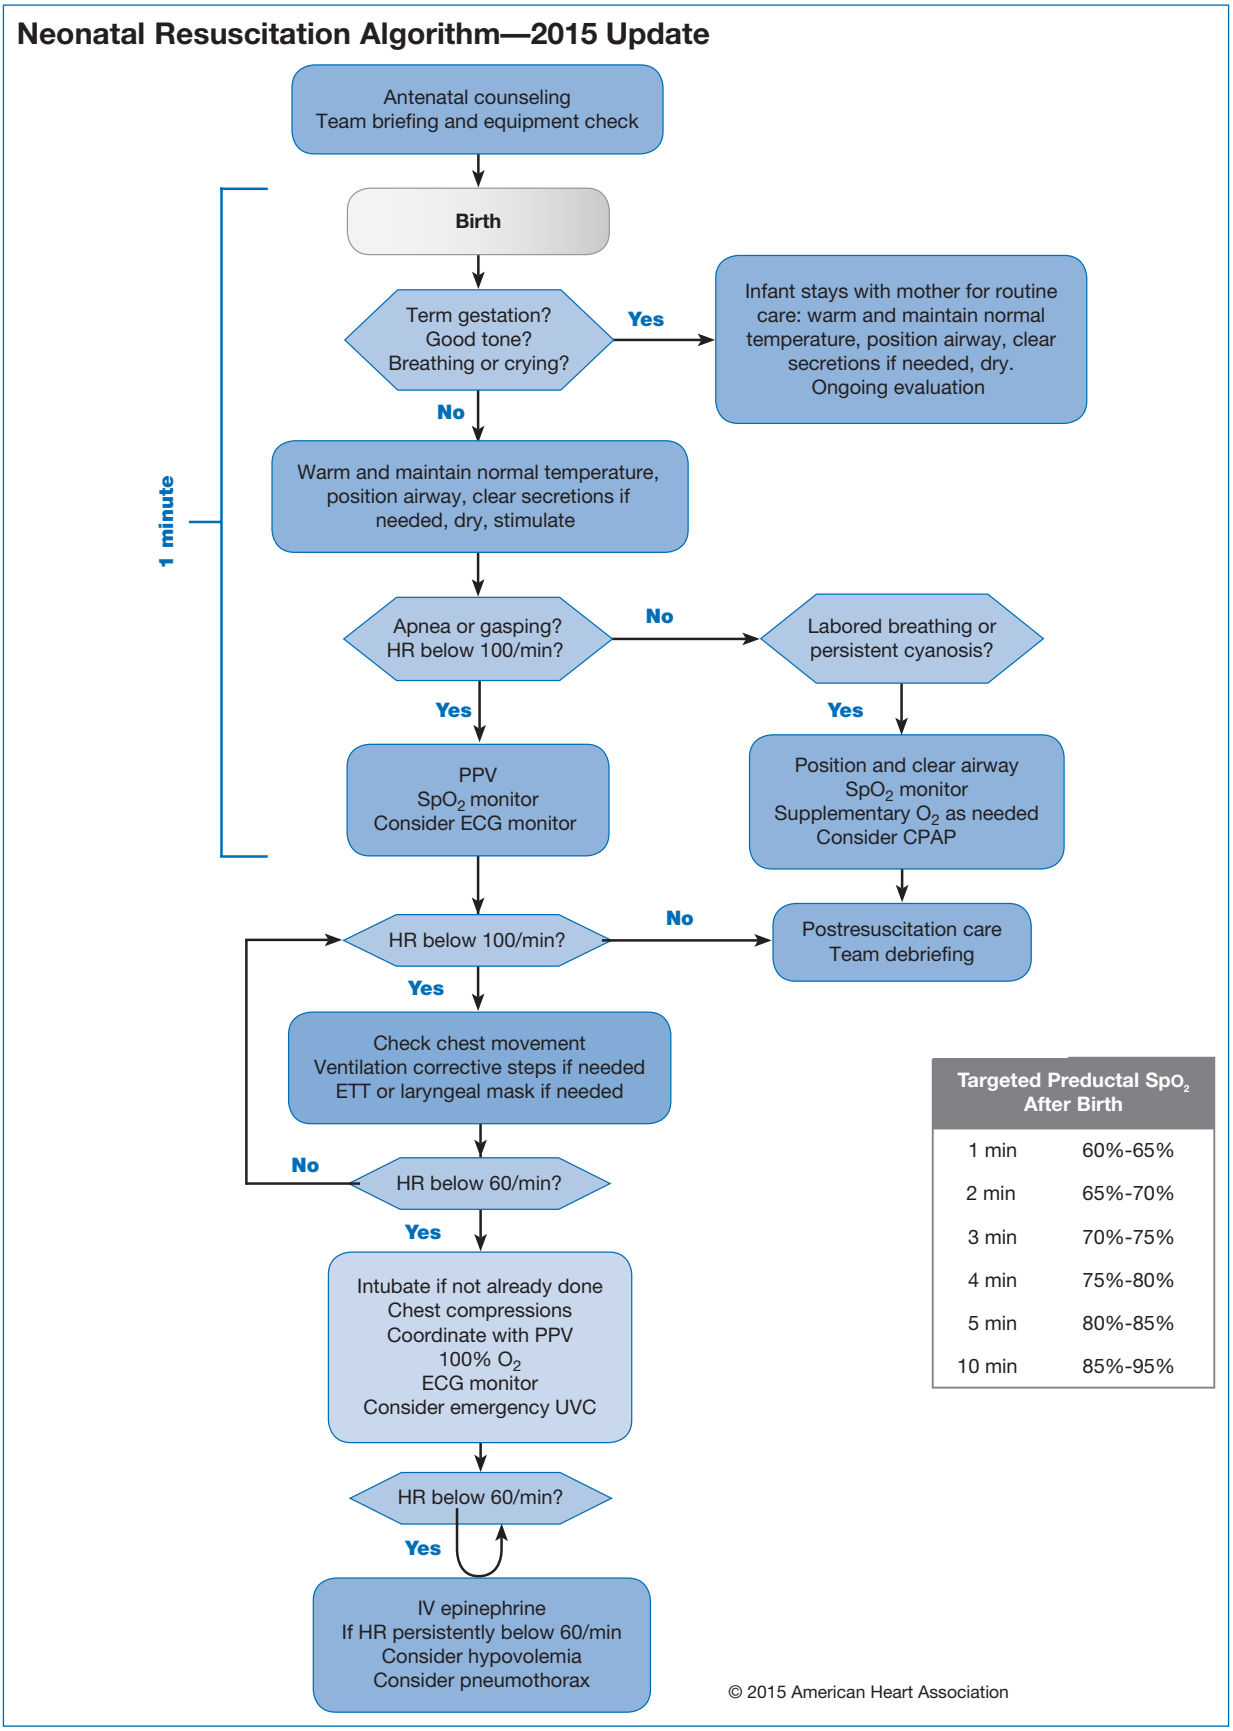
The additional equipment and supplies needed to carry out a full resuscitation (Box 3.1) should be checked as part of the daily routine. Small supplies should be organized according to frequency of use and may be displayed on a wall board, kept in the radiant warmer (if there is sufficient drawer space), or stored in a cart or specially designed tackle box. Breakaway security clips may be used to safeguard materials when they are not in use, but foolproof or locking closures that require a key or a code are not appropriate in delivery rooms, birthing rooms, or nurseries. A bedside table or flat surface (other than the bed) should be within reach to provide space for catheter trays and medication preparation.

As the delivery nears, the team should be assembled with the identified team leader. A pre-resuscitation briefing should occur, and all equipment and supplies should be double-checked to ensure they are in working order. Having an organized routine of checking the equipment will ensure that all equipment is present and in working order. Hospital infection control policies dictate how far in advance packaged supplies can be opened, connected to tubing, and otherwise prepared. A backup or duplicate set of materials should be maintained in case of equipment failure, contamination, or multiple births. All items used should be restocked as soon as possible after the resuscitation.

Good Communication and Teamwork

Communication and teamwork are behavior skills that are essential to a successful neonatal resuscitation. The best clinicians working together in resuscitation will not work effectively together if they do not possess the skills to communicate and coordinate with each other. Learning to communicate and assign tasks is as essential to a neonatal resuscitation as the ability to perform bag/mask ventilation or cardiac compressions. Key behavioral skills that are needed during a resuscitation are know your environment, use all information available, anticipate and plan, clearly identify the team leader, communicate effectively, delegate the workload optimally, allocate time wisely, use resources wisely, call for additional help when needed, and maintain professional behavior (Weiner, 2016).

For the majority of healthcare professionals, these behavioral skills do not come naturally in an emergency situation, so practicing these skills along with technical skills, such as bag/mask ventilation, on a regular basis is important. While the AAP only requires a healthcare provider to take the NRP course every 2 years, studies have shown that skills, knowledge, and self-confidence were improved when training occurred at least every 6 months or more frequently in a simulation lab or at the bedside (Matterson et al., 2018; Mosley & Shaw, 2013; Surcouf, Chauvin,



Targeted Preductal SpO_2 After Birth

Box 3.1

EQUIPMENT AND SUPPLIES NEEDED FOR FULL RESUSCITATION

Thermoregulation

- Radiant warmer—preheated or other heat source
- Temperature probe and probe cover
- Warm towels, blankets, and cap
- Warm delivery room

Suction Equipment

- Bulb syringe
- Mechanical suction device set at 80–100 mmHg
- Suction tubing
- Suction catheters (5 or 6 French, 8 French, 10 French, 12 French, or 14 French)
- Meconium aspirator
- 8 French feeding tube and 20-mL syringe

Bag and Mask Equipment

- Device for delivering positive pressure ventilation, capable of delivering 90%–100% oxygen
- Face masks, newborn and premature sizes (cushioned rim masks preferred)
- Oxygen and compressed air source
- Oxygen blender set to 21% (21%–30% for infants <35 weeks' gestation)
- Flowmeter (flow rate up to 10 L/minute) and oxygen tubing to provide free-flow oxygen
- Pulse oximeter with sensor
- O_2 saturation table

Intubation Equipment

- Laryngoscope with straight blades, No. 0 (preterm) and No. 1 (term)
- Extra bulbs and batteries for laryngoscope
- ET tubes—2.5, 3.0, 3.5, and 4.0 mm internal diameter
- Stylet (optional)
- Scissors
- Tape or securing device for ET tube
- Tape measure or ET tube depth table
- CO_2 detector or capnograph
- Laryngeal mask airway—size 1.0 and 5 mL syringe

Medications

- Epinephrine 1:10,000 (0.1 mg/mL)
- Normal saline for volume expansion and flushes
- 10% Dextrose (optional)
- Syringes—1, 3, 5, 20, and 60 mL sizes

Umbilical Vessel Catheterization Supplies

- Sterile gloves
- Scalpel or scissors
- Antiseptic prep solution
- Umbilical tape
- Umbilical catheters—3.5, 5 French
- Three-way stopcock
- Syringes—1, 3, 5, 10, 20, 50 mL
- Needles—25, 21, 18 gauges—or puncture device for needleless system

(*continued*)

Box 3.1 (*continued*)

Miscellaneous

- Gloves and appropriate personal protection
- Firm, padded resuscitation surface
- Clock with second hand (timer optional)
- Stethoscope (neonatal head preferred)
- Tape, ½ or ¾ inch
- Cardiac monitor and electrodes
- Oropharyngeal airways—0, 00, 000 sizes or 30, 40, and 50 mm lengths

For Very Preterm Babies

- Size 00 laryngoscope blade (optional)
- Reclosable, food-grade plastic bag (1-gallon size) or plastic wrap
- Chemically activated warming pad
- Delivery room temperature increased to 78°F–82°F
- Transport incubator to maintain baby's temperature during move to the nursery

Source: Adapted from Weiner, G. M. (Ed.). (2016). *Textbook of neonatal resuscitation* (7th ed.). Elk Grove, IL: American Academy of Pediatrics, and American Heart Association.

Ferry, Yang, & Barkemeyer, 2013). Simulation-based training on a regular basis should be done at all facilities to help healthcare providers maintain their cognitive, technical, and behavioral skills.

GENERAL CONSIDERATIONS

The two goals of resuscitation are (1) to remove or ameliorate the underlying cause of asphyxia and (2) to reverse or correct the associated chain of events (hypoxia, hypercarbia, acidosis, bradycardia, and hypotension). To achieve these ends, resuscitation management should be centered on attempts to expand, ventilate, and oxygenate the lungs, with cardiac assistance provided as necessary. Intervention must, however, be specific to each infant in extent and form and must be determined by appropriate assessment.

The Apgar score provides a shorthand description of the neonate's condition at specific intervals after birth and may be useful as a rough prognostic indicator of long-term outcome; however, it does have limitations. Although it is a quantitative tool, the scoring often is subjectively or retrospectively applied. It often is poorly correlated with other indicators of well-being, such as cord pH. Its usefulness is suspect with extremely preterm infants, who may have poor respiratory drive and who may be relatively hyporeflexive and hypotonic because of immaturity rather than distress. Finally, waiting until the first Apgar score is assigned at 1 minute of age causes unnecessary delay in care. For these reasons, the Apgar score should not be used to determine the need for or course of resuscitation, but it may have a role in the determination of the continuation of resuscitation (Perlman et al., 2015; Weiner, 2016).

Delayed cord clamping for greater than 30 seconds in vigorous term and preterm newborns that have an intact placental circulation has been shown to be advantageous to the newborn. Preterm newborns who had delayed cord clamping for 30 to 60 seconds had higher blood pressure, higher blood volume, decreased need for blood transfusion, and decreased incidence of intraventricular hemorrhages (IVH) and necrotizing enterocolitis (AAP, 2017; ACOG, 2017). For the term neonate, the advantages are less incidence of iron-deficiency anemia, although it may increase the amount and severity of jaundice (AAP, 2017; ACOG, 2017). The determination of whether delayed cord clamping should occur in the delivery room should be discussed between the obstetrical and neonatal providers prior to the delivery of the infant. The condition of the neonate at birth will determine if delayed cord clamping can occur. More information on delayed cord clamping is discussed in Chapter 13, Hematologic System.

As soon as the need for resuscitation is determined, the initiation of resuscitation is based on two signs: respirations and heart rate. Heart rate is the most sensitive indicator of resuscitation efforts. In the review of literature it was found that the use of a 3-lead electrocardiography (ECG) was more accurate than auscultation, palpation of the umbilical cord, or the use of a pulse oximeter in determining the neonate's heart rate (Kamlin, O'Donnell, Everest, Davis, & Mosely, 2006; van Vonderen et al., 2015). The authors of the studies demonstrated that healthcare providers could not palpate the umbilical cord accurately or that they underestimated the heart rate when auscultating the heart with a stethoscope. In addition, the 3-lead ECG was quicker and more reliable than the pulse oximeter (Dawson et al., 2013; Katheria, Rich, & Finer, 2012; Mizumoto et al., 2012; van Vonderen et al., 2015).

As the resuscitation progresses, oxygenation is added to the signs that are assessed to determine the effectiveness of the resuscitation. Visual assessment of cyanosis is not a reliable method for judging a neonate's color or oxygen saturation in the delivery room and should not be used. In addition, with studies demonstrating that hyperoxia is as detrimental as hypoxia at the cellular and functional levels, the most accurate way of determining a neonate's oxygen saturation is to use a pulse oximeter in the delivery room (Weiner, 2016). When placing a pulse oximeter, place it on the neonate's right hand or wrist, as preductal values are higher than postductal values. Always place the probe on the neonate prior to connecting the probe to the machine to produce quicker and more reliable values.

As soon as the infant has been positioned under a radiant warmer, thoroughly dried, airway cleared if necessary and stimulated, the assessment of these three signs is to occur at 30-second intervals until compressions began, at which time assessment will

occur in 60 second intervals and interventions are carried out as needed. The basics of neonatal resuscitation are as easy as ABCD: *airway, breathing, circulation, and drugs*. These are the critical elements of any resuscitative effort.

Airway Control

Positioning. Airway control is a fundamental prerequisite for effective oxygenation and ventilation. To achieve this, the infant should be placed in a flat supine position unless there is spinal deformity; then the neonate would be placed in a side-lying position. The practice of placing the infant in a slight head-down tilt (Trendelenburg position) has been abandoned. This maneuver historically was used under the presumption that fluids from the lower extremities would be redistributed to the intrathoracic compartment. Studies with healthy adults in the Trendelenburg position have demonstrated improvement, albeit transient (lasting <10 minutes), in the stroke volume of the heart, but they have also indicated that a tilt as slight as 10° may cause blood to pool in the dependent cerebrovascular bed. Infants have only a limited ability to increase the stroke volume of their heart but are at greater risk than older children and adults for intraventricular hemorrhages secondary to rupture of the vulnerable micro-vessels of the germinal matrix; consequently, the potential benefit, if any, of the head-down tilt position is not believed to be worth the risk.

Once the infant is in the supine position, the neck is placed in a neutral or slightly extended *sniffing* position that aligns the posterior pharynx, larynx, and trachea (Weiner, 2016; Wyckoff et al., 2015). Compared with the adult tongue, an infant's tongue is relatively large in proportion to the mouth, and this slight extension moves the tongue and epiglottis away from the posterior pharyngeal wall and opens the airway. Care must, however, be taken to avoid full extension, which reduces the circumference of the airway and increases airway resistance. The reasonably safe extension posture appears to be no more than 15° to 30° from neutral. An oral airway should be placed if the tongue is unusually large (as in the Beckwith–Wiedemann syndrome) or if the chin is unusually small, causing posterior displacement of the tongue (as in the Pierre Robin sequence or the Potter association). Because newborns also have a relatively large head in comparison with the chest and tend naturally to fall into a flexed position, a shoulder roll made of a blanket or small towel may be used to raise the chest and align the cervical vertebrae. This roll may be particularly helpful if the occiput is exaggerated in size by molding, edema, or prematurity. If these procedures fail to provide an unobstructed airway, the placement of a laryngeal mask airway (LMA) or intubation is indicated (Weiner, 2016).

Suctioning. Routine suctioning of neonates on the perineum was a standard of care for all deliveries whether the amniotic fluid was clear or meconium stained. There was no evidence to support this practice so routine intrapartum oropharyngeal and nasopharyngeal suctioning for babies born with either clear or meconium-stained amniotic fluid was discontinued in 2011 as a recommendation for neonates at birth. After delivery, the infant is placed on the warming bed, quickly dried and positioned, and the airway is cleared by wiping the nose and mouth with a towel or by suctioning with a bulb syringe, or suction catheter if necessary. Increasing amounts of evidence show that suctioning, either bulb or mechanical, of the nasopharynx can create bradycardia during resuscitation; therefore, in 2010 the recommendations for suctioning (including bulb suction) immediately following birth changed. Suctioning is now reserved for only those neonates who have an obvious obstruction to spontaneous breathing or for those babies requiring PPV (Weiner, 2016). Because suctioning may cause inadvertent stimulation and gasping, the mouth should always be suctioned before the nose, *M* before *N*. Mechanical suction is often mentioned as an alternative to the bulb syringe, but it generally should not be used immediately after delivery. If infants are suctioned vigorously within the first 5 minutes of life, apnea or arrhythmias may follow. These symptoms probably are due to vagal stimulation, with reflex bradycardia. If a bulb syringe can be used instead of a suction catheter, this situation can usually be avoided. If mechanical suction is required, it should be applied for no longer than 5 seconds at a time with an 8 or 10 French suction catheter and with the equipment set to produce no more than 100 mmHg (136 cm H_2O) negative pressure (Weiner, 2016). To assist with the removal of a large amount of secretions from the mouth, turn the baby's head to the side, which will allow for the secretions to pool in the baby's cheek where they will be more easily removed.

If meconium is present in the amniotic fluid and the baby is vigorous (strong respiratory effort, good muscle tone, and heart rate >100 bpm), the baby should be treated as a non-meconium baby and remain with the mother doing skin-to-skin care, although gentle bulb suctioning of the baby's mouth and nose may be needed. If meconium is present and the baby is non-vigorous (depressed respirations, decreased muscle tone, and/or a heart rate below 100 bpm), proceed with the initial steps of resuscitation. Routine direct suctioning of the trachea before beginning the steps of resuscitation to decrease the chance of the baby aspirating the meconium is no longer recommended, as there is insufficient evidence to continue the practice (Perlman et al., 2015; Weiner, 2016; Wyckoff et al., 2015).

Tactile Stimulation. In a mildly depressed infant, drying and suctioning will usually be enough stimulation to induce effective respirations. If the respiratory rate and depth are nevertheless diminished, rubbing the back, trunk, or extremities as well as slapping or flicking the soles of the feet briefly will stimulate the infant to breathe. If the infant's reflexes are intact, 10 to 15 seconds of stimulation should be sufficient to elicit a response. Longer and more vigorous methods of stimulation should be avoided. Never spend more than 30 seconds to further stimulate an infant, as it is a waste of valuable time. Remember that the first 60 seconds after birth are referred to as the *Golden Minute*, so if clearing the airway and stimulating the neonate to breathe does not result in improvement after 60 seconds, PPV should be started (Weiner, 2016).

VENTILATION AND OXYGENATION

The most important and effective action in a neonatal resuscitation is ventilation of the compromised neonate. In fact, most infants who require resuscitation can be revived with ventilation and oxygen as needed, alone. Even when more aggressive therapies are required, they ultimately are undertaken to support oxygen delivery to the tissues, either by optimizing the airway (i.e., LMA or intubation) or by supporting the heart, which *pushes* oxygen to the periphery (i.e., chest compressions, medications).

Free-Flow Administration of Oxygen

Blow-by of 100% oxygen given at delivery was a common intervention in the past, but as stated earlier, increasing numbers of research studies show that increasing the compromised neonate's oxygen saturation more quickly than a normal healthy term neonate can be toxic and detrimental to not only a preterm infant, but to term infants as well. Studies have shown that giving a neonate 100% oxygen with PPV demonstrated no advantage in improvement when compared to neonates given PPV with room air (RA),

and actually delayed the time to the first breath and/or cry in term infants. Because of the increasing evidence from randomized controlled trials and meta-analyses of the studies demonstrating the detriments of hyperoxia, such as increased incidence of chronic lung disease and changes in the cerebral blood flow, especially in preterm babies, the use of RA at the beginning of resuscitation has been recommended since 2010. If there is no improvement, however, in heart rate or oxygenation by pulse oximetry despite adequate ventilation, increasing the amount of oxygen the neonate is receiving should be considered (Perlman et al., 2015; Weiner, 2016; Wyckoff et al., 2015). An infant who is breathing spontaneously but appears cyanotic or fails to maintain its SpO_2 within the range for the age of the infant, in room air (Table 3.2), needs supplemental oxygen. The oxygen can be provided directly from the end of the oxygen tube held in a cupped hand, by a funnel or face mask attached to the tubing, by a flow-inflating ventilation bag, by a T-piece resuscitator, or by the tail of a self-inflating bag. The blender attached to a flowmeter should be set to deliver to 10 L/minute, and the tubing, funnel, or mask should be held close to the infant's face to maximize the inhaled concentration of oxygen, but not so close that pressure would build up (Weiner, 2016).

The NRP guidelines changed in 2010 to reflect the use of room air initially on both free-flow ventilation and PPV for term infants and the use of room air to 30% oxygen for preterm infants. During resuscitation, start with room air (21%) at sea level for term infants, and then, using the preductal pulse oximeter as your guide, increase your oxygen concentration as necessary to maintain the appropriate O_2 saturation for the infant's age in minutes after birth. When determining the amount of oxygen to use in preterm infants, several studies were analyzed that looked at preterm infants younger than 35 weeks' gestation who were resuscitated using either room air or oxygen concentrations of 65% or greater. The studies showed no difference in long-term outcomes of bronchopulmonary dysplasia, retinopathy of prematurity, or intraventricular hemorrhages, but because of concerns of the effects of hyperoxia the recommendation is to start with a low range of oxygen, between room air and 30%, when resuscitating the preterm infants younger than 35 weeks' gestation (Weiner, 2016; Wyckoff et al., 2015).

Ventilation

If the infant fails to obtain a normal O_2 saturation with free-flow oxygen that has been increased to 100% or shows other signs of cardiorespiratory decompensation (apnea or gasping respirations or a heart rate below 100 bpm), PPV should be instituted. Begin PPV with a pressure of 30 to 40 cm H_2O to inflate the lungs of term neonates and 20 to 25 cm H_2O for preterm neonates. You may need to adjust the pressure as needed to achieve a rising heart rate, chest expansion, and audible breath sounds. Occasionally, it may become necessary to increase the positive pressure if no improvement occurs. Positive end expiratory pressure (PEEP) has been shown to achieve lung inflation quicker, remove the fetal lung fluid more rapidly, and prevent collapse of the alveoli between breaths. When using PEEP, set the PEEP to 5 cm as this has been found to be beneficial for both term and preterm infants requiring PPV. A ventilation rate of 40 to 60 breaths/minute should be used when ventilating the newborn (Perlman et al., 2015; Weiner, 2016).

Continuous Positive Airway Pressure

The use of continuous positive airway pressure (CPAP) in the delivery room for preterm babies is a common practice to assist them to breathe. Studies have been conducted to assess the outcomes for preterm neonates who had CPAP in the delivery room versus being intubated and given PPV. Several studies have demonstrated that spontaneously breathing infants younger than 30 weeks' gestation given CPAP had reduced rates of intubation, decreased length of time on mechanical ventilation, and possibly decreased incidence of death and development of BPD with no increase in the development of air leaks or IVHs (Dunn et al., 2011; Finer et al., 2010). Taking the results of these and other studies into consideration, the recommendation now is that spontaneously breathing preterm neonates with respiratory distress may be supported initially with CPAP rather than intubation and PPV (Weiner, 2016; Wyckoff et al., 2015).

Positive Pressure Devices

Three types of ventilation devices are available for neonatal use: the self-inflating bag, the flow-inflating bag, and the T-piece resuscitator. Whichever device is used, it should have the capability of delivering an oxygen concentration between 21% and 100%.

Self-inflating bags do not require gas flow but do require a reservoir to deliver high concentrations of oxygen. Traditionally, these bags have been fitted with a pressure-release *popoff* valve preset at 30 to 40 cm H_2O to prevent overinflation of the lungs and the risk of pneumothorax. Most self-inflating bags must be squeezed to move gas through the circuit and are not capable of passive, free-flow oxygen delivery.

Flow-inflating bags, on the other hand, are closed systems and therefore must be connected to a compressed gas source. Although self-inflating bags have the advantages of being both easy to operate and gas-flow independent, flow-inflating bags provide more reliable oxygen concentrations (particularly at low flow rates), better control of inspiratory times, and a greater range of peak inspiratory pressures, as well as free-flow oxygen.

T-piece resuscitator is a mechanical device that provides flow-controlled and pressure-limited breaths. Like the flow-inflating bag, it requires a compressed gas source to operate. The peak inspiratory pressure and end expiratory pressure are set manually with adjustable controls and the breaths are delivered manually when the operator alternately occludes and opens the aperture on the tubing attached to the mask, LMA, or endotracheal tube (ET).

All three of the devices can be used to provide ventilation by mask, LMA, or ET tube. Both types of ventilation bags can be

equipped with a manometer to monitor airway pressure as well. Though a manometer is important, visualization of the chest is equally, if not more, important. The degree of chest rise should simulate that seen when a normal newborn takes an easy breath. Excessive chest rise reflects overzealous delivery of tidal volume; if there is no movement, delivery is inadequate. A self-inflating or flow-inflating bag that has a regulatory valve with a minimum volume of 200 mL and a maximum volume of 750 mL should be used in resuscitating neonates. Term newborns require only 10 to 25 mL with each ventilation (4–6 mL/kg). A bag larger than this makes delivering the correct size breath difficult (Weiner, 2016).

Methods of Ventilation

For mask ventilation, a face mask is used to provide an oxygen-enriched *microenvironment*. An anatomically shaped mask with a cushioned rim is preferred for this purpose. Because masks are available in a variety of sizes, care must be taken to select one that covers the tip of the chin, the mouth, and the nose but not the eyes. Mask ventilation is a simple, noninvasive method of oxygen delivery that can be initiated without delay but the use of a mask has disadvantages. First, it may be difficult to obtain and maintain a good seal between the mask and the infant's face, particularly around the nose. Any leakage of air results in underventilation, which is aggravated if low lung compliance or high airway resistance is a factor. The seal should be *airtight* without excessive pressure applied. Second, the mask itself has a considerable amount of dead space. Consequently, a sufficient tidal volume must be delivered to prevent accumulation and rebreathing of carbon dioxide. Masks used for neonatal resuscitation ideally should have a dead space of less than 5 mL. Finally, prolonged bag and mask ventilation may produce gastric distention from swallowed gas, which in turn impedes diaphragmatic excursions and places the infant at risk of regurgitation and aspiration. This problem can be easily avoided, however, by inserting an 8 French orogastric tube if mask ventilation continues beyond several minutes. The gastric contents should be suctioned, and the tube left in place as a vent as long as mask ventilation is provided (Weiner, 2016).

Mask ventilation suffices for most infants, but if it proves ineffective (as evidenced by poor chest rise or continuing bradycardia) or if prolonged ventilation is expected, an LMA or ET tube should be inserted. Premature infants (certainly those weighing <1,000 g) who have diminished lung compliance, immature respiratory musculature, and decreased respiratory drive may also benefit from early intubation (Weiner, 2016).

Infants suspected of having a diaphragmatic hernia, hydrops fetalis, or certain airway or gastrointestinal abnormalities also benefit from immediate intubation. Uncuffed ET tubes with a uniform internal diameter should be used. The proper tube size and depth of insertion are determined by the infant's size, by weight, gestational age, and nasal–tragus length (NTL; Table 3.3). Most neonatal ET tubes have a set of black lines (vocal cord guide) near the tip of the tube that serve as a guide for insertion. When the vocal cords are situated between the two lines, the tube should be properly positioned with its tip in the mid-trachea. In the past the distance from the mid-trachea (tube tip) to the infant's upper lip was used to determine proper tube placement, but it was not always accurate. A more accurate method for determining the proper depth of an ET tube is to measure the NTL in a neonate and add 1 cm. This method has been shown to be more accurate in both term and preterm infants. Gestational age has also been shown to be accurate in determining insertion tube depth. (Weiner, 2016).

When the tube is properly situated, the centimeter marking on the side of the tube at the level of the upper lip should be at or near NTL. Tubes with metallic markers or fiber-optic illumination at the tip may make it possible to determine the depth of the tube transdermally (i.e., by observing a circle of light on the skin or by hearing an audible signal from a transcutaneous locator instrument), but these modifications do not allow differentiation between ET intubation and esophageal intubation, and therefore offer no advantage in an emergency situation. Similarly, capnometers used during resuscitation to measure end-tidal carbon dioxide, and thus confirm tube placement in the trachea, may be inaccurate when pulmonary blood flow is poor or absent (Weiner, 2016).

TABLE 3.3

ENDOTRACHEAL TUBE SIZE AND PLACEMENT

Infant's Weight (g)	Infant's Gestational Age (weeks)	Tube Size (mm)	Insertion Depth (cm)
500–600	23–24	2.5	5.5
700–800	25–26	2.5	6.0
900–1,000	27–29	2.5	6.5
1,100–1,400	30–32	3.0	7.0
1,500–1,800	33–34	3.0	7.5
1,900–2,400	35–37	3.5	8.0
2,500–3,100	38–40	3.5	8.5
3,200–4,200	41–43	3.5 or 4.0	9.0

Neonatal resuscitation. *Journal of the American Medical Association, 268*, 2276–2281. doi:10.1001/jama.268.16.2276; Weiner, G. M. (Ed.). (2016). *Textbook of neonatal resuscitation* (7th ed.). Elk Grove, IL: American Academy of Pediatrics and American Heart Association.

Correct placement is best demonstrated by the tried-and-true methods: improved clinical signs (heart rate, improving oxygenation, and activity), symmetric chest rise, bilateral and equal breath sounds (as auscultated in the axillae), and fogging of the tube on exhalation. Air should not be heard entering the stomach, and the abdomen should not be distended. If any doubts exist, tube placement can be checked by repeated laryngoscopy; the tube should be clearly seen passing through the glottic opening (Weiner, 2016).

ET intubation is the definitive technique for airway management and ventilation. Agility and accuracy in placement, however, require continual practice. Also, many hospital personnel are restricted by policy or statute from learning or using this skill. The LMA, which was approved by the U.S. Food and Drug Administration in 1991, has been enthusiastically accepted in some settings as an alternative that offers most of the advantages of intubation but does not require laryngoscopy for placement.

The LMA (Figure 3.2) is a relatively long tube with a bag connector and an inflation port at one end and an inflatable soft cuff at the other. The tube is blindly passed into the hypopharynx so that the tip of the cuff lodges in the esophageal opening. Inflated, the cuff creates a seal around the larynx. The tube then is connected

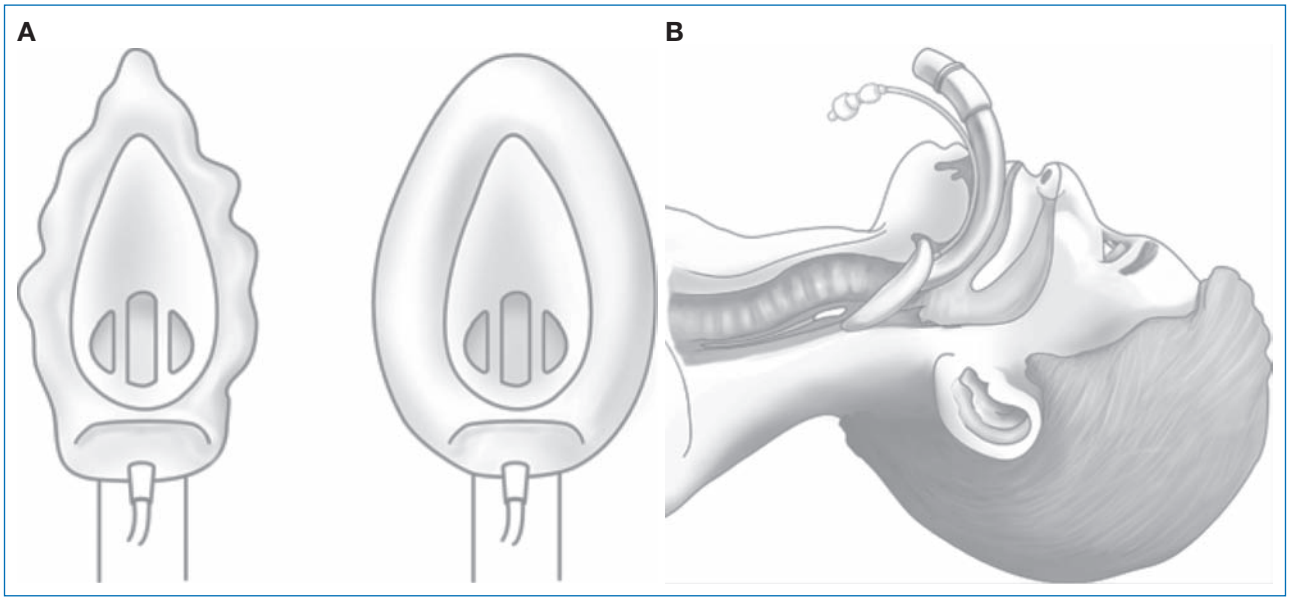

FIGURE 3.2 (A) LMA deflated for insertion (*left*) and with cuff inflated (*right*). (B) LMA in position with cuff inflated around laryngeal inlet.

LMA, laryngeal mask airway.

to a bag that delivers oxygen by ventilation through the central aperture of the laryngeal mask.

Since the LMA was approved for use by the Food and Drug Administration, research has been done to assess effectiveness in neonates. For ventilation purposes, the LMA is as effective as, but never more effective than, intubation. Placement of the LMA has been studied in neonates who are 34 weeks and older or who weigh more than 2,000 g, and case reports have shown LMAs to be an effective alternative when mask ventilation and intubation were unsuccessful. These studies also showed that effective ventilation was achieved quickly using an LMA (Trevisanuto et al., 2004; Zanardo, Simbi, Savio, Micaglio, & Trevisanuto, 2004; Zhu, Lin, Zhang, Ye, &Yu, 2011). An advantage of LMA is that it can be placed by an registered nurse (RN), respiratory therapist (RT), or physician, making providing an airway to neonates in distress easier in facilities where a physician might not be in-house 24 hours a day. Training healthcare professionals to place an LMA can be done using a mannequin. Studies have shown it to be an effective training tool (Gandini & Brimacombe, 2004; Micaglio et al., 2006).

Situations where an LMA may be useful include those where a neonate has a congenital anomaly of the mouth, lip, or palate; anomalies of the head, neck, tongue, or pharynx; a small mandible; or when ventilation with a mask is ineffective and intubation is not feasible. A disadvantage of LMA is that even with successful placement, nearly a quarter of infants with an LMA subsequently develop airway obstruction, probably because of displacement during patient movement. The cuff provides only a low-pressure seal around the larynx, which limits the airway pressures that can be achieved during ventilation. The risks of gastric insufflation and regurgitation of gastric contents are reduced but not eliminated. Because of its size, the LMA is currently restricted to infants greater than 34 weeks' gestation or 2 kg, although there have been anecdotal reports of successful use in very small infants (1–1.5 kg). The LMA also does not provide access to the lower airway, and therefore, is not suitable for meconium removal or drug administration, nor does it preserve the airway during laryngospasm. Its usefulness in neonates who require chest compressions or with the use of emergency medication administration still needs to be assessed (Perlman et al., 2015; Weiner, 2016; Wyckoff et al., 2015).

Chest Compressions. Chest compressions are rarely required for resuscitation in the delivery room. They are performed in only 1 of every 1,000 deliveries but probably are avoidable even in most of these cases. According to some authorities, approximately one-third of the infants who received chest compressions showed biochemical evidence of asphyxia (acidemia), but the remaining two-thirds were found to have a malpositioned ET tube or inadequate ventilatory support (i.e., insufficient rate or pressure). Clearly, the airway should be reassessed, and respiratory support should be optimized before chest compressions are initiated. Assuming that these components are satisfactory, chest compressions are begun if the heart rate drops below 60 bpm after 30 seconds of *effective* ventilation (Weiner, 2016).

Chest compressions provide temporary support for circulation and oxygen delivery. Pressing on the sternum has two effects: It compresses the heart against the vertebral column, and it increases intrathoracic pressure. Both effects cause blood to be pushed out of the heart into the arterial circulation. When the sternal pressure is released, the ventricles return to their original shape, intrathoracic pressure falls toward zero, and venous blood is pulled into the heart by a suction effect (Weiner, 2016).

There are two techniques to perform chest compressions, but the thumb method is preferred by the AAP. For the thumb method, both hands encircle the chest; the fingers support the back, and the thumbs (pointing cephalad either side by side or one on top of the other, depending on the infant's size) are used to press the sternum downward. The two-finger method should only be used if the compressor's hands are too small to encircle the neonate's chest. In this method, one hand supports the back from below while two fingers of the free hand are held perpendicular to the chest and the fingertips are used to apply downward pressure on the sternum. The two-thumb method is preferred as comparative studies have shown that higher systolic blood pressure, higher diastolic

blood pressure, higher mean arterial pressure, and higher coronary perfusion pressure are generated with less external compression force when the thumb method is used. This method also has had fewer reports of trauma to the liver and other abdominal organs. Moreover, the thumb method is perhaps easier and certainly less tiring to perform. If access to the umbilicus is needed to facilitate placement of an umbilical venous catheter (UVC) for administration of emergency drugs, the compressor should move to the head of the bed next to the person providing ventilation and continue compressing with the two-thumb method, though the thumbs will now be pointing caudally (Weiner, 2016).

For both methods, the pressure is applied to the lower-third of the sternum (just below the nipple line but above the xiphoid process), where the right ventricle lies closest to the sternum. Just enough force is used to depress the sternum one-third of the anterior/posterior chest wall diameter (Weiner, 2016). To obtain the most optimal myocardial and cerebral blood flows, the downward stroke and release phases of the compression should be equal in time. This equalization is best accomplished with a smooth stroke and release rhythm.

No matter which method of compression is utilized, compressing the heart for a full 60 seconds with coordinated ventilation is essential prior to reassessing the heart rate. Studies have demonstrated that it takes at least a minute for the diastolic pressure to increase enough to begin perfusing the coronary arteries. For this reason, the most recent recommendations are for a full 60 seconds of coordinated compressions and ventilation before reassessing the heart rate (Weiner, 2016; Wyckoff et al., 2015.)

PPV with 100% oxygen must be given while chest compressions are performed. The most recent guidelines recommend interposing chest compressions with ventilations at a 3 to 1 ratio. Every fourth compression is dropped to allow delivery of a single effective breath. During the course of a full minute, 90 compressions and 30 ventilations are given (Weiner, 2016). In order to provide an adequate number of compressions without simultaneous compression/ventilation, the ventilation rate is dropped to 30 from the 40 to 60 that was done with ventilation alone.

Faster rates were recommended in the past, but they only increase the chance of administering simultaneous compressions and ventilations. Most studies indicate that simultaneous delivery increases the intrathoracic pressure to a level at which ventilation is impeded and coronary perfusion is reduced. Whether there is any effect on cerebral blood flow is equivocal, but there have been other reports of lower survival rates when simultaneous compression and ventilation were used.

Experimental techniques, such as external circulatory assist devices (e.g., mechanical *thumpers*, pneumatic vests, and abdominal binders), counterpoint abdominal compressions (e.g., cough cardiopulmonary resuscitation), and active decompression (e.g., plumber's plunger), have shown promise in animal studies. Only a few large-scale clinical trials have been conducted, however, and most of those used adults. Consequently, these methods cannot be advocated for neonatal resuscitation at this time.

Medications

Medications are rarely used in neonatal resuscitation, and if they are needed, only two are used: epinephrine and normal saline. Sodium bicarbonate and other medications are no longer used in the immediate resuscitative period but may be considered in postresuscitation care.

Epinephrine. Epinephrine is a direct-acting catecholamine with both alpha-adrenergic and beta-adrenergic effects. These effects lead to peripheral vasoconstriction, acceleration of the heart rate, and an increase in the forcefulness of cardiac contractions. The net effect is a sharp rise in blood pressure (pressor effect) and an increase in cardiac output. The marked pressor effect combined with the increased aortic diastolic pressure increases the cerebral and myocardial perfusion pressures, maintaining blood flow to these critical organs during resuscitation. Epinephrine is, therefore, considered the drug of choice with asystole or persistent bradycardia (heart rate <60 bpm) despite effective ventilation with 100% oxygen and chest compressions for 60 seconds. For newborns the recommended dosage is 0.1 to 0.3 mL/kg of 1:10,000 solution (0.01–0.03 mg/kg) intravenously (Perlman et al., 2015; Weiner, 2016; Wyckoff et al., 2015). The drug is rapidly inactivated by an enzymatically driven process known as *sulfoconjugation*, in which the active compound is conjugated with sulfate. The half-life of infused epinephrine is approximately 3 minutes. Consequently, the dose may be repeated every 3 to 5 minutes as clinically indicated.

Epinephrine ideally should be administered via the IV/UVC/IO route. Because IV/UVC placement may be difficult and time consuming during resuscitation and not all neonates are candidates for an intraosseous (IO), an initial dose of epinephrine can be given by the ET tube. Unfortunately, absorption into the circulation from the pulmonary capillary bed may be highly variable because of the low blood-flow state associated with resuscitation. In addition, much of the ET-instilled drug remains along the walls of the ET tube and in the conducting airways, with a relatively small amount finding its way into the deep absorptive surfaces of the alveoli. If epinephrine is given by the ET tube, a higher dose of 0.5 to 1 mL/kg of 1:10,000 solution (0.05–0.1 mg/kg) should be given (Perlman et al., 2015; Weiner, 2016; Wyckoff et al., 2015).

A number of steps can be taken to aid delivery when the ET route is necessary. First, to optimize blood flow to the lungs, every effort must be made to ensure that chest compressions are performed effectively. Second, epinephrine may be dispersed more quickly to deeper pulmonary tissues by following the instillation with a few forceful ventilations. When giving epinephrine via the ET tube you will be giving higher doses, which will lead to increased volume of fluid of up to 1 mL, so dilution is no longer needed (Weiner, 2016).

Although higher doses of epinephrine administered by the ET route may have a role in exceptional situations, routine IV/UVC administration of high-dose epinephrine is not recommended in newborns. Studies with adults and older children have shown a dose–response relationship, with higher doses bringing about greater improvements in coronary and cerebral blood flow; in neonates, however, the efficacy and safety of high-dose IV/UVC epinephrine have not been adequately evaluated. Most of these studies have been conducted with patients with a history of coronary artery disease who demonstrate ventricular fibrillation. Neonates, however, more commonly have bradycardia caused by hypoxia. These pathophysiologic differences prevent the extrapolation of findings. Furthermore, administration of high doses has generally been followed by a prolonged period of hypertension. Because the newborn, particularly the prematurely born, has a vascular germinal matrix, the risk may be greater for intraventricular hemorrhage. In fact, this area of the brain is most susceptible to hemorrhage when hypertension is preceded by hypotension, which is the case with resuscitation. For this reason, only the standard dose of epinephrine (0.1–0.3 mL/kg) should be given by the IV/UVC route.

Volume Expanders. Volume expanders are indicated with evidence or suspicion of acute blood loss with signs of hypovolemia. These signs include pallor despite oxygen therapy, hypotension with weak pulses despite a normal heart rate, delayed capillary

refill, and failure to respond to resuscitation (Perlman et al., 2015; Weiner, 2016; Wyckoff et al., 2015). Low hematocrit and hemoglobin concentrations are diagnostic of blood loss, but the levels may be misleadingly normal immediately after acute loss. In general, it takes about 3 hours for a sufficient amount of fluid to shift from the interstitial to the intravascular space to produce the degree of compensatory hemodilution reflected by a fall in laboratory values.

The basic requirement for any replacement solution is that the electrolyte and protein composition be roughly equivalent to that which was lost. Otherwise, an osmotic pressure gradient is created, and fluids are driven out of the capillaries into the interstitial tissue. The expansion of circulatory volume is only transient, and the infant is put at risk for secondary problems, particularly pulmonary edema. Clearly, whole blood is the fluid of choice for volume replacement, and it offers the added benefit of oxygen-carrying capacity. Fresh O-negative blood cross-matched against the mother should be used. When blood is not readily available, isotonic fluids, such as 0.9% normal saline, may also be used (Weiner, 2016). Glucose-containing fluids (e.g., D_5W or $D_{10}W$) should not be given by bolus because of the risk of profound hyperglycemia. Hyperglycemia with untreated asphyxia may aggravate metabolic acidosis.

For emergency treatment of hypovolemia, 10 mL/kg of volume expander is given slowly over 5 to 10 minutes by the IV/UVC/IO route (Weiner, 2016). Rapid infusion must be avoided, because abrupt changes in vascular pressure in the vulnerable germinal matrix capillaries place the infant (especially a preterm infant) at greater risk of intraventricular hemorrhage. The response is usually dramatic, with a prompt improvement in blood pressure, pulses, and color. If the signs of hypovolemia continue, however, a second volume replacement may be given. Persistent failure beyond this point probably indicates some degree of *pump failure*, and further improvement is not likely until cardiac function is improved.

Naloxone. In the past naloxone was used for the infant of the mother who received a narcotic analgesic for pain control during labor, as these lipid-soluble drugs rapidly cross the placenta within 2 minutes of administration and can cause neonatal respiratory depression. Peak fetal narcotic levels occur 30 minutes to 2 hours after administration to the mother. The degree and duration of depression shown by the newborn depend on the dose, the route, and how soon before delivery the drug was given. Affected neonates show decreased respiratory effort and muscle tone but typically have a good heart rate and perfusion. Due to insufficient evidence existing to evaluate the safety and efficacy of this drug in the neonate and animal studies that report complications, the use of this drug is, however, no longer recommended (Weiner, 2016).

Other Drugs. Sodium bicarbonate, dopamine, atropine, and calcium were at one time used routinely in the acute phases of neonatal resuscitation, but are no longer used as they are rarely very useful (Weiner, 2016). These drugs, along with glucose boluses, are more commonly used now in the postresuscitation period in the neonatal special care or intensive care unit.

Special Circumstances. For some infants, changes in or variations of the usual resuscitative measures are needed. Most of these infants are extremely premature, have congenital anomalies, structural defects, or conditions that compromise the cardiovascular system, such as neural tube defects, abdominal wall defects, diaphragmatic hernias, hydrops fetalis, esophageal atresia, pneumothorax, choanal atresia, and laryngeal anomalies. Resuscitative measures with these disorders are discussed in greater detail elsewhere in this textbook.

Withholding or Discontinuing Resuscitation. The law and its underlying ethical principles require that treatment be provided and continued as long as it is judged to be effective in ameliorating or correcting an underlying pathophysiologic process. Unfortunately, the data is insufficient to allow a general recommendation for how long resuscitation should be performed before continuation can be deemed futile and efforts are terminated. There is evidence that survival is unlikely at any birth weight if the Apgar score remains 0 after 10 minutes of resuscitation that has effective ventilation, coordinated with chest compressions and administration of medication, but recently some controversy has arisen with the standard of stopping resuscitation on a neonate at 10 minutes as reports have emerged regarding intact survival in infants who have received therapeutic hypothermia after birth (Perlman et al., 2015). Taking into consideration this evidence, NRP still recommends that it may be reasonable to stop resuscitation at 10 minutes if the Apgar is 0 and the resuscitative efforts have been effective, but each resuscitation should be individualized to the situation at hand (Weiner, 2016).

In the past, NRP made recommendations on when noninitiation of resuscitation would be appropriate, but the current NRP recommendation is to follow the AMA Code of Medical Ethics on determining whether noninitiation should occur. The AMA states that five factors need to be weighed to make that determination. **Emergency Alert: The five factors are (1) the chance that the therapy will succeed, (2) the risks involved with treatment and nontreatment, (3) the degree to which the therapy, if successful, will extend life, (4) the pain and discomfort associated with the therapy, and (5) the anticipated quality of life for the newborn with and without the treatment.** This information would need to be discussed with the parents prior to the delivery of the neonate, if time allows. If time does not allow or sufficient information is not available, then initiation of resuscitation should occur, and discontinuation can occur as more information becomes available (Weiner, 2016).

Although many hospitals have guidelines for withholding full resuscitation for extremely low-birth-weight infants and those with lethal anomalies, early and well-documented discussion with parents is recommended when such events are anticipated prenatally. If the event was not anticipated, great attention should be given to postmortem evaluation. Blood for chromosome examination and other pertinent laboratory work, radiographs, and an autopsy are important both for family counseling and for evaluation of the resuscitation process.

Postresuscitation Management. A successfully resuscitated neonate requires special consideration and care postresuscitation. The goal of care of stabilization is to reverse the causes of cell death and tissue injury (hypoxia, ischemia, and acidosis) and avoid or treat any exacerbating conditions (hypothermia, hypoglycemia, respiratory failure, infection). The level of neonatal care the facility is designated for and the baby's condition will help determine whether the baby should be kept at the same facility as the mother or transported from the facility to a tertiary or quarternary referral center. When transporting a baby from one facility to another, a dedicated neonatal transport team should be used to improve the outcomes for the neonate, as adult transport teams do not have the knowledge or skill set to care for the critically ill neonate.

A main goal for the newly resuscitated neonate is to prevent future complications if at all possible. A concept that originated in the emergency medicine domain and is being adopted in the neonatal domain due to improved outcomes is the *Golden Hour* concept. In trauma medicine, it was found that if a patient was treated in the first 60 minutes following the accident, then irreversible internal damage was prevented, and survival improved. In recent years this concept has been applied to the newly resuscitated neonate, especially the extremely premature neonate, and refers to the first hour of a neonate's life. Principles of the Golden Hour include the standardization of treatment protocol during and after resuscitation of the neonate, improving teamwork, maintaining thermoregulation,

the administration of glucose-containing fluids to prevent hypoglycemia, and providing appropriate developmental support for the neonate. By standardizing how care is implemented, both short- and long-term outcomes related to thermoregulation, hypoglycemia, respiratory complications, sepsis, and intraventricular hemorrhages in the neonate may be decreased (Castrodale & Rinehart, 2014; Lambeth, Rojas, Holmes, & Dail, 2016).

There are several postresuscitation programs available to train healthcare providers in the care of the recently resuscitated neonate. The Perinatal Continuing Education Program and the S.T.A.B.L.E. Program are two such programs that are available to assist healthcare professionals with learning the skills necessary to stabilize the successfully resuscitated neonate. Both programs cover fluid administration, maintenance of the glucose levels, temperature regulation, airway management, blood pressure stabilization, lab work needed, antibiotic administration, parental support, and skills acquisition in the form of simulation. All of these topics are discussed in detail in other sections of this textbook.

Documentation. No resuscitative event can go unrecorded. Unfortunately, the circumstances surrounding resuscitation are fraught with medicolegal hazards. Assessment of the infant is generally limited to the most basic measurements (respiratory rate, heart rate, and oxygenation). Immediate response may be affected by many factors unrelated to professional competence. Furthermore, the ultimate outcome may not become apparent for years. Even the best, most appropriate care can look *bad* in retrospect if documentation is incomplete or inaccurate. Yet no area of the hospital is perhaps less conducive to quality documentation than the delivery room, where a variety of professionals (nurses, physicians, and respiratory therapists) from different clinical areas (obstetrics, neonatology, anesthesiology), each with a unique perspective on the situation, are brought together in an emergency. Notes are jotted on bed linen, scrub clothes, paper towels, or anything at hand. More often than not, these brief notes are so hastily written that they are little more than a list of the medications given. When transcribed, the events may be documented in two totally separate charts, one for the mother and another for the infant. Great care must be taken with record keeping so that events and actions can be accurately reconstructed many years into the future.

Descriptive charting is most appropriate in this situation. The record should include the pertinent perinatal factors, the physical findings, the activities performed, and the infant's response, but definitive diagnoses should not be offered. It is particularly important that information concerning the pregnancy, labor, and delivery be based on fact and not hearsay. Terms such as *fetal distress* and *asphyxia* tend to take on a life of their own once they have been committed to paper, even if they are not supported by clinical evidence. It is best to record factual data, such as vital signs and blood gas determinations, without adding an interpretation. Ventilation, chest compressions, and administration of medications are essential items for documentation, but the basics should not be dismissed. It is just as important to note that attempts were made to keep the infant dry and warm.

Accurate timing of notes can be critical, because actions are judged by the minute-to-minute changes noted in the chart. A preprinted recording form or an electronic form not only helps in this regard but can also provide a structure for evaluation and decision making.

Care of the Family During Resuscitation and Stabilization

An ill neonate is a crisis for families as no one expects their baby to be born prematurely or ill. When risk factors are known that could result in a neonate needing to be resuscitated (i.e., extremely premature baby), the physician should discuss with the parents prior to the delivery, if time allows, the options available as well as survival rates of the diagnosed condition of the infant. Parents have a role in deciding the goals of the care to be delivered to their baby, but they cannot make an informed decision unless they have been presented complete and reliable information. Unfortunately, many times this type of information may not be available until after the initial resuscitation or many hours later.

During resuscitation and stabilization, healthcare professionals should keep the parents informed of what is occurring to their newborn. Parents' wishes should be honored, if appropriate. Parents may wish to be present during resuscitation efforts. Research studies have supported this presence from both a health professional's and parent's point of view (Flanders & Strasen, 2014). Some professionals are concerned about legal ramifications of the family's presence during cardiopulmonary resuscitation but the positives for both the family and healthcare team outweigh the negatives (Jones, Parker-Raley, Maxson, & Brown, 2011; Oczkowski et al., 2015).

Resuscitation and Stabilization in Low-Resource Settings

The content of this chapter has focused on resuscitation and stabilization in high-resource settings. With the globalization of healthcare and the increase in healthcare providers from developed countries traveling to countries with limited resources to teach neonatal resuscitation and care to improve neonatal survival, it has, however, become evident that our care practices do not translate to the low-resource settings where medical equipment, supplies, personnel, and even electricity are limited. Because of this, AAP joined with the United States Agency for International Development, Laerdal Global Health, Johnson & Johnson, Save the Children, and other global organizations to develop an educational program to teach healthcare providers in a limited resource setting to resuscitate and care for term and preterm newborns. The program is called Helping Babies Survive and consists of three educational suites: Helping Babies Breathe (HBB), Essential Care for Every Baby (ECEB), and Essential Care for Small Babies (ECSB). HBB was launched in 2010 and was the first of the three educational programs. The HBB goal is to give every baby born in the world a chance to take its first breath and focuses on resuscitation. Since it has been in use, HBB has been translated into over 25 languages and has helped improve neonatal care in over 80 countries. The other two educational suites, ECEB and ECSB, were launched in 2014 and 2015, respectively, to help improve care after the birth of the baby (AAP, 2018).

The HBB is an evidence-based hands-on training tool that uses the same evidence incorporated into NRP. NRP and HBB are not interchangeable courses, though, and the main difference between the two is that HBB was designed for resource limited (equipment and personnel) settings and uses different educational methodology, mentorship, and quality improvement components. Since HBB was launched in 2010, a 47% reduction in neonatal mortality and a 24% reduction in fresh stillbirths has been documented in areas that have implemented the program (AAP, n.d.). Because of the success of HBB, ECEB and ECSB were developed to help with the post-delivery care of the neonate. The same methodology of education is used with both ECEB and ECSB as in HBB.

SUMMARY

Although most depressed infants respond to drying, warming, positioning, suctioning, and tactile stimulation, every obstetric and neonatal unit should be adequately equipped and well prepared to

handle neonatal emergencies. To provide neonatal care effectively, nurses must understand the cardiorespiratory transition and must be able to identify factors that may interfere with successful transition, comprehend the principles of resuscitation, and intervene on the basis of assessment of respirations, heart rate, and color.

CASE STUDY

A 22-year-old Caucasian female is admitted to your hospital labor and delivery unit via the emergency squad. She was brought in with complaints of contractions and the feeling of *pressure* in her groin area. The mother states that she is approximately 25 weeks' gestation and her contractions began several hours ago. On exam, bulging intact membranes are found in the vagina and fetal heart tones are audible with a Category III tracing. She is prepped for an emergency cesarean section.

1. ***What equipment, personnel, and medications are needed to prepare for the resuscitation of the infant?***

   Increase the delivery room temperature to 76°F, preheat a radiant warmer in manual mode, and assure that a polyethylene bag and chemical thermal mattress are available for use. Assemble personal protective equipment and ensure that a pediatric or neonatal stethoscope is present. A bulb syringe should be present as well as a suction catheter with tubing connected to wall suction set at 100 mmHg. For intubation a properly functioning laryngoscope with an appropriate size blade, a 2.5 and 3.0 ET tube, a pulse oximeter and cardiac monitor should be at the bedside. An umbilical cord insertion tray with a 3.5 umbilical catheters should be present as well as 1:10,000 epinephrine 0.5 to 1.0 mL/kg drawn up in a 3 mL syringe for ET administrations and 0.1 to 0.3 mL/Kg drawn up in a 1 mL syringe for IV administration. Additional personnel will be required to assist with the resuscitation, with at least one that is capable of intubating and placing an umbilical line if needed.

   The baby is born by cesarean section; she appears to be 25 weeks' gestation and approximately 600 g and the obstetrician delays cord clamping for 30 seconds, holding the baby at the level of the introitus with a sterile towel covering the baby. The baby is handed to you blue, limp, and not breathing.

2. ***What are your initial steps?***

   Place on preheated radiant warmer in a polyethylene bag; place temperature probe on infant and switch to servo mode; place hat on baby's head; position head in a sniffing position; continue to stimulate; suction the infant's mouth, then nose; provide blow-by oxygen; place pulse oximeter on baby's right hand.

   Your evaluation after carrying out the initial steps of resuscitation shows that the infant remains apneic with a heart rate of 40 and a pulse oximeter reading of 50.

3. ***What do you do next?***

   Start bag/mask ventilation with oxygen between 30% and 40% concentrations at a rate of 40 to 60 bpm. Reevaluate the infant in 30 seconds.

   After 30 seconds of bag/mask ventilation, the infant remains apneic; her heart rate remains at 40 bpm, pulse oximeter reading 50.

4. ***What are your next steps?***

   Check to ensure that the chest is rising and, if not, take steps for correction per the NRP and continue bag/mask ventilation with oxygen at 100%; begin cardiac compressions at a ratio of 3 to 1. Prepare equipment for intubation.

   The baby is intubated orally with a 2.5 ET tube on the first attempt. There are no spontaneous respirations, and the heart rate improves to 60 bpm and pulse oximeter 60.

5. ***What are your next steps?***

   Discontinue compressions, secure the ET tube, and continue to bag with oxygen at a rate of 40 to 60 breaths/minute.

   The infant is pink, has no spontaneous respirations, and her heart rate continues to increase to 100 bpm and pulse oximeter reading is now 70.

6. ***What would you do next?***

   Continue to bag the infant via the ET tube, and move the infant from the delivery room to the newborn unit.

7. ***What would your initial steps of stabilization be upon the infant's admission to the unit?***

   Place in a neutral thermal environment with 80% humidity
   Obtain glucose
   Start an IV of $D_{10}W$ at 80 mL/kg/day
   Obtain a complete blood count with differential and platelets
   Obtain a blood culture
   Place infant on a ventilator: FiO_2—100%, P/P—20/5, IMV—40, IT—.3
   Obtain a blood gas
   Surfactant—4 mL/kg
   Ampicillin—100 mg/kg q12h
   Gentamicin—5 mg/kg q36h

EVIDENCE-BASED PRACTICE BOX

In recent years the use of 100% oxygen in neonatal resuscitation has been reevaluated to the point that the new AAP NRP advocates the starting of resuscitation for term infants in 21% oxygen and something greater than 21% but less than 100% for preterm infants. This change of philosophy in the use of oxygen is a result of multiple studies that show that there are no advantages of 100% oxygen over 21% and the hyperoxia effects of oxygen to a neonate can be detrimental in the long term.

One set of studies (Cnattingius et al., 1995; Naumberg, Bellocco, Cnattingius, Jonzon, & Ekbom, 2002) that has shown the negative effects of oxygen use in the immediate postpartum period for the neonate shows an increase in childhood lymphatic leukemia. Both studies showed that infants resuscitated with 100% oxygen with a face mask immediately postpartum had an increased risk of developing childhood lymphatic leukemia, and if they received oxygen for greater than 3 minutes by manual ventilation, the risks increased.

Randomized controlled clinical studies have shown that there are no advantages in starting resuscitation with 100% oxygen over 21% oxygen, and it actually takes longer for an infant to take its first breath or to cry. Meta-analyses by Davis, &

(*continued*)

EVIDENCE-BASED PRACTICE BOX (*continued*)

Dawson (2012) and Rabi Singhal, & Nettel-Aguirre (2011) show that neonates resuscitated with 21% oxygen had slightly lower mortality rates than those resuscitated with 100% oxygen. Animal studies have shown potentially harmful damage at the cellular level from oxygen.

Research continues on the effects of oxygen on the developing neonate, and as more evidence continues to emerge, there will be changes to how we resuscitate newborns.

CHAPTER 4

Assessment of the Newborn and Infant

Terri A. Cavaliere

INTRODUCTION

Assessment is a continuous process of evaluation throughout the course of routine care of the neonate and infant. However, periodically a more formalized, comprehensive examination must be undertaken to determine wellness or to evaluate a specific problem. The results of the comprehensive physical assessment serve as the database on which clinical judgments about diagnosis and treatment are based.

A comprehensive physical assessment is performed for various reasons. The assessment may be the initial examination at birth, assessment of extrauterine transition, determination of gestational age (GA), comprehensive assessment after transition, discharge examination, well-baby outpatient examination, or evaluation of an illness or injury. Although these assessments have many commonalities, each has a somewhat different purpose. The importance of a comprehensive physical assessment cannot be overstressed. While advances in technology have improved our ability to provide care to newborns, there is no substitute for hands-on assessment. This chapter discusses various aspects of a comprehensive physical assessment.

FIRST NEONATAL ASSESSMENT AND THE APGAR SCORE

The initial neonatal assessment occurs immediately after delivery with the assignment of Apgar scores. These scores were devised in 1952 by Virginia Apgar as a means of assessing the clinical status of infants immediately after delivery (Apgar, 1953). The Apgar score consists of five components—heart rate, respiratory effort, muscle tone, reflex irritability, and color—and each component is given a score of 0, 1, or 2; the scores are then added to obtain a total score (Table 4.1). It should be assigned at 1 and 5 minutes; however, if the total score is below 7 at 5 minutes, the assessment is repeated every 5 minutes for up to 20 minutes.

The Apgar score, once used to direct resuscitative efforts, has now become an acknowledged and rapid means of evaluating a neonate's clinical condition and/or the response to resuscitation (American Academy of Pediatrics [AAP] Committee on Fetus and Newborn & American College of Obstetricians and Gynecologists [ACOG] Committee on Obstetric Practice, 2015). It is important to recognize that elements of the Apgar score may be influenced by a variety of factors besides birth asphyxia, including, but not limited to, preterm birth, administration of drugs to the mother,

TABLE 4.1

APGAR SCORING SYSTEM

Component	Assigned Score		
	0	1	2
Heart rate (beats/minute)	Absent	<100 (slow)	100
Respiratory effort	None	Weak cry; hypoventilation	Good, strong cry
Muscle tone	Limp	Some flexion	Active motion
Reflex irritability	No response	Grimace	Cough or sneeze
Color	Blue or pale	Body pink; extremities blue	Completely pink

Source: Adapted from Goldsmith, J. P. (2015). Overview and initial management of delivery room resuscitation. In R. J. Martin, A. A. Fanaroff, & M. C. Walsh (Eds.), *Fanaroff & Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (10th ed., Vol. 1, pp. 460–470). Philadelphia, PA: Elsevier.

interobserver variability, and congenital anomalies. A low 1-minute Apgar score does not correlate with the newborn's future outcome. The 5-minute Apgar score, especially the change in the score between 1 and 5 minutes, reflects the effectiveness of resuscitation efforts. However, even a 5-minute score of 0 to 3, although possibly a result of hypoxia, is limited as an indicator of the severity of the problem and in and of itself correlates poorly with future neurologic outcome (Stanley, 1994; Weiner, Zaichkin, & Kattwinkel, 2016).

The Apgar score is not meant to be used to determine the need for resuscitation nor should it be used in isolation to predict morbidity or mortality for any particular neonate, but to convey information about the newborn's response to resuscitation (Goldsmith, 2015). Values of components of the Apgar score are affected by

resuscitation; therefore, the chart should reflect what measures, if any, are underway (Weiner et al., 2016).

An Apgar score assigned during resuscitation is not equivalent to a score assigned to a spontaneously breathing infant. No accepted standard exists for assigning an Apgar score during resuscitation after birth; many of the elements contributing to the score are affected by resuscitation. The creation of a score that accounts for resuscitative efforts has been proposed; however, the predictive reliability of such a tool has not been established (AAP Committee on Fetus and Newborn & ACOG Committee on Obstetric Practice, 2015).

In addition, appropriateness of the Apgar score to evaluate extremely premature infants has also been examined. The maturity of the infant influences certain elements of the Apgar score, such as reflex irritability, muscle tone, and respiratory effort; thus, it is likely that healthy premature infants, without indications of asphyxia, may have lower Apgar scores than term infants (AAP Committee on Fetus and Newborn & ACOG Committee on Obstetric Practice, 2015; Als & Butler, 2011).

OTHER CONSIDERATIONS FOR THE INITIAL NEONATAL ASSESSMENT

Before the infant leaves the delivery area, a brief physical examination should be performed. Considerations for this assessment include inspection for birth injuries and major congenital anomalies and evaluation of pulmonary and cardiovascular adjustment to extrauterine life. Evaluation of early transition to extrauterine life includes observation of color for adequacy of perfusion and oxygenation; assessment of respiratory effort; auscultation of breath sounds and heart sounds; and inspection of the amount, color, and consistency of secretions. Tone activity and appropriateness of state should also be noted at this time. A cursory inspection of all external areas should be performed before the infant leaves the delivery area, including a general evaluation of the external genitalia and, in males, palpation for testes in the scrotum. The entire examination should be performed under a radiant heat source to prevent significant heat loss from the infant.

Evaluation of Transition

Adaptation to both intrapartum and neonatal events is reflected in the transition from a fetal to an extrauterine environment. These events result in sympathetic activity that affects the infant's color, respiration, heart rate, behavioral state, gastrointestinal function, and temperature (Gardner & Hernandez, 2016). It is important to remember that the physiologic and biochemical changes peculiar to the period of transition to extrauterine life affect the physical findings of early examinations. The examination performed during transition is described separately because characteristics that are normal during transition may be abnormal if they appear at other times.

As the neonate's circulation converts from the fetal route, there may be a period in which pulmonary vascular resistance remains greater than systemic vascular resistance, resulting in a right to left shunt across the ductus arteriosus. Higher preductal oxygen saturation causes the neonate's face and upper body to appear pink while the lower body and legs appear pale or blue; this creates a visible demarcation across the chest. As the fetal circulation successfully converts to the neonatal pathway, this transitional differential cyanosis disappears (Levy & D'Harlingue, 2013). Acrocyanosis is common during this period. To evaluate babies with deeper skin pigmentation, the nurse should observe the color of the mucous membranes. When the neonate is stimulated, the skin may appear blushed or bright red; this change in color is called erythema neonatorum, or generalized hyperemia, which develops a few hours after birth. It generally resolves within several minutes to an hour and rarely appears with the same intensity (Gomella, 2013). Erythema neonatorum is not synonymous with erythema toxicum neonatorum.

The neonatal heart rate may range from 160 to 180 beats/minute (bpm) in the first 15 minutes of life; it slowly falls to a baseline rate of 100 to 120 bpm by 30 minutes of life. The heart rate is labile, and brief periods of asymptomatic, irregular heart rates are not pathologic. Murmurs are common, because the ductus arteriosus may still be patent. Respirations are also irregular during the first 15 minutes, with rates ranging from 60 to 100 breaths/minute. Grunting, flaring, retractions, and brief periods of apnea may also be seen in the neonate. Crackles may be present on auscultation (Gardner & Hernandez, 2016).

Despite the changes in the heart and respiratory rates during the initial 15 to 30 minutes of life, healthy term infants are awake and alert. They may rest quietly, cry periodically, startle spontaneously, and breastfeed during this period. Full-term babies often show flexed posture with good muscle tone; preterm newborns, in comparison, have less flexion and tone (Cavaliere & Sansoucie, 2014). Temperature is decreased, and gastrointestinal activity includes the establishment of bowel sounds and the production of saliva. This first period of reactivity may be prolonged in infants who have experienced difficult labor and delivery, in sick term infants, and in well premature infants (Gardner & Hernandez, 2016).

After the first period of reactivity, the infant is relatively unresponsive or sleeping, and the heart rate drops to a baseline of 100 to 120 bpm. This interval, which lasts approximately 60 to 100 minutes, is followed by a second period of reactivity, which lasts anywhere from 10 minutes to several hours. During this time the infant may show rapid color changes, intermittent tachypnea and tachycardia, and changes in tone. A healthy infant may have periods during which the respiratory rate is considerably higher than 60 breaths/minute; however, the infant does not appear distressed and can slow this rate enough to nipple feed successfully. Meconium often is passed during this period (Cavaliere, 2016; Gardner & Hernandez, 2016). The chart in Figure 4.1 summarizes some of the physical changes seen during the transition period.

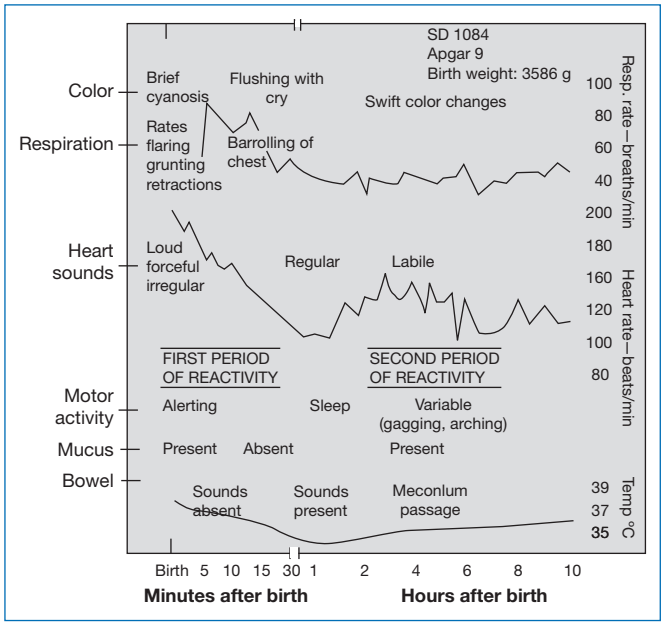

FIGURE 4.1 Normal transition period.

Source: Based on Desmond, M. M., Rudolph, A. J., & Phitaksphraiwan, P. (1966). The transitional care nursery. A mechanism for preventive medicine in the newborn. *Pediatric Clinics of North America, 13*(3), 651–668. doi:10.1016/S0031-3955(16)31875-2

Newborn Examination

The comprehensive newborn examination generally is performed within the first 12 to 18 hours of life, after transition has been completed successfully. The examination should be initiated when the infant is quiet and should progress from assessments that are least likely to bother the infant to those that are most irritating. An examination sequence based on the infant's state is outlined in Table 4.2.

Discharge Examination

The purpose of the discharge examination is to assess the infant's ability to be cared for outside the controlled environment of the hospital. The focus of the assessment depends primarily on how long the infant has been hospitalized and for what reasons. The needs of a healthy, full-term infant being discharged home with the mother are different from those of a growing, preterm infant who has been hospitalized for weeks or months and who has significant

sequelae. Evaluating the caretaker's capability to care for and observe changes in the infant is an important aspect of the discharge assessment and follow-up plan. Anticipatory guidance regarding feedings, sleeping position and environment, skin care, safety practices, and recognition of signs and symptoms of illness should be provided at this time.

Outpatient Examination

The focus of the first outpatient examination is the infant's adaptation to the home environment. This examination includes assessment of any issues highlighted at discharge. Some factors to be considered in the infant are temperature stability, ability and success at feeding and elimination, sleep patterns, normal color, drying of the umbilical cord, reassessment of hip stability, and normal state and behavior. Any areas that may have been relatively inaccessible during earlier examinations should be included, such as the eyes, ear canals, and eardrums (Fletcher, 1998).

The birth history, including the birth weight, GA, and any problems, should be reviewed. As part of the complete physical examination, height, weight, and head circumference should be plotted and developmental progress observed. The results of newborn metabolic screening and the infant's immunization status

should be reviewed. For sick infants, general assessment assists in the establishment of priorities. For example, if a child is experiencing pronounced respiratory problems, assessment of this area is a priority. Anticipatory guidance issues include nutrition, elimination, sleep patterns, development and behavior, social and family relationships, and injury prevention. A more detailed description of health maintenance for high-risk infants during the first year of life is presented later in this chapter.

Environment

The routine neonatal assessment should take place in a quiet, warm environment. The room should be lighted well enough for appropriate observation, but the light should not be so strong that the infant is deterred from opening the eyes. Prevention of heat loss is critical to the infant's comfort and to the maintenance of thermal neutrality and glucose homeostasis. Most healthy term infants can tolerate being undressed in a reasonably warm room for the 5 to 10 minutes required to perform the physical assessment. If the environment is cool or drafty or if the infant is sick or preterm, an external heat source should be provided, such as a radiant warmer or heat lamps. If heat lamps are used, the infant's eyes should be shielded to prevent adverse effects from prolonged exposure of the infant's eyes to the bright light of the lamps. The examiner should warm the hands and examination equipment before beginning the assessment. This practice not only prevents heat loss but also avoids upsetting an otherwise quiet and cooperative infant.

The examination should be conducted in a quiet environment with a calm infant. A placid infant provides the best opportunity for gathering meaningful data. Extraneous environmental noise hampers auscultation and assessment of bodily sounds and may overwhelm a sick or immature infant, causing changes in state and cardiovascular status (Honeyfield, 2019). Handling the infant gently and speaking in a soothing voice may allow the examiner to complete most of the assessment without distressing the infant. Disturbing components of the examination, such as deep palpation of the abdomen and assessment of the hips, should be performed last.

Having one or both parents present during the routine neonatal assessment offers the opportunity to assess their competence in care giving and to educate them about the unique physical traits, behavior, and coping skills of their infant. The examiner may also use this time to build rapport and trust with the parents, to listen to their concerns, and to offer pertinent information. Some issues may require privacy for discussion; therefore, confidentiality should be considered when conversing with parents in the presence of others.

COMPONENTS OF A COMPREHENSIVE HISTORY

The neonatal history is very similar to that for an older child or adult, including information about the past medical history, the current condition, and the family. For a newly delivered infant, the initial neonatal assessment probably will be conducted before the nurse speaks to the parents. Basic information about the pregnancy and delivery should be available in the maternal records, but a complete history lays the foundation for the comprehensive newborn examination and should be elicited directly from the parents. Without a complete history, the examiner may lack adequate information to formulate an accurate impression.

The components of a complete history are the identifying data; chief complaint; interim neonatal history or history of presenting problem or illness; antepartum history; obstetric history; intrapartum history; and the maternal medical, family medical, and social histories (Table 4.3). After data collected from the complete history and physical assessment are organized and all expected and unexpected findings have been reviewed, areas of concern are identified and prioritized for further evaluation and attention. This forms the framework for the clinical diagnosis and plan of care.

Interviewing the Parents

The interview with the parents is a vital component of the health assessment of a newborn or an infant. This interview offers the nurse an excellent opportunity to develop a therapeutic partnership with the parents in the care of their baby. Ideally, the interview is conducted in a quiet, comfortable setting; if it takes place at the bedside in a busy intensive care unit, the parents may be distracted and overwhelmed by the sounds and sights customary to this environment. If the ideal setting is not possible, the nurse can provide a focal point of warmth and attention by using a conversational tone of voice, maintaining eye contact, and concentrating fully on the parents. However, this can be done only with a discipline that dispels both personal and professional distractions.

It is important that nurses introduce themselves and clearly state their names and roles in the baby's care. Nurses should make sure they understand the parents' names and should pronounce them correctly. They should ask the baby's name and use it often during the conversation. During this session, the purposes of the health interview and physical assessment should be clarified. Cooperation and sharing are more likely if the parents understand that the questions lead to better care for their infant.

The use of silence and listening, as well as allowing ample time for response to questions, is crucial to reassuring parents that what they say is worthwhile. Also, the parents can easily be shown that the interview is important and will not be rushed. Nurses should fix their attention on the parents and listen and should not interrupt unless necessary. They also should avoid asking the next questions before listening to the complete answer to the current question. They should indicate that they understand the responses and should request clarification if necessary. Nurses should take care to avoid overly technical language, medical jargon, and the tendency to inundate the parents with information. They should attempt to verify that the parents understand what has happened and what they have been told and that they seem to be coping. Nurses should always discuss and explain what the parents can expect to happen next; they should also bring up methods of keeping in touch, pertinent telephone numbers, and the visitation policy, if appropriate.

It is often difficult to approach parents about sensitive matters, such as drug or alcohol use or concerns about the death of their infant. The following is a list of suggestions that may assist in the discussion of sensitive issues as offered by Ball, Dains, Flynn, Solomon, and Stewart (2015):

- Respect the individual's privacy
- Avoid discussing sensitive topics where the conversation might be overheard
- Begin the discussion with open-ended questions and ask the least threatening questions first
- Not be patronizing, but use language that is straightforward and understandable
- Take a direct and firm approach
- Avoid apologizing for asking a question (the nurse is doing nothing wrong)
- Avoid lecturing (the nurse is not there to pass judgment)

TABLE 4.3

COMPONENTS OF A COMPREHENSIVE NEONATAL HISTORY

Component	Data Required
Identifying data	Infant's name; parents' names; parents' telephone numbers (home and work); infant's date of birth, gender, and race; and source of referral (obstetric or pediatric provider) if any.
Chief complaint	Statement of initial known status (age, gender, birth and current weights, and GA by dates and examination) and problems infant might have; for a newborn or well-baby examination, the statement simply reflects the current health status (e.g., "Full-term male infant, now 1 week of age, for well-baby follow-up").
Interim history/ history of newborn	Chronologic record of newborn's history from time of delivery to present or, if older infant, presenting problem chronologic narrative of chief complaint. Narrative should answer questions related to where (location), what (quality, factors that aggravate or relieve symptoms), when (onset, duration, frequency), and how much (intensity, severity).
Antepartum history	Historical data about the pregnancy, including maternal age, gravidity, parity, last menstrual period, and estimated date of delivery. Date and GA at which prenatal care began, provider of care, and number of visits should be recorded here. Mother's health during pregnancy, infections, medications taken, use of illicit drugs or alcohol, abnormal bleeding, and results of prenatal screening tests should also be included.
Obstetric history	Significant history regarding previous pregnancies; neonatal problems or subsequent major medical problems of previous children and current age and health status of living children should be noted.
Intrapartum history	Duration of labor, whether it was spontaneous or induced, duration of rupture of membranes, type of delivery, complications; infant's birth weight, presentation at delivery, and Apgar scores; resuscitative measures if required and response to those measures.
Past medical history	Significant maternal history of chronic health problems or diseases treated in the past or during the pregnancy, including surgical procedures and hospitalizations before or during the pregnancy. For older infants, also obtain information about infant's history, including feeding, development, illness, and immunizations.
Family medical history	Significant family medical history of chronic disorders, disabilities, known hereditary diseases, or consanguinity.
Social history	Parents' marital status, paternal involvement, parents' occupations, and educational level; sources of financial support, housing accommodations, and insurance status must be noted, as well as any support agencies involved. Family unit should be defined and religious and cultural affiliations noted, along with number of individuals living in the home. Plans for child care should be elicited, as well as any current family stressors (e.g., moving, death in the family).

GA, gestational age.

- Understand that defensive behavior might be the individual's way of coping
- Proceed slowly and take care not to demean the individual's behavior
- Offer feedback to ensure that the individual agrees that your interpretation is appropriate
- Provide an opportunity for the individual to ask relevant questions

It is vital that, in communicating with parents from diverse cultures, nurses appreciate and respect differences in communication patterns and in childbearing and health practices. Knowledge of cultural variations in family and health practices assists nurses in developing sensitivity to differences; however, the family must be observed carefully for cues to family practices and relationships with children and one another.

Incorporation of a family history tool such as *My Family Health Portrait Tool* (www.hhs.gov/programs/prevention-and-wellness/family-health-history) developed by the U.S. Department of Health and Human Services will give at least a three-generation history that may reveal genetic conditions. Some families will already have completed this information online. The tool takes very little time to complete and can be used in conjunction with the standard history questions.

Physical Assessment Techniques

The techniques used for physical assessment are inspection, palpation, percussion, and auscultation. Learning these skills requires patience and practice, and the inability of the newborn to provide verbal cues presents an additional challenge. With experience, the practitioner learns to process a multitude of observations while assessing individual systems and then to use these data to form a clinical impression and plan of care.

Inspection. Inspection is the simple yet intricate use of the auditory and visual senses to evaluate an infant's state, color, respiratory effort, posture, and activity, as well as the shape and symmetry of

various body regions. It is a crucial skill in the physical assessment of neonates, but it is also a difficult one to master. The sense of smell may be used to note unusual odors. The impression obtained from methodical observation establishes priorities for the remainder of the systematic assessment. In the physical examination, thoughtful observation, rather than simple looking, is the most efficient means of detecting changes. Inspection should be used throughout the physical assessment and should continue as long as the infant remains in the nurse's care.

Auscultation. Auscultation is the process of listening for sounds made by the body. The bell of the stethoscope is used for low-pitched sounds (e.g., cardiovascular sounds) and the diaphragm for higher pitched sounds (e.g., lung and bowel sounds). The stethoscope should be placed lightly but firmly against the wall of the body part being assessed. A calm infant and quiet environment facilitate auscultation. Practice in recognizing normal body sounds is required before abnormal sounds can be identified accurately.

Palpation. With palpation, the examiner uses the sense of touch to determine hydration, texture, tension, pulsation, vibration, amplitude, and tenderness, as well as the depth, size, shape, and location of deep structures. The touch used for palpation must be gentle and is performed with the flats of the finger pads rather than the fingertips (Fletcher, 1998; Honeyfield, 2019). To gather the most accurate information, the infant should be calm at the onset of the abdominal examination. Relaxing the abdominal musculature by flexing the infant's knees and hips with one hand facilitates palpation of the liver and spleen. Gentle pressure must be emphasized during palpation of sensitive organs (e.g., liver, spleen, and skin) that are at greater risk for injury and bleeding in neonates, particularly preterm infants, or those that have hepatomegaly. Warming of the examiner's hands, use of a pacifier, and progression from superficial to deep palpation help maintain the infant's comfort throughout most of the examination. Tender areas should always be palpated last.

Percussion. Percussion is the use of tapping to produce sound waves that may be assessed according to intensity, pitch, duration, and quality (Table 4.4). Percussion may be direct or indirect. For direct percussion, the examiner directly strikes the body part to be assessed with the tip of the middle right finger. For indirect percussion, the examiner places the middle finger of the nondominant hand against the skin of the body part to be assessed and strikes the distal joint with the tip of the middle finger of the dominant hand. The wrist must make a snapping motion, creating a brisk thump with the tip of the right middle finger against the left middle finger's distal joint. Vibrations are transmitted from the bones of the finger joint touching the infant's body to the underlying tissue (Figure 4.2). Although percussion is rarely used in neonatal assessment, it may be a useful technique for examining the older infant or child.

Assessment of Size and Growth

Well-being in the fetal and neonatal periods is reflected by a normal growth pattern. Fetal and neonatal growth rates are predictable and can be measured by various methods. To determine if an individual infant's growth is adequate, an appropriate standard must be used with which the child's measurements can be compared. The growth curves used must match the patient as closely as possible in gender, race, GA, genetic potential, and environmental factors, such as altitude. A discussion of the techniques used to estimate and assess fetal growth is beyond the scope of this chapter and can be found elsewhere in this text. Two methods of evaluating adequacy of growth in the newborn are the GA assessment and the clinical assessment of nutritional status. One tool that may be used to assess nutritional status in the clinical setting is the clinical assessment of nutritional status score (CANSCORE) developed by

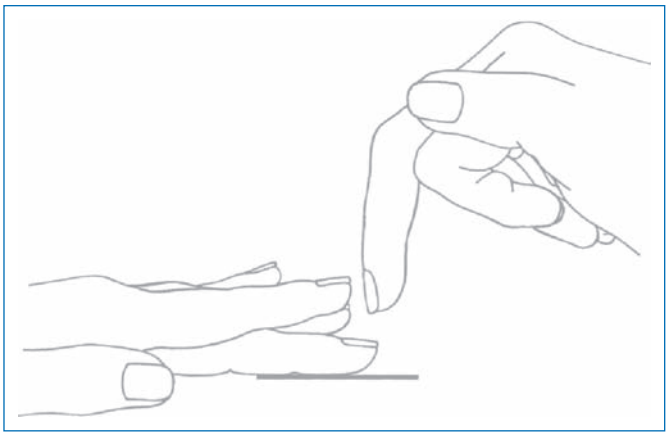

FIGURE 4.2 Percussion technique. Note the position of the fingers.

McLean and Usher (1970). See the text that follows for more information about the CANSCORE.

Assessment of GA

A determination of GA is part of the physical examination of every newborn. Classification of newborns by GA enables the healthcare provider to determine the neonatal mortality risk (Figure 4.3) and to identify possible disorders (Figure 4.4) and initiate intervention or screening (Gardner & Hernandez, 2016). Figure 4.5 shows the classification of newborns by intrauterine growth and GA. Table 4.5 presents terms used in GA assessment and in determining the adequacy of in utero growth.

As was previously mentioned, morbidity and mortality can be predicted from the GA assessment (see Figures 4.3 and 4.4). Neonates with the lowest risk of problems associated with morbidity and mortality are term infants who developmentally are appropriate for gestational age (AGA). Risks associated with categories of GA and intrauterine growth restriction are shown in Table 4.6.

After birth, GA is determined by the evaluation of physical, neurologic, and neuromuscular characteristics. A number of methods have been developed to assess GA in newborns. The New Ballard score (NBS) is a widely used assessment tool (Figure 4.6). It includes six neurologic and six physical criteria and permits assessment of extremely premature infants. Despite its advantages over the other scoring systems, the NBS is accurate only to within 2 weeks and tends toward overestimating the GA of extremely premature neonates (Lissauer, 2015). Performing the examination as soon as possible in the first 12 hours of life enhances its accuracy.

Although GA assessment is discussed separately, the components of the assessment should be performed as part of the infant's general physical examination. Table 4.7 presents the essentials of the NBS; each component is scored as shown in Figure 4.6. The total score is calculated, and the resulting GA is plotted on a graph (see Figure 4.5).

Clinical Assessment of Nutritional Status

GA assessment does not identify all infants with intrauterine malnutrition. Although the terms *small for gestational age* (SGA) and *intrauterine growth retardation/restriction* (IUGR) are related, they are not synonymous. IUGR represents a reduction in the expected fetal growth pattern, whereas SGA refers to an infant whose birth weight is less than population norms. Not all IUGR infants are SGA, and not all SGA infants are IUGR (Calkins & Devaskar, 2015; Trotter, 2019).

Many but not all infants who are either SGA or IUGR are malnourished in utero. However, malnutrition can occur in neonates of any birth weight. Because malnutrition alters body composition and can prevent adequate brain growth, it is important to identify infants who have been affected in utero. These infants may be at risk for problems associated with aberrant growth (Calkins & Devaskar, 2015).

McLean and Usher (1970) initially described physical findings that are suggestive of weight loss or poor nutrition. These physical characteristics form the basis of the CANSCORE that may still be used in the clinical evaluation of nutritional status in the

clinical setting (Singhal, Agal, & Kamath, 2012). In addition to the CANSCORE, other tools that may be useful in assessing nutritional status are the ponderal index (PI) and the body mass index (BMI; Ezenwa & Ezeaka, 2018).

Measurement Techniques

For most infants the parameters of weight, length, and occipito-frontal circumference (OFC) are adequate for the basic physical assessment. These measurements are compared against standard growth curves. If the infant has any abnormalities in the size of a body component or if the infant shows disproportionate growth, the involved areas should be measured and compared with established norms (Fletcher, 1998).

Weight and Length. The infant should be weighed while unclothed and quiet. Weight can be falsely increased by several factors, including clothing and infant motion. The weight of the average full-term that is AGA is 3.5 kg, with a range of 2,700 to 4,000 g (Burton-Mota, 2014; Tappero, 2019). Birth weights are affected by genetics and geographic location. For instance, African American, Hawaiian, and Asian neonates weigh less than

TABLE 4.5

TERMS AND ABBREVIATIONS USED IN ASSESSMENT OF GA AND ADEQUACY OF INTRAUTERINE GROWTH

Term and Abbreviation	Description
Low birth weight	Infant weighing <2,500 g[a]
Very low birth weight	Infant weighing <1,500 g[a]
Extremely low birth weight	Infant weighing <1,000 g[a]
AGA	Parameter (weight) within the 10th–90th percentile for GA
LGA	Parameter above the 90th percentile for GA
SGA	Parameter below the 10th percentile for GA
IUGR	Slowing of intrauterine growth documented by ultrasound; a neonate may be IUGR without being SGA
Symmetric IUGR	Measurements for weight, length, and head circumference all within the same growth curve even if neonate is AGA, LGA, or SGA
Asymmetric IUGR	Measurements for weight, length, and head circumference in different growth curves
Term gestation	Neonate born between 37 and 42 weeks gestation
Preterm gestation	Neonate delivered before completion of week 37 of gestation
Postterm gestation	Neonate delivered after completion of week 42 of gestation

[a] Regardless of length of gestation.

AGA, appropriate for gestational age; IUGR, intrauterine growth restriction; LGA, large for gestational age; SGA, small for gestational age.

TABLE 4.6

RISKS ASSOCIATED WITH GESTATIONAL AGE AND INTRAUTERINE GROWTH RESTRICTION

Category	Risks
SGA, LGA, IUGR	Perinatal and long-term problems
Preterm SGA	Problems associated with immaturity of body systems and placental insufficiency
Preterm	Problems associated with immaturity of body systems
Postterm	Problems associated with placental insufficiency
Term LGA	Risks are greatest in perinatal period, but long-term problems can develop

IUGR, intrauterine growth retardation/restriction; LGA, large for gestational age; SGA, small for gestational age.

FIGURE 4.6 Maturational assessment of GA: New Ballard scoring system.

Source: From Ballard, J. L., Khoury, J. C., Wedig, K., Wang, L., Eilers-Walsman, B. L., & Lipp, R. (1991). New Ballard score, expanded to include extremely premature infants. *Journal of Pediatrics, 119*, 417–423. doi:10.1016/S0022-3476(05)82056-6

TABLE 4.7

NEW BALLARD SCORING SYSTEM

Component	Assessment Technique	Effect of Maturity	Comments
Neuromuscular Maturity			
Posture	Observe infant while baby is unrestrained and supine; note amount of flexion and extension of extremities	Extensor tone is replaced by flexor tone in a cephalocaudal progression	Knees may be hyperextended in a frank breech delivery
Square window	Flex wrist; measure minimum angle formed by ventral surface of forearm and palm	Angle decreases; at term no space exists between palm and forearm	Response depends on muscle tone and intrauterine position
Arm recoil	Place infant in supine position with head in midline; flex elbow and hold forearm against arm for 5 seconds; fully extend elbow, then release; note time required for infant to resume flexed position	Angle decreases and recoil becomes more rapid	
Popliteal angle	Flex hips, placing thighs on abdomen; keeping hips on surface of bed, extend knee as far as possible until resistance is met; estimate popliteal angle	Popliteal angle decreases	Amount of extension can be beyond point where resistance is first met; this assessment also is affected by intrauterine position and hip dislocation
Scarf sign	With head in midline, pull hand across chest to encircle neck; note position of elbow relative to midline	Increased resistance to crossing the midline	Reflects muscle tone; response is altered by obesity, hydrops, or fractured clavicle
Heel to ear	Keep infant supine with pelvis on mattress; press feet as far as possible toward head, allowing knees to be positioned beside abdomen; estimate angle created by arc from back of heel to mattress	Angle decreases; hip flexion decreases toward term	Reflects muscle tone
Physical Maturity			
Skin	Observe translucency of skin over abdominal wall	Skin becomes thicker and ultimately dry and peeling; pigmentation increases	Skin becomes drier hours after birth; phototherapy or sunlight enhances pigmentation
Lanugo	Assess for presence and length of hair over back	Lanugo emerges at 19–20 weeks and is most prominent at 27–28 weeks; then gradually disappears, first from the lower back and then from at least half of the back	The degree of pigmentation and quantity of hair are related to race, nutritional status
Plantar surface	Measure length of foot; determine presence or absence of true deep creases (not merely wrinkles)	Early in gestation, foot length correlates with fetal growth; creases develop from toes to heel, and absence of creases correlates with immaturity	Plantar creases also reflect intrauterine fetal activity; accelerated creasing is seen with oligohydramnios; diminished creasing suggests lack of activity in a mature fetus
Breast	Estimate diameter of breast bud; assess color and stippling of areola	Definition and stippling of areola and pigmentation are evident near term; bud size increases because of maternal hormones and fat accumulation	With intrauterine growth restriction, breast tissue may be diminished, but development of areola proceeds regardless of malnutrition

(*continued*)

TABLE 4.7

NEW BALLARD SCORING SYSTEM (*continued*)

Component	Assessment Technique	Effect of Maturity	Comments
Ear cartilage	Fold top of auricle; observe speed of recoil	Cartilage becomes stiff, and auricle thickens	Compression in utero and absence or dysfunction of auricular muscles diminishes firmness
Eyelid opening	Without attempting to separate eyelids, evaluate degree of fusion	Opening begins at 22 weeks; lids are completely unfused by 28 weeks	Fused eyelids should not be considered a sign of nonviability; lids may be fused at term with anophthalmia
External Genitalia			
Male	Palpate scrotum to assess degree of descent of testes; observe rugae and suspension (cryptorchidism)	At 27–28 weeks, testes begin to descend into scrotum; rugae formation of scrotum begins at about 28 weeks; by term, rugae are well defined, and scrotum is pendulous	Rugae are decreased with scrotal edema; testes may be absent
Female	Assess size of labia minora and labia majora	Labia minora increase in size before labia majora; at term labia majora cover labia minora completely	Size of labia majora depends on amount of body fat; with malnutrition, size may be diminished; edema may increase size of labia majora

Martin, A. A. Fanaroff, & M. C. Walsh (Eds.), *Fanaroff & Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (10th ed., pp. 391–406). St. Louis, MO: Mosby.

Caucasian infants (Tappero, 2019) and populations that live in high altitudes have babies that are normally smaller than cohorts born at sea level. It is helpful to use growth graphs that are specific for populations and locations if they are available.

The crown-to-heel length can be obtained using a measurement board or a standard tape measure. With the infant supine and legs extended, the nurse draws a line on the bed at the baby's head and another at the heels and then measures the distance between these two points (Figure 4.7). The average full-term newborn is 50 cm long with a range of 48 to 53 cm (Tappero, 2019). Other measurement techniques are described in the appropriate sections.

Physical Examination of the Neonate

The following sections describe the newborn examination beyond the transition period.

Vital Signs. Once transition is complete, the neonate has a respiratory rate between 40 and 60 breaths/minute, and the rate may be irregular. Respirations are easy and unlabored; breath sounds should be clear on auscultation. The heart rate varies from 100 to 160 bpm, depending on the infant's state and GA (Vargo, 2019). Premature neonates have a higher baseline heart rate. The resting heart rate is the most representative for any baby.

Normal blood pressure ranges depend on GA and chronologic age and the methods used. Blood pressure in premature babies is proportional to size; therefore, normal values are lower than for term babies (Hegyi et al., 1994). Figures 4.8 and 4.9 and Tables 4.8 through 4.10 show normal blood pressure values over various time frames and GAs.

Temperature is determined by axillary measurement; acceptable values range from 35.5°C to 37.5°C (Gardner & Hernandez, 2016).

Cardiovascular Values. The heart is assessed for rate, rhythm, character of heart sounds, and presence of murmurs. During infancy the position of the heart changes and the point of maximal impulse (PMI) shifts (Fletcher, 1998). In the first few days of life the PMI is located at the fourth intercostal space at or to the left of the midclavicular line. Auscultation should be performed at the second and fourth intercostal spaces, cardiac apex, and axilla (Vargo, 2019). Murmurs are commonly heard before the ductus arteriosus closes completely. However, murmurs that are persistent may not be normal and require evaluation. Brief asymptomatic irregularities in rate and rhythm are not uncommon, especially in the preterm baby. The most common benign dysrhythmias are sinus bradycardia or tachycardia and premature atrial or ventricular contractions (Vargo, 2019). An ECG or heart monitor is needed to properly identify the abnormality. Exact identification of the abnormality cannot be made solely by auscultation.

A precordial impulse may be visible along the left sternal border during the first 6 hours (Fletcher, 1998; Vargo, 2019). In premature neonates, because of their thin skin and absence of subcutaneous fat, the precordial impulse may be visible for a longer period. Pulses are palpated for rate, strength, and synchrony.

Figure 4.10 shows the location of pulses in the neonate (Vargo, 2019). Radial or brachial pulses are compared for timing and intensity, and the same is then done for bilateral femoral pulses. Finally, the preductal and postductal pulses are examined.

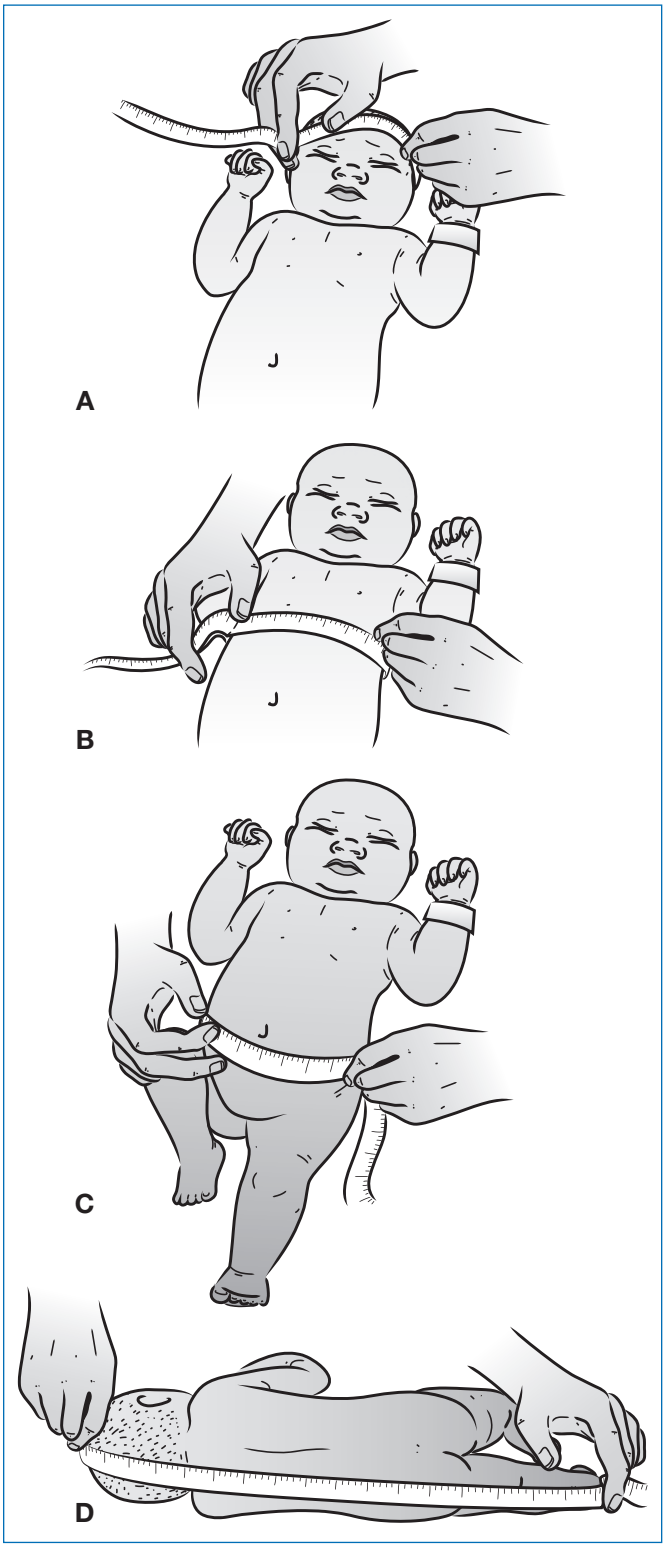

FIGURE 4.7 Newborn measurements. (A) Circumference of head, (B) circumference of chest, (C) circumference of abdomen, (D) length, crown to rump. (Total length includes the length of the legs.) If the measurements are taken before the infant's first bath, the nurse must wear gloves.

Source: Modified from Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.

The adequacy of the infant's perfusion is determined by checking the capillary refill. This is assessed by depressing the skin over the abdomen or on an extremity until the area blanches. The capillary refill time is the number of seconds that elapse until the color returns to the area. This should be less than 3 seconds.

General Appearance. The infant's general appearance is indicative of nutritional status, maturity, and overall well-being. Term neonates normally are well formed and rounded and have stores of subcutaneous fat. They assume the fetal position at rest. Premature babies may display less flexion than those born at term. Movement should be spontaneous and tremulous. Neonates range in mood from quiet to alert; they are consolable when crying. A normal cry is strong and sustained.

Skin. The skin is assessed for maturity, consistency, and color. Discolored areas, variations, or abnormalities are noted for size and

TABLE 4.8

BLOOD PRESSURE VALUES ACCORDING TO SITE AND AGE

	Blood Pressure (mmHg)		
Site and Age	Systolic	Diastolic	Mean
Calf			
<36 hours old	61.9 ± 7	39.6 ± 5.3	47.6 ± 6
>36 hours old	66.8 ± 10.1[a]	42.5 ± 7.3[a]	51.5 ± 9[a]
Total	63.6 ± 8.6	40.6 ± 6.3	49 ± 7.5

Notes: Values were obtained by blood pressure cuff measurement in 219 healthy term infants, 140 less than 36 hours old and 79 over 36 hours old. Values are given as means ± standard deviation.

[a] Significantly different from values in infants less than 36 hours old ($p < .05$).

TABLE 4.9

BLOOD PRESSURE RANGES IN DIFFERENT WEIGHT GROUPS OF PREMATURE NEWBORNS

	Blood Pressure (mmHg)	
Birth Weight (g)	Systolic	Diastolic
501–750 ($n = 18$)	50–62	26–36
751–1,000 ($n = 39$)	48–59	23–36
1,001–1,250 ($n = 30$)	49–61	26–35
1,251–1,500 ($n = 45$)	46–56	23–33
1,501–1,750 ($n = 51$)	46–58	23–33
1,751–2,000 ($n = 61$)	48–61	24–35

Notes: Measurements were obtained by blood pressure cuff or umbilical artery transducer in the first 3 to 6 hours of life.

Source: From Hegyi, T., Carbone, M. T., Anwar, M., Ostfeld, B., Hiatt, M., Koons, A., … Paneth, N. (1994). Blood pressure ranges in premature infants. I. The first hours of life. *Journal of Pediatrics, 124*, 627–633. doi:10.1016/S0022-3476(05)83146-4

location. The skin of a full-term newborn contains subcutaneous fat that provides insulation against heat loss. It is smooth, pink, and wrinkle free. Premature infants lack subcutaneous fat; their skin is thinner than that of term babies and has visible blood vessels over the chest and abdomen. Extremely immature babies often have a gelatinous appearance with transparent skin. They commonly have a red, ruddy color caused by underdevelopment of the stratum corneum. Subcutaneous fat also is lacking in neonates

TABLE 4.10

OSCILLOMETRIC MEASUREMENTS: MEAN ARTERIAL BLOOD PRESSURE

	Mean Arterial Pressure ± Standard Deviation		
Birth Weight (g)	Day 3	Day 17	Day 31
501–750	38 ± 8	44 ± 8	46 ± 11
751–1,000	43 ± 8	45 ± 7	47 ± 9
1,001–1,250	43 ± 8	46 ± 9	48 ± 8
1,251–1,500	45 ± 8	47 ± 8	47 ± 9

who are IUGR. This group of babies may have loose skin folds, particularly around the knees.

Vernix is the greasy yellow or white substance found on fetal skin, particularly in the axillary, nuchal, and inguinal folds. Composed of sebaceous gland secretions, lanugo, and desquamated epithelial cells, it protects against fluid loss and bacterial invasion (Sherman, 2015; Witt, 2019). Vernix is most abundant during the third trimester and decreases in amount as the fetus approaches 40 weeks.

Lanugo is fine, downy hair that first appears on the fetus at 19 to 20 weeks gestation and becomes most prominent at 27 to 28 weeks. It begins to disappear from the lower back and usually is not present at term.

Head. The head is inspected for shape, symmetry, bruises, and lesions. Neonates delivered by cesarean section generally have a rounded head. Infants born vaginally in vertex position can have overriding sutures; this results in an irregularly shaped head that persists only for a few days in full-term neonates but may be evident for several weeks in premature babies (Lissauer, 2015). The head circumference is measured in the occipitofrontal plane and is the largest diameter around the head. It is obtained with the tape measure placed snugly above the ears, the eyebrow ridges, and the occiput of the head. The average OFC in a full-term neonate is 35 cm, with a normal range of 31 to 38 cm (Johnson, 2019). The major bones of the head, as well as sutures and fontanelles, are shown in Figure 4.11.

The head should be palpated to assess the firmness of bone and the size and configuration of fontanelles and sutures and also to detect swelling, masses, or bony defects. The amount of overlap of sutures may vary, depending on the extent of molding. Normally the sutures should move freely when gentle pressure is applied to the bones on opposite sides of the suture lines (Furdon & Clark, 2003). Directly after birth, it may be difficult to determine if the sutures are fused or merely overlapping. Reevaluation when molding and overlap have resolved may yield more reliable information about the presence of craniosynostosis (Johnson, 2019).

The anterior fontanelle is 2 to 3 cm wide, 3 to 4 cm long, and diamond shaped (see Figure 4.11). It should be flat and soft; tense, bulging fontanelles may be reflective of intracranial pressure, while a sunken fontanelle can signify dehydration (Johnson, 2019). The

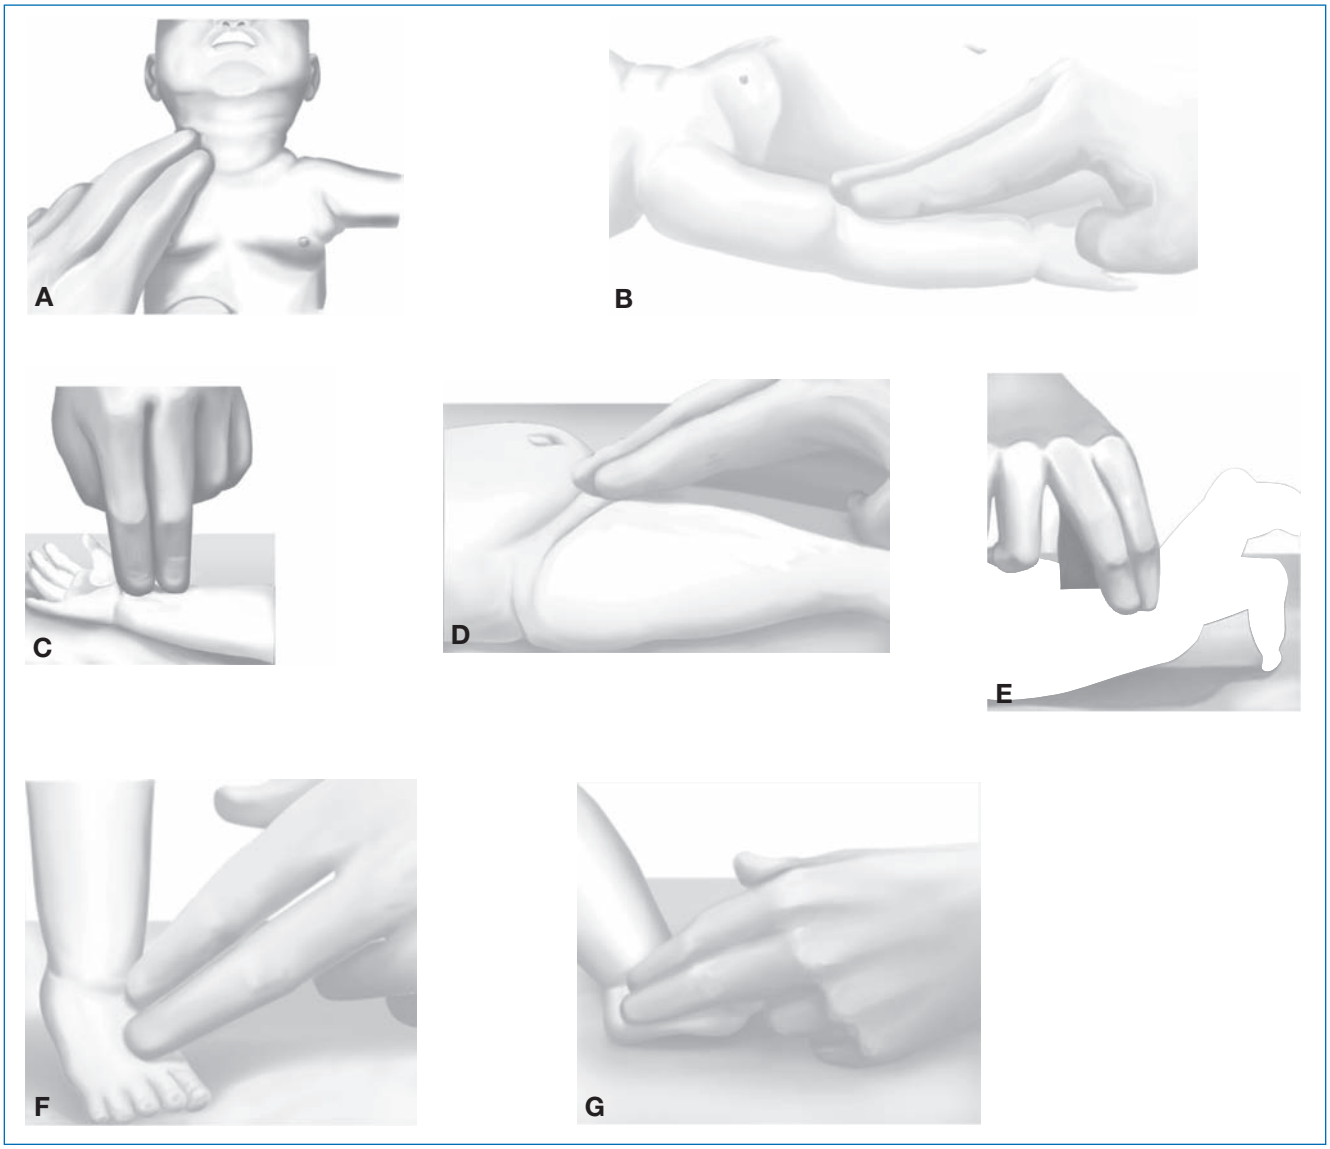

FIGURE 4.10 Palpation of arterial pulses. (A) Carotid, (B) brachial, (C) radial, (D) femoral, (E) popliteal, (F) dorsalis pedis, and (G) posterior tibial.

posterior fontanelle is 1 to 2 cm wide and triangular. It may be difficult to palpate the fontanelles directly after birth because of cranial molding. Tension in the fontanelle should be assessed with the infant both recumbent and upright. Serial measurements of the width of the anterior fontanelle are more helpful than a single measurement because of wide variations in size and differences in measurement techniques (Fletcher, 1998).

Hair is evaluated for color, length, continuity, texture, quantity, position and number of hair whorls, and hairlines. Term newborns have fine hair with identifiable individual strands. Hair may appear disheveled for the first several weeks to months (Fletcher, 1998). In premature neonates the hair is more widely dispersed and is described as "fuzzy." Normally, hair color is fairly uniform, although some neonates have a blend of light and dark hair (Furdon & Clark, 2003). Sporadic patches of white hair may be a familial trait and is a benign finding, but a white forelock and other pigmentation defects in the eyes or skin may be associated with deafness or mental retardation (Fletcher, 1998; Waardenburg, 1951). The anterior hairline varies, with normal growth of pigmented hair onto the forehead of hirsute babies. The posterior hairline ends at the neck crease. Usually one off-center hair whorl is present in the parietal region (Furdon & Clark, 2003).

Face and Neck. The face should be inspected for shape, symmetry, and the presence of bruising or dysmorphic features. The overall facial configuration should be evaluated; the features should be proportional and symmetric. Unusual facial features may be familial or pathognomonic of a malformation syndrome. Gag, sucking, and rooting reflexes should be evaluated.

The newborn has a relatively short neck that should be palpated or observed for symmetry, appearance of the skin, range of motion, masses, and fistulous openings. The neck should be symmetric with the head, demonstrating full range of motion (Carley & Duderstadt, 2019). In utero positioning can cause asymmetry of the neck. Redundant skin or webbing may be evident (Walker, 2018). The clavicles can be palpated at this time; they should be intact and without crepitus or swelling.

Ears. The ears are evaluated and compared for shape, configuration, position, amount of cartilage, and signs of trauma. The position

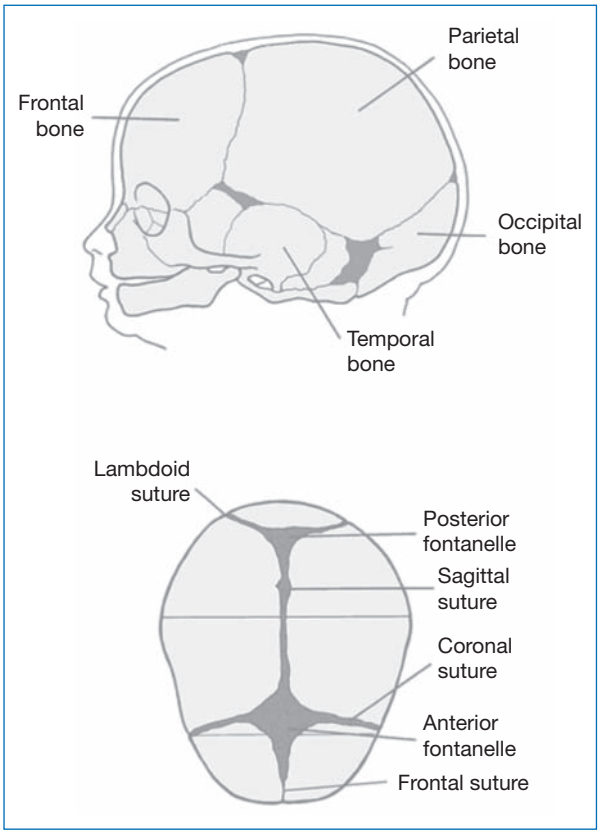

FIGURE 4.11 Major bones of the head in the newborn with sutures and fontanelles.

Source: Modified from Fletcher, M. A. (1998). *Physical diagnosis in neonatology.* Philadelphia, PA: Lippincott-Raven.

of the ears at term should be similar bilaterally; approximately 30% of the pinna should lie above a line from the inner and outer canthi of the eye toward the occiput. The rotation of the ears should also be assessed; the long axis of the pinna should lie approximately 15° posterior to the true vertical axis of the head (Fletcher, 1998; Figure 4.12). Abnormalities of the external ear may be associated with syndromes, but often they represent minor structural variations and may be within the normal range (Johnson, 2019).

The presence and patency of the auditory canal can be documented by inspection. Otoscopic examination is not usually part of the examination in the newborn period because the ear canals are filled with vernix, amniotic debris, and blood. This condition clears in approximately 60% of term infants by 1 week of age but may persist for weeks. Less debris is seen in preterm babies, whose canals may clear more quickly.

Because infants frequently remain hospitalized beyond the neonatal period and because evaluation of the middle ear is part of a health maintenance examination, it is appropriate to include otoscopic examination in this section. The otoscope is used differently in young infants than in adults. In a neonate the ear lobe is pulled toward the chin, and the speculum is directed toward the face. The ear canals of preterm babies are prone to collapse because they are more pliable. Positive pressure applied through the pneumatic otoscope prevents the cartilaginous ear canal from obscuring the view (Fletcher, 1998). The neonatal tympanic membrane is thicker, grayer, and more vascular than that of an adult or older child (Figure 4.13).

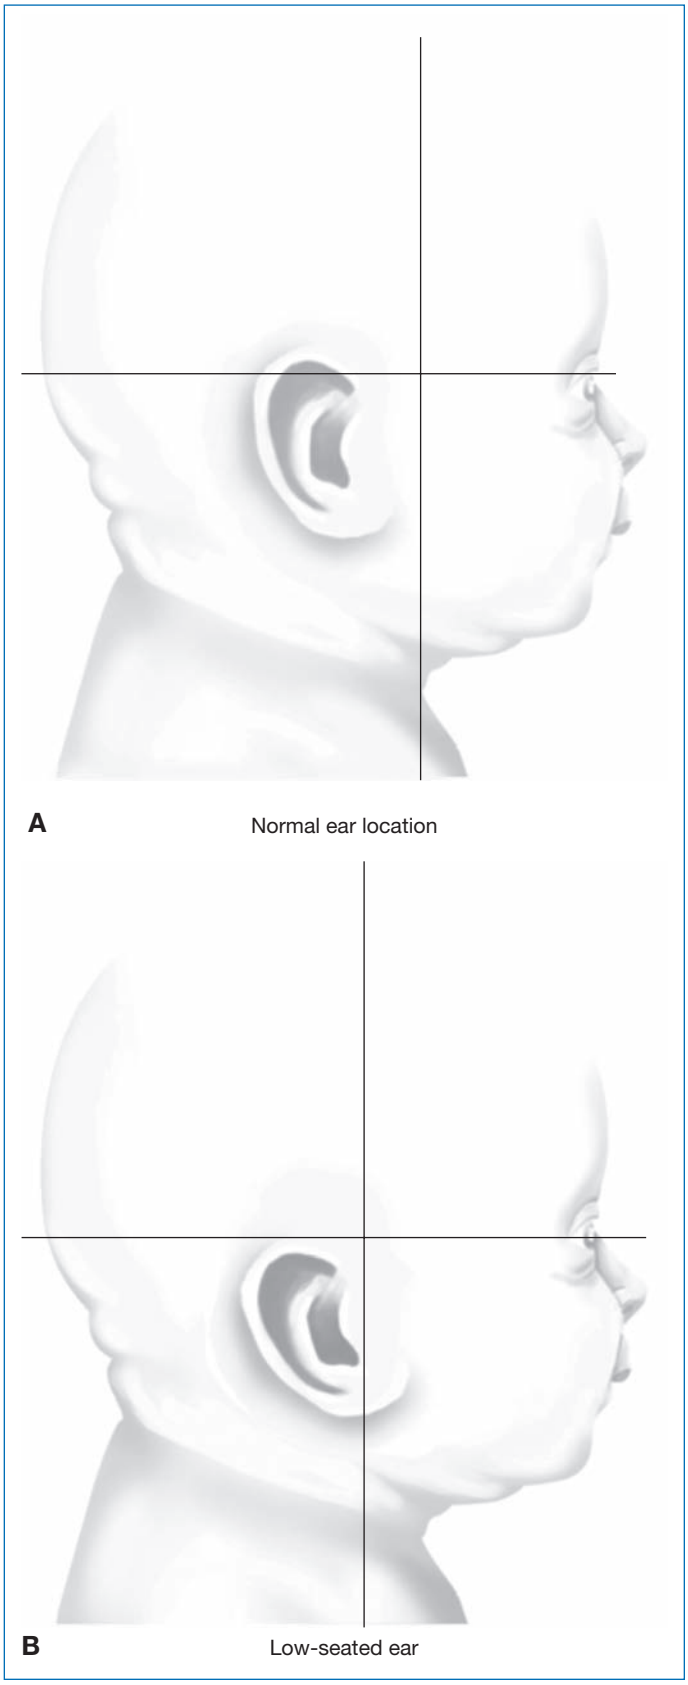

FIGURE 4.12 Normal (left) and low-seated (right) ear positions.

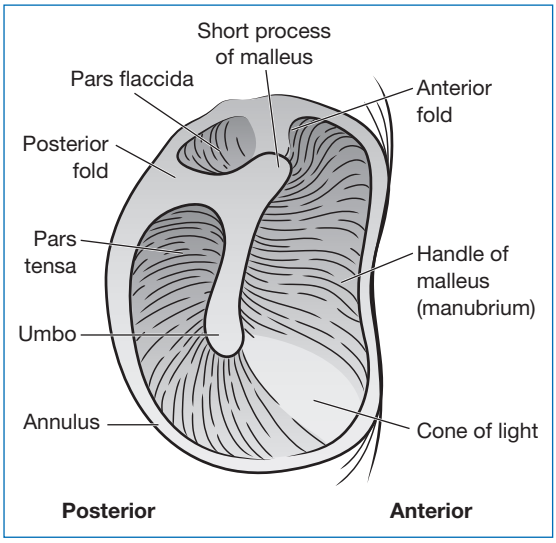

FIGURE 4.13 Normal landmarks of the right tympanic membrane as seen through an otoscope.

Source: Modified from Lewis, S. M., Bucher L., Heitkemper, M. M., Harding, M. M, Kwong, J., & Roberts, D. (2017). *Medical-surgical nursing: Assessment and management of clinical problems* (10th ed.). St. Louis, MO: Elsevier.

Universal hearing screening programs are mandated by law in all 50 states (Centers for Disease Control and Prevention, n.d.).

Eyes. The eyes should show spontaneous range of motion and conjugate movements. The lids should be symmetric in both horizontal and vertical placement, and the lashes should be directed outward in an orderly fashion. The eyes should be clear and should have an evenly colored iris, which may be dark gray, blue, or brown, depending on race. Pigmentation should be similar between the two eyes. Permanent eye color is not established for several months, but darker races may show permanent pigmentation in the first week of life. The surface of the conjunctiva should be smooth. During the first few days of life, the cornea may appear slightly hazy as a result of corneal edema, but thereafter the cornea should be clear and shiny. The sclerae normally are white, but a bluish coloration may be noted in premature and other small infants because their sclerae are thinner (Fletcher, 1998; Orge & Grigorian, 2015).

An ophthalmoscope is used to assess the pupillary and red reflexes. The light should be directed on the pupils from a distance of approximately 6 inches. The pupils should be round and equal in diameter and should constrict equally in response to light (pupils equal and reactive to light, or PERL; Johnson, 2019). The beam of light illuminating the retina causes the red reflex. The retina (fundus) appears as a yellowish-white/gray or red background, depending on the amount of melanin in the pigment epithelium. The pigment varies with the complexion of the baby; in dark-skinned infants, the reflex will be pale or cloudy (Honeyfield, 2019; Lissauer, 2015).

Nose. The nose should be evaluated for shape and symmetry, patency of nares, skin lesions, or signs of trauma. The nasal mucosa should be pink and slightly moist; secretions should be thin, clear, and usually scanty (Fletcher, 1998). The nose should be midline. Immediately after birth the nose may be misshapen as a result of compression in utero, but this should correct spontaneously in a few days (Fletcher, 1998). Obstructions and deformities may denote anatomic malformations or congenital syndromes. The patency of the nares can be demonstrated by alternate occlusion of each naris using gentle pressure (Fletcher, 1998). Nasal flaring may be indicative of respiratory distress, but in an otherwise healthy newborn it does not indicate respiratory distress when it appears as the only symptom (Gardner & Hernandez, 2016).

Mouth. The mouth is inspected for size, shape, color, and presence of abnormal structures and masses. It should be evaluated both at rest and while the infant is crying. The speed of response and intensity of neonatal reflexes, such as rooting, gagging, and sucking, are also assessed. The mouth is a midline structure and symmetric in shape and movement. The mouth, chin, and tongue should be in proportion, with the lips fully formed (Johnson, 2019; Heaberlin, 2019).

The mucous membranes should be pink and moist, and oral secretions should be thin and clear. Excessive secretions or drooling suggests inability to swallow or esophageal or pharyngeal obstruction. Both the hard and soft palates should be inspected and palpated to rule out clefts. A high-arched palate may be seen in malformation syndromes, but it generally is insignificant if it appears as an isolated characteristic (Lissauer, 2015).

The tongue should be smooth on all surfaces; the lingual frenulum may be short but not so short as to restrict tongue movement. Limitation of movement would be obvious on crying, when the tip of the tongue would form an inverted *V* (Fletcher, 1998; Johnson, 2019).

Thorax. The chest is evaluated for size, symmetry, musculature, bony structure, number and location of nipples, and ease of respiration. It should be symmetric in shape and movements. Because the anteroposterior diameter is approximately equal to the transverse diameter, the chest appears round. The chest circumference of a term infant should be about 2 cm smaller than the head circumference (Fraser, 2019). At all GAs, the chest measurement normally is smaller than the OFC (Duderstadt, 2019).

Occasional mild subcostal retractions may be seen in healthy newborns because of decreased compliance of the ribs. A paradoxical breathing pattern is typical of newborns, especially during sleep. On inspiration the chest wall is drawn in and the abdomen protrudes; the reverse occurs on expiration (Fletcher, 1998). However, in neonates with respiratory distress, this may be indicative of inadequate lung compliance and deficiency of lung volume (Fraser, 2019).

The amount of breast tissue depends on the GA and birth weight, whereas areolar development reflects only GA. Two nipples should be present in equal alignment. The internipple distance varies by GA and chest circumference, but the distance from the outer edge of one areola to the outer edge of the other should be less than 25% of the circumference of the chest (Fraser, 2019). Widely spaced nipples are associated with a variety of congenital syndromes (Fraser, 2019).

Newborn breast tissue may hypertrophy as a result of the influence of maternal hormones. A milky substance (witch's milk) may appear toward the end of the first week of life, and this discharge may persist for a few weeks to several months (Fraser, 2019).

Abdomen. The abdomen is inspected for contour and size, symmetry, character of skin, and umbilical cord location and anatomy. Palpation yields information about muscle mass and tone of the abdominal wall, location and size of viscera, tenderness, and masses (Goodwin, 2019). Bowel sounds are detected on auscultation; they are relatively quiet in newborns until feedings are established. Compared with term babies, preterm neonates have less active bowel sounds. Evaluating changes in bowel sounds from the infant's baseline is more clinically useful than an isolated assessment (Fletcher, 1998).

The normal abdomen in an infant is round and soft and protrudes slightly. The umbilical cord should be bluish white, shiny, and moist and should have two arteries and one vein. To facilitate palpation, the knees and legs should be flexed toward the hips,

which allow the abdominal muscles to relax. The edge of the liver can be palpated 1 to 2 cm below the right costal margin at the midclavicular line; this edge should be smooth, firm, and well defined (Goodwin, 2019). The tip of the spleen can be felt below the left costal margin in newborn infants. The size of the spleen depends on variables such as circulating blood volume, day of life, method of delivery, and type of therapy, which must be considered when interpreting the significance of mild enlargement (Fletcher, 1998).

The kidneys are located in the flanks. The lower pole of both kidneys should be palpable because of the reduced tone of neonatal abdominal muscles (Vogt & Dell, 2015). The kidneys should be smooth and firm to the touch. Enlarged kidneys are somewhat easy to detect, but normal-size neonatal kidneys may be somewhat more difficult to find. The presence of renal tissue is confirmed when voiding has occurred (Cavaliere, 2019).

Anogenital Area. The anogenital area should be examined with the infant supine. GA affects the appearance of the external genitalia. Maturational changes are described in Figure 4.6 and Table 4.7. The genitalia should be readily identifiable as male or female.

- *Males:* The normal length of the penis at term is 3.5 cm (±0.7 cm; Fletcher, 1998). Gentle traction is applied on the foreskin to visualize the urethral meatus; the opening should be at the central tip of the glans. Physiologic phimosis, a nonretractable foreskin, normally is seen in newborns. The opening in the prepuce should be large enough to allow urination. The urine stream should be forceful and straight. The inguinal area and scrotum should be palpated for masses, swelling, and the presence of testes. The testes should be firm, smooth, and comparatively equal in size. Testicular descent begins at approximately 27 weeks' gestation. At term both testes should be in the scrotum, which should be fully rugated. The scrotum should be more deeply pigmented than the surrounding skin (Cavaliere, 2019).
- *Females:* The labial, inguinal, and suprapubic areas are inspected and palpated to detect masses, swelling, or bulges. The clitoris should be located superior to the vaginal opening. Hymenal tags and mucous/bloody vaginal discharges are benign, transient findings.

Edema of the genitalia is common in both sexes in breech deliveries. It may also be due to the effects of transplacentally acquired maternal hormones. The perineum should be smooth and should have no dimpling, fistulae, or discharges (Cavaliere, 2019; Gardner & Hernandez, 2016).

The anus is evaluated for patency and tone. Patency can be documented by gentle insertion of a soft rubber catheter. The passage of meconium does not confirm a patent anus, because meconium may be passed through a fistulous tract (Fletcher, 1998; Parry, 2015). Gentle stroking of the anal area should produce constriction of the sphincter, known as the anal wink (Goodwin, 2019).

Back. The infant should be placed in the prone position while the back is examined for curvature, patency, and presence of structural abnormalities. Vertebrae are palpated for enlargement and pain. Symmetry should be seen on both sides of the back and between the two scapulae. The spine should be straight and flexible and should have no visible defects, such as pits, hair tufts, or dimples (Tappero, 2019).

Extremities and Hips. The extremities are observed for symmetry, degree of flexion, and presence of defects and fractures. Full range of motion should be present, and the extremities should move symmetrically. Although symmetry of gluteal skin folds suggests normal hips, the Ortolani and Barlow maneuvers should be performed to confirm the stability of the hips (Figure 4.14). The Ortolani maneuver reduces a dislocated femoral head into the acetabulum, and the Barlow maneuver reflects the ability of the femoral head to be dislocated (Tappero, 2019).

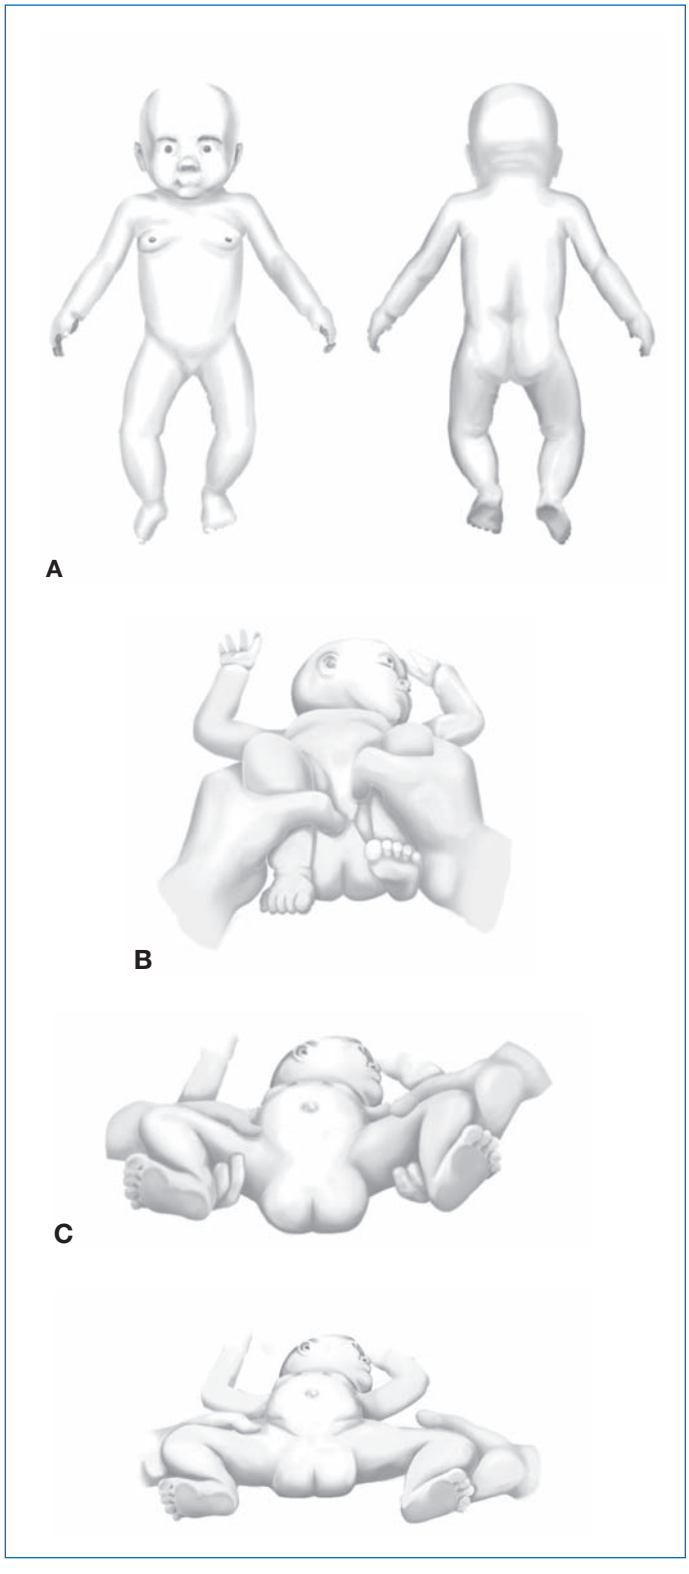

FIGURE 4.14 Signs of congenital dislocation of hip. (A) Asymmetry of gluteal and thigh folds, (B) Barlow maneuver, and (C) Ortolani maneuver.

The limbs should be equal in length, and they should be in proportion to the body; they also should be straight and should have no

TABLE 4.11

ASSESSMENT OF NEONATAL REFLEXES

Reflex	Technique	Response	Comments
Asymmetric tonic neck	With infant supine and in light sleep or quiet awake state, turn head to right until jaw is over shoulder; hold for 15 seconds, then release.	Occipital flexion and mental extension; right arm and leg are extended; left arm and leg are flexed. Premature neonates may lie at rest in this position for extended periods.	Reflex appears at 35 weeks gestation and disappears by 6–7 months of age.
Babinski	Using thumbnail, scratch sole of foot at lateral side from toes to heel.	Dorsal flexion of great toe with extension of other toes.	Care must be taken not to elicit plantar grasp by stimulating sole of foot. Reflex appears at 34–36 weeks gestation, is well established at 38 weeks, and disappears at 12 months of age.
Doll's eyes	Rotate head from side to side, observing eye movement.	As head is moved to right or left, eyes move in opposite direction.	Lack of eye movement with head rotation or movement of eyes in same direction as head may indicate brainstem or oculomotor nerve dysfunction. Reflex is well established and may even be exaggerated at 24–25 weeks' gestation.
Galant (truncal incurvation)	Place infant prone, either lying on flat surface or in suspension; lightly stroke along either side of spinal column from shoulder to buttocks.	Normal response is strong incurvation of whole vertebral column toward stimulated side.	Reflex is first seen at 28 weeks' gestation.
Glabellar	Hold head firmly and tap forehead just above nose.	Normal response is tighter closure of both eyes and wrinkling of brow.	Asymmetry, absent or exceptionally strong response (closure longer than 1 second), or generalized startle is abnormal.
Moro	Hold infant suspended over mattress, supporting head with one hand and body with other hand; rapidly lower both hands 10–20 cm without flexing neck, but do not allow baby to drop back to mattress.	Symmetric abduction of arms and extension at elbows with hands open completely, followed by adduction of arms and flexion at elbows with curling of fingers; infant cries or grimaces at conclusion.	Response attenuates and ultimately disappears with repetition as habituation occurs. No response is seen at <26 weeks' gestation; extension only at 30 weeks; variable adduction at 34 weeks; complete response at 38 weeks. Reflex disappears at 6 months of age.
Palmar grasp	Stimulate palmar surface of hand with a finger.	Neonate grasps finger; grasp tightens with attempt to remove finger.	Reflex appears at 28 weeks' gestation, is well established after 32 weeks, and disappears at 2 months of age.
Pupillary	Elicit in darkened environment by presenting bright, sharply focused light from periphery.	Pupils constrict equally.	Reflex is sluggish but present between 28 and 32 weeks' gestation in healthy neonates; it is fully present after 34 weeks.
Rooting	Stroke cheek and corner of mouth.	Mouth opens and head turns toward stimulus.	Reflex appears at 28 weeks' gestation, followed by long latency period beginning at 30 weeks; it is well established at 32–34 weeks and disappears by 3–4 months of age.
Stepping	Hold neonate upright and allow feet to touch flat surface.	Alternating stepping movements.	Reflex appears at 35–36 weeks gestation, is well established at 37 weeks, and disappears at 3–4 months of age.
Sucking	Touch or stroke lips.	Mouth opens, and neonate begins to suck.	Reflex appears at 28 weeks' gestation, is well established by 32–34 weeks, and disappears at 12 months of age.

Source: Data from Heaberlin, P. D. (2019). Neurologic assessment. In E. P. Tappero & M. E. Honeyfield (Eds.), *Physical assessment of the newborn* (6th ed., pp. 167–192.). New York, NY: Springer Publishing Company.

edema or crepitus. Palpation or movement of the limbs should not produce a painful response. The digits should be equally spaced and have no webbing. The nails should extend to the end of the nail beds.

Reflexes. The most common neonatal reflexes are presented in Table 4.11.

Variations and Abnormal Findings on Physical Examination

Minor variations and abnormal findings of the physical examination are presented in Table 4.12.

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS

Finding	Definition/Description	Comments
Skin		
Color	Acrocyanosis (blue discoloration of the hands, feet, and perioral area), commonly seen in the first 6–24 hours of life.	Occurs when blood flow to an area is sluggish and all available oxygen has been extracted (Carley & Duderstadt, 2019); exacerbated by cooling and diminished by warming; normal variation but abnormal if persists beyond the first 24 hours of life.
	Cutis marmorata (mottling of the skin in response to cold or other stressful stimuli); caused by dilation of capillaries, usually greatest on the extremities but may be seen on the trunk.	May be suggestive of other conditions (e.g., cardiovascular hypertension, hypothyroidism) if mottling is extensive, shows no improvement with warming, or persists beyond first few months (Fletcher, 1998; Vargo, 2019).
	Cyanosis (blue discoloration of the skin, tongue, and mucous membranes).	Caused by excess of desaturated hemoglobin in the blood (cardiopulmonary disease) or a structural defect in the hemoglobin molecule (methemoglobin); always an abnormal finding.
	Jaundice (yellow coloring of the skin, mucous membranes, and sclerae).	Caused by deposition of bilirubin; may be physiologic.
	Pallor (absence of color or paleness of the skin).	Caused by a decrease in cardiac output, subcutaneous edema, anemia, or asphyxia (Lissauer, 2015).
	Plethora (ruddy skin coloration in the newborn).	Caused by high circulating red blood cell volume (abnormal finding).
Lesions	Café au lait spots (light tan or brown macules with well-defined borders, representing areas of increased epidermal melanosis); except for deeper pigmentation, appearance is not different from that of surrounding skin.	More common in normal infants of color. Six or more macules, regardless of spots' size or infant's race, may be pathologically significant, especially if located in the axilla.
	Cutis aplasia (localized or widespread foci of absence of some or all layers of skin); defect may be covered by a thin, translucent membrane or scar tissue, or area may be raw and ulcerated.	Occurs predominantly on the scalp and less frequently on the limbs and trunk (Hoath & Narendran, 2015).
	Ecchymosis (nonblanching purple or blue-black macule larger than 2 mm in diameter); represents extravasation of blood into subcutaneous tissue.	Results from trauma to underlying blood vessels or fragility of the vessel walls.
	Erythema toxicum (white or yellow papules on red macular base), commonly found on face, trunk, or proximal extremities but not on hands or feet.	Common, benign finding; vesicles are rare, sterile, and composed primarily of eosinophils (Witt, 2019). When vesicles are pronounced or coalescent, they may mimic postural infectious rash.

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
	Harlequin fetus (most severe form of congenital ichthyosis; skin is completely covered with thick, horny scales resembling armor that are divided by deep red fissures).	Most such infants die of dehydration, infection, or respiratory insufficiency within a few hours or days (Hoath & Narendran, 2015).
	Harlequin sign (vascular phenomenon represented by distinct midline demarcation in side-lying infants; dependent half is deep red, upper half is pale).	Benign finding that lasts a few seconds to 30 minutes, occasionally reverses when position is changed. The physiologic basis is unidentified; without pathologic significance. Occurs most frequently in LBW neonates (Hoath & Narendran, 2015; Witt, 2019).
	Strawberry hemangioma (red, raised, circumscribed, soft, compressible, lobulated tumor; may occur anywhere on the body).	Benign tumor of the vascular endothelium that has a proliferative and an involutional phase; most involute spontaneously. Treatment is unnecessary unless vital functions are affected (Hoath & Narendran, 2015; Witt, 2019).
	Cavernous hemangioma (similar to strawberry hemangioma; involves dermis and subcutaneous tissue and is soft and compressible on palpation; overlying skin is bluish-red in color).	Cavernous lesions may cause thrombocytopenia (Kasabach–Merritt syndrome) or hypertrophy of bone and soft structures of extremities (Klippel-Trenaunay-Weber syndrome; Hoath & Narendran, 2015; Witt, 2019).
	Mongolian spot (blue-black macule, lacking a sharp border, most frequently seen on sacrum, buttocks, flanks, or shoulders).	Benign lesion, common in dark-skinned neonates, resulting from delayed disappearance of dermal melanocytes; lesion gradually disappears during the first years of life (Witt, 2019).
	Milia (1 mm, pearly white or yellow papules without erythema; in the mouth these are called Epstein's pearls).	Epidermal inclusion cysts caused by blockage of sebaceous glands; a benign finding that resolves during the first weeks of life (Witt, 2019).
	Miliaria—three types 1. Crystallina (1–2 mm, thin-walled vesicles with nonerythematous and nonpigmented base [without inflammation]). 2. Rubra—small, erythematous, grouped papules [prickly heat]). 3. Pustulosis or profunda (nonerythematous pustules).	Lesions caused by blockage of sweat glands. They are exacerbated by a warm, humid environment and most frequently develop in intertriginous areas and over the face and scalp. They resolve when the environmental factors are eliminated (Hoath & Narendran, 2015; Witt, 2019).
	Neonatal pustular melanosis (small, superficial vesiculopustules with little or no surrounding erythema; crusted or scaly collarettes appear after vesicles rupture; lesions eventually resolve into hyperpigmented areas).	Transient and benign; frequently confused with infectious lesions. Smears of pustular material reveal predominantly neutrophils and no bacteria. (Hoath & Narendaran, 2015; Witt, 2019).
	Salmon patch (nevus; dull, pink-red, irregularly shaped macules that blanch on pressure; commonly found on nape of neck [stork bite], glabella, forehead, eyelids, and upper lip).	Benign finding; lesions are composed of distended, dilated capillaries, and most lesions (except those on the neck) disappear by 1 year of age (Witt, 2019).
	Port wine stain (nevus, macular lesion; present at birth but may be pale and hard to discern; initially pink in color with sharply delineated borders; progresses to dark red/purple; some develop small, angiomatous nodules).	Developmental vascular malformation that occurs mostly on the face; does not increase in size but grows with the infant; may occur alone or with structural anomalies (e.g., Sturge–Weber syndrome; Hoath & Narendran, 2015; Witt, 2019).

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
	Petechiae (tiny red or purple, nonblanching macules that range from pinpoint to pin head size).	Caused by minute hemorrhages in the dermal or submucosal layers; may be benign and self-limiting or pathognomonic of serious underlying conditions. They are benign when found on presenting part and when localized areas appear at the same time; progressive, widespread areas require evaluation (Fletcher, 1998; Witt, 2019).
Redundant skin	More skin than is necessary or normally present in a particular area.	Seen in the neck after resolution of cystic hygroma or in the abdomen in a neonate with prune belly syndrome.
Sclerema neonatorum	Diffuse, stone-hard, nonpitting cutaneous induration; overlying skin appears pale and waxy; face has a mask-like appearance; joints are stiff.	Occurs in debilitated neonates; diffuse systemic process with grave prognosis (Hoath & Narendran, 2015).
Subcutaneous fat necrosis	Firm, nonpitting, poorly circumscribed, reddish violet lesions appearing in the first weeks of life on the face, arms, trunk, thighs, and buttocks. Affected areas may be slightly elevated above adjacent skin (Mangurten, Puppala, & Prazad, 2015).	Most often seen in areas where a fat pad is present. May occur secondary to cold or trauma and sometimes accompanied by hypercalcemia (Hoath & Narendran, 2015).
Head and Neck		
Acrocephaly	Congenital malformation of the skull caused by premature closure of the coronal and sagittal sutures; accelerated upward growth of the head gives it a long, narrow appearance with a conic shape at the top (also called oxycephaly).	May be associated with premature closure of sutures; found with certain syndromes (e.g., Crouzon's, Apert's; Robinson & Cohen, 2015a).
Anencephaly	Failed closure of the anterior neural tube without skull formation; the brain is severely malformed, lacking definable structure, although a rudimentary brainstem usually is present.	Most affected neonates (75%) are stillborn; without intervention; the remainder die in the neonatal period (Gressens & Huppi, 2015; Robinson & Cohen, 2015a).
Brachycephaly	Congenital malformation of the skull caused by premature closure of the coronal suture; excessive lateral growth of the head gives it a short, broad appearance.	Condition found with certain syndromes (e.g., trisomy 21, Apert's; Robinson & Cohen, 2015a).
Bruit	Abnormal murmur-like sound heard on auscultation of an organ or gland that is caused by dilated, tortuous, or constricted vessels. The specific character of the bruit, its location, its association with other clinical findings, and the time of occurrence in a cycle of other sounds is of diagnostic importance.	Bruits heard over the fontanelle or lateral skull associated with signs of congestive heart failure may denote intracranial arteriovenous malformation (Heaberlin, 2019; Johnson, 2019).
Caput succedaneum	Vaguely demarcated pitting edema of the scalp that may extend across suture lines and can shift in response to gravity.	Benign finding that appears at birth (from pressure of the maternal cervix on the fetal skull) and resolves in a few days (Mangurten et al., 2015).

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
Cephalohematoma	Extradural fluid collection caused by bleeding between the skull and periosteum; generally occurs over one or both parietal bones and does not cross the suture lines; has distinct margins and may be fluctuant or tense.	1. May form during labor and enlarges for the first 12–24 hours; most resolve spontaneously over several weeks to months (Johnson, 2019; Johnson, 2017). 2. Linear skull fracture is found in 5% of unilateral and 18% of bilateral lesions (Abdulhayoglu, 2017; Johnson, 2019; Mangurten et al., 2015). 3. May result in hyperbilirubinemia (Mangurten et al., 2015).
Craniosynostosis	Premature closure of one or more cranial sutures, causing abnormal skull shape and possibly a palpable ridge along the suture line.	Head growth is restricted in the area perpendicular to the stenotic suture and is excessive in unrestricted areas. Most cases are isolated events, but the condition can occur in some syndromes (Robinson & Cohen, 2015a).
Craniotabes	Congenital thinness of bone at the top and back of the head. Bones may collapse with gentle pressure and recoil (ping-pong).	1. May be a normal variant if present to a mild degree near suture lines. May be caused by the pressure of the skull against the maternal pelvic brim; spontaneous resolution usually occurs in a few weeks (Fletcher, 1998). 2. May be associated with congenital syphilis and other congenital conditions (osteogenesis imperfecta); due to bone resorption or delay in ossification (Walker, 2018).
Dolichocephaly or scaphocephaly	Congenital malformation of the skull in which premature closure of the sagittal suture results in restricted lateral growth.	Long, narrow head (Robinson & Cohen, 2015a).
	Skull shape often seen in premature babies as a result of prolonged positioning with head turned to the side.	
Encephalocele	Protrusion of brain tissue through a congenital defect in the cranium; most often occurs in the occipital midline but may also be seen in the frontal, temporal, or parietal areas.	Other cranial defects, congenital anomalies (hydrocephalus, microcephaly, craniosynostosis), and autosomal recessive syndromes (Walker–Warburg) are frequently seen (Gressens & Huppi, 2015).
Hair whorls	Two or more hair whorls, or abnormally placed whorls (other than parietal area).	May indicate brain anomaly; it has been postulated that the pattern of hair development correlates with underlying brain development (Johnson, 2019).
Macrocephaly	Excessive head size in relation to weight, length, and GA. OFC is over 90th percentile.	1. Familial; facial features usually are normal. 2. May reflect pathologic condition (e.g., hydrocephaly, hydranencephaly) or chromosomal or neuroendocrine disorder (Bauer-Huang & Doherty, 2018).
Microcephaly	Abnormally small head size relative to weight, length, and GA. OFC is under 10th percentile.	Associated with either microcephaly (marked reduction in size of brain or cerebral hemispheres) or acquired brain atrophy.
Molding	Process by which the head shape is altered as the fetus passes through the birth canal.	Benign finding; condition usually resolves during the first few postnatal days.
	The biparietal diameter becomes compressed, the head is elongated, and the skull bones may overlap at the suture lines.	
Neck masses	May be detected on palpation or inspection.	Most common neck mass; caused by development of sequestered lymph channels, which dilate into cysts (Lissauer, 2015; Johnson, 2019).

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
	Cystic hygroma (soft, fluctuant mass that is easily transilluminated; usually laterally placed or over clavicles).	
	Goiter (anterior mass caused by hypothyroidism).	Rare in neonates (Johnson, 2019).
	Thyroglossal duct cyst/branchial cleft cyst; a mass may be found high in the neck.	Rare in neonates (Johnson, 2019).
Plagiocephaly	Asymmetry of the skull due to flattening of the occiput. Can be deformational (positional) or due to premature or irregular closure of the coronal or lambdoidal sutures.	1. Posterior plagiocephaly almost always due to mechanical forces (positional; "back to sleep"). 2. Anterior plagiocephaly most commonly due to premature fusion of the sutures (Robinson & Cohen, 2015a).
Subgaleal	Bleeding into the potential space between the epicranial aponeurosis and the periosteum of the skull; manifests as a firm to fluctuant scalp mass with poorly demarcated borders that may extend onto the face, forehead, or neck and may be accompanied by signs of hypovolemia.	May be a life-threatening condition; can be caused by hemorrhage coagulopathy, asphyxia, or vacuum extraction (Mangurten et al., 2015).
Webbed neck	Redundant skin at posterolateral region of neck.	Found with Turner's, Noonan's, and Down syndromes (Bennett & Meier, 2019).
Face		
Asymmetry	Unequal appearance or movement of mouth and lips; unequal closure of eyes; uneven appearance of nasolabial folds.	Often caused by in utero positioning but may be due to facial nerve paresis; in mild cases may be evident only with crying (affected side fails to move or moves less when infant cries).
Ears		
Auricular appendage	Accessory tragi, most commonly in pretragal area; may occur within or behind the ear. These structures contain cartilage and are not truly skin tags.	Primarily of cosmetic significance unless accompanied by other diffuse malformations. Seen in certain congenital syndromes (e.g., Goldenhar's, Treacher Collins); hearing assessment is indicated when other anomalies are present (Johnson, 2019; Parikh & Mitchell, 2015).
Auricular sinus	Narrow, fistulous tract most often located directly anterior to helix.	May be familial or may be associated with microtia, auricular appendage, facial cleft syndromes, and syndromic anomalies of the outer ear (Parikh & Mitchell, 2015; Spilman, 2002).
Low-set ears	Superior attachment of pinna lies below imaginary line drawn between both inner canthi and extended posteriorly.	May be associated with chromosomal or renal anomalies (Lewis, 2014a, b).
Microtia	Severely misshapen, dysplastic external ear.	Frequently associated with other malformations that result in conductive hearing loss (i.e., atresia of auditory meatus, abnormalities of middle ear; Parikh & Mitchell, 2015; Walker, 2018).

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
Eyes		
Blepharophimosis	Narrow palpebral fissures in the horizontal measurement; also known as short palpebral fissures.	Usually caused by lateral displacement of the inner canthi; seen in certain dysmorphic or chromosomal syndromes (Fletcher, 1998; Orge & Grigorian, 2015).
Brushfield spots	Pinpoint white or light yellow spots on the iris.	Seen in 75% of neonates with Down syndrome but may also be a normal variant; not always visible at birth (Johnson, 2019; Orge & Grigorian, 2015).
Coloboma	Cleft-shaped defect in ocular tissue (eyelid, iris, ciliary body, retina, or optic nerve).	Result of incomplete embryologic closure of ocular structures; may be an isolated finding or part of a malformation syndrome (CHARGE, trisomies 13, 18, 22; Bennett & Meier, 2019; Orge & Grigorian, 2015).
Ectropion	Eversion of the margin of the eyelid, which leaves the conjunctiva exposed.	Seen in facial nerve paralysis, in certain syndromes, and in harlequin fetus and collodion baby (Fletcher, 1998; Orge & Grigorian, 2015).
Entropion	Inversion of the eyelid; eyelashes may be in contact with the cornea and conjunctiva.	Congenital condition that usually resolves spontaneously without damage (Fletcher, 1998; Lissauer, 2015; Orge & Grigorian, 2015).
Epicanthal folds	Vertical fold of skin at the inner canthus on either side of the nose.	A feature of normal fetal development and may be present in normal infants. Characteristic of trisomy 21 but may occur in malformation syndromes, especially those with a flat nasal bridge; may also be a physical manifestation of in utero compression (Potter facies; Parikh & Mitchell, 2015).
Exophthalmos	Abnormal displacement of the eye characterized by protrusion of the eyeball.	May be caused by increased volume of the orbit (tumor), swelling secondary to edema or hemorrhage, endocrine disorder (e.g., Graves' disease, hyperthyroidism); known as proptosis when accompanied by shallow orbits (Crouzon's disease; Fletcher, 1998; Orge & Grigorian, 2015).
Hypertelorism	Increased distance between the orbits, observed clinically as a large interpupillary distance (see Telecanthus; Parikh & Mitchell, 2015).	Frequently seen in craniofacial syndromes (Orge & Grigorian, 2015).
Hypotelorism	Decreased distance between the orbits, observed clinically as smaller than normal interpupillary distance (Parikh & Mitchell, 2015).	Frequently seen in trisomies 13 and 21 and in other syndromes (Orge & Grigorian, 2015).
Leukocoria	White pupil, denoting an abnormality of the lens, vitreous, or fundus; an indication for further evaluation (Orge & Grigorian, 2015).	May be seen on direct visualization, or as absence of a red reflex; most commonly seen in cataracts; also found in retinoblastoma, retinal detachment, and vitreous hemorrhage.
Microphthalmia	Small eye; diameter measures less than two-third of the normal 16 mm at birth (Orge & Grigorian, 2015).	Can be hereditary or caused by chromosomal anomalies and environmental influences during development. Associated with multisystem conditions or syndromes (e.g., CHARGE, trisomy 13, fetal rubella effects).

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
Nystagmus	Involuntary, rhythmic movements of the eye; may be horizontal, vertical, rotary, or mixed. Optokinetic nystagmus reflexive response to a moving target.	Occasional, intermittent nystagmus in an otherwise healthy newborn may be normal in the neonatal period; however, it must be evaluated if frequent or persistent (or both). Pathologic forms may be due to ocular, neurologic, or vestibular defects (Orge & Grigorian, 2015).
Ptosis (blepharoptosis)	Abnormal drooping of one or both upper eyelids; lid does not rise to normal level.	Caused by congenital or acquired weakness in the levator muscle or paralysis of the third cranial nerve; may be difficult to detect in neonates unless unilateral with asymmetry between the eyelids (Orge & Grigorian, 2015).
Strabismus	Misalignment of the visual axes: Esotropia—crossed eyes Exotropia—wall eye.	Refer for ophthalmologic evaluation if present by third month of age. Results from inheritance, paralysis of the lateral rectus muscle, or refractive errors; may be due to diseases that reduce visual acuity in one eye (Orge & Grigorian, 2015).
Subconjunctival hemorrhage	Bright red area on sclerae.	Caused by rupture of a capillary in the mucous membrane that lines the conjunctiva; commonly seen after vaginal delivery, does not reflect ocular trauma unless massive and associated with other findings; usually resolves in 7–10 days (Mangurten et al., 2015).
Synophrys	Meeting of the eyebrows in the midline.	Seen in multisystem conditions or syndromes (e.g., Cornelia de Lange's, congenital hypertrichosis; Parikh & Mitchell, 2015).
Telecanthus	Lateral displacement of the inner canthi; eyes appear too widely set because of a disproportionate increase between the inner canthi; interorbital distance is appropriate (Parikh & Mitchell, 2015).	Evident in fetal alcohol syndrome and other syndromes; not synonymous with hypertelorism, although its presence can lead to a false impression of hypertelorism (Sharma, 2014).
Nose		
Choanal atresia	Obstruction of posterior nasal passages.	Patency is assessed in the quiet state. If condition is bilateral, neonate is cyanotic at rest and pink when crying; if unilateral, baby is unable to breathe if mouth is held closed and unaffected naris is occluded with examiner's finger. Atresia/stenosis may be confirmed by passing a catheter.
Nasal deformation	May result from pressure in utero.	Benign condition that resolves in a few days.
	May be due to dislocation of the septal cartilage.	Attempts to restore normal anatomy are unsuccessful; nares remain asymmetric when tip of nose is compressed (Johnson, 2019; Mangurten et al., 2015).
Mouth		
Cleft lip/palate	Failure of midline fusion during first trimester.	May occur alone or with other malformations.
Epstein's pearls	Small, white, pearl-like inclusion cysts that appear on the palate and gums.	Benign finding that disappears spontaneously by a few weeks of age (Johnson, 2019).

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
Micrognathia	Underdevelopment of the jaw, especially the mandible.	Dysmorphic feature seen in certain malformation syndromes (e.g., Pierre Robin sequence; Bennett & Meier, 2019; Johnson, 2019).
Thorax/Chest		
Asymmetry	May be unequal in shape or excursion.	1. Asymmetric shape caused by positioning in utero or presence of air trapping or space-occupying lesions. 2. Unequal excursion caused by diaphragmatic hernia, phrenic nerve damage, or air leakage or trapping (Fraser, 2019).
Auscultation	Adventitious breath sounds	Fraser (2019).
	Crackles	Discrete, noncontinuous bubbling sounds during inspiration; classified as fine, medium, or coarse. Previously called rales.
	Rhonchi	Continuous, nonmusical, low-pitched sounds occurring on inspiration and expiration; caused by secretions or aspirated matter in large airways.
	Stridor	Rough, harsh sounds caused by narrowing of upper airways; present during both phases of respiratory cycle but worse during inspiration; common with laryngomalacia, subglottic stenosis, and vascular ring.
	Wheezes	Musical, high-pitched sound generated by air passing at high velocity through a narrowed airway; heard most often on expiration but can be noted during both phases of respiratory cycle if airway diameter is restricted and fixed.
	Grunting	Sound produced by forceful expiration against a closed glottis; compensatory mechanism to prevent or reverse alveolar collapse.
	Murmur	Grades I through VI assigned depending on intensity and presence of thrill.
Barrel chest	Increased anteroposterior diameter of the chest.	Result of air trapping in the pleural space (pneumothorax) or distal airways (aspiration or pneumonia), space-occupying lesions, or over distention from mechanical ventilation (Fletcher, 1998; Fraser, 2019).
Heave	Diffuse, gradually rising impulse seen in the anterior chest overlying the ventricular area. A **parasternal heave** is a precordial impulse that may be felt (palpated) in patients with cardiac or respiratory disease. Precordial impulses are visible or palpable pulsations of the chest wall, which originate on the heart or the great vessels.	Can be associated with hypertrophied ventricles or volume overload (Felner, 1990).
Pectus carinatum	Deformation of chest wall caused by protuberant sternum; also called pigeon chest.	May be associated with Marfan, Noonan's, and other syndromes (Fraser, 2019).

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
Pectus excavatum	Deformation of chest wall caused by depressed sternum; also called funnel chest.	May be associated with Marfan, Noonan's, and other syndromes (Fraser, 2019); may develop after birth in neonates with laryngomalacia.
Retractions	Drawing in of the soft tissues of the chest between and around the firmer tissue of the cartilaginous and bony ribs; seen in intercostal, subcostal, substernal, and suprasternal areas.	Mild subcostal retractions may be seen in healthy newborns; intercostal, substernal, and suprasternal retractions reflect increased work of breathing and suggest respiratory distress.
Supernumerary nipples (polythelia)	Extra nipples; may appear as slightly pigmented linear dimples or may be more defined, with palpable breast nodules.	Normal variant; nipples appear along the mammary line. Prospective studies have refuted the association with renal anomalies; no indication for further evaluation based solely on the presence of supernumerary nipples.
Abdomen		
Abdominal wall defects	Exstrophy of the bladder (protrusion and eversion of the bladder through an embryologic defect, resulting in absence of muscle and connective tissue on the anterior abdominal wall).	Often associated with other defects of the GU and musculoskeletal systems and the GI tract (Cavaliere, 2019; Zderic, 2005).
	Gastroschisis (protrusion of viscera through an abdominal wall defect arising outside the umbilical ring; the cord therefore is not inserted on the defect, and the herniated organs are not covered by peritoneum).	Defect usually is to the right of the umbilicus (Goodwin, 2019; Parry, 2015).
	Omphalocele (herniation of viscera through an abdominal wall defect within the umbilical ring; defect usually is covered by a translucent, avascular sac at the base of the umbilicus).	Umbilical cord always inserts into the sac; occasionally, the sac may rupture. Defect usually is larger than 4 cm and may be associated with other congenital defects and chromosomal anomalies (Goodwin, 2019; Parry, 2015).
	Umbilical hernia (failure of the umbilical ring to contract, allowing protrusion of bowel or omentum through the abdominal wall).	Characterized by a fascial defect smaller than 4 cm and intact umbilical skin (Fletcher, 1998; Parry, 2015).
Bruit	See section under Head and Neck	Persistence after a position change may indicate abnormalities of the umbilical vein or hepatic vascular system, hepatic hemangioma, or renal artery stenosis (Goodwin, 2019).
Diastasis rectus	Midline bulge from xiphoid to umbilicus, seen when abdominal muscles are flexed.	Caused by separation of the two rectus muscles along the median line of the abdominal wall; a common benign finding in newborns that has no clinical significance; resolves without intervention (Goodwin, 2019).
Distention	Increase in abdominal girth caused by an increase in the volume of intraperitoneal, thoracic, or pelvic contents.	May be pathologic or benign. Pathologic causes include GI obstruction, ascites, abdominal mass, organomegaly, and depression of the diaphragm (tension pneumothorax). Benign causes include postprandial state, crying, swallowing of air with feedings, air leakage with mechanical ventilation, and administration of CPAP.

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
Patent urachus	Postnatal persistence of communication between the urinary bladder and the umbilicus; may result in passage of urine from the umbilicus, which otherwise appears normal. Other signs are a large, edematous cord that fails to separate after the normal interval and retraction of the umbilical cord during urination.	Lower urinary tract obstruction should be considered (Cavaliere, 2019).
Prune belly syndrome	Congenital deficiency of abdominal musculature, characterized by a large, flaccid, wrinkled abdomen, cryptorchidism, and GU malformations.	Almost always seen in males (Vogt & Dell, 2015).
Scaphoid abdomen	Abdomen with a sunken anterior wall.	May be present with a diaphragmatic hernia or malnutrition.
Single umbilical artery		Seen in fewer than 1% of neonates; ~40% of affected newborns have other major congenital malformations. When condition occurs without other abnormalities, it usually is a benign finding (Lissauer, 2015).
Genitalia/Perineum		
Ambiguous	Presence of a phallic structure not discretely male or female, abnormally placed urethral meatus, and inability to palpate one or both gonads in a male.	May be associated with serious endocrine disorders; rapid evaluation and diagnosis are critical (Al Remeithi & Wherrett, 2015; Cavaliere, 2019).
Anal atresia	Absence of an external anal opening; imperforate anus.	Infant may fail to pass meconium; however, meconium may be passed through a rectovaginal or rectovestibular fistula in a female or rectoperineal or rectourethral fistula in a male (Goodwin, 2019).
Chordee	Ventral or dorsal curvature of the penis; most evident on erection.	May occur alone but often accompanies hypospadias (Cavaliere, 2019; Palmer & Palmer, 2016).
Clitoromegaly	The appearance of an enlarged clitoris, with no regard to cause (Al Remeithi & Wherrett, 2015); it may be swollen, enlarged, widened, or merely prominent, as in premature females.	May be a normal finding in a premature female or may represent masculinization from exposure to excess androgens during fetal life.
Cryptorchidism	Testis or testes in extrascrotal location (undescended testis or testes); characterized by empty, hypoplastic scrotal sac.	In most cases descent occurs spontaneously by 6–9 months of age; descent after 9 months is rare. Bilateral cryptorchidism occurs in up to 30% of patients; consider disorder of sexual differentiation until proven otherwise (Al Remeithi & Wherrett, 2015; Cavaliere, 2019; Palmer & Palmer, 2016).
Epispadias	Abnormal location of urethral meatus on the dorsal surface of the penis; abnormal urine stream may be seen.	Varies in severity from mild (glanular) to complete version seen in exstrophy of the bladder; all forms are associated with dorsal chordee; may require evaluation by a urologist before circumcision (Palmer & Palmer, 2016; Vogt & Dell, 2015).
Hydrocele	Nontender scrotal swelling caused by fluid collection; arises from passage of peritoneal fluid through patent processus vaginalis.	May be seen with inguinal hernia but can be distinguished from hernia because hydrocele appears translucent on transillumination; entire circumference of testis may be palpated; and it cannot be reduced (Cavaliere, 2019; Elder, 2016; Palmer & Palmer, 2016).

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
Hydrocolpos/ hydrometrocolpos	Manifests as suprapubic mass or protruding perineal mass as a result of accumulation of secretions in vagina or vagina and uterus.	Caused by excessive intrauterine stimulation by maternal estrogens, with obstruction of the genital tract by an intact hymen, hymenal bands, vaginal membrane, or vaginal atresia (Cavaliere, 2019; Karfer, 2016).
Hymenal tag	Redundant tissue manifesting as an annular tag protruding from the vagina.	Benign finding; most disappear during the first year of life.
Hypospadias	Abnormal location of urethral meatus on the ventral surface of the penis; caused by incomplete development of the anterior urethra; abnormal urine stream may be seen.	Urethral opening may be found on the glans, scrotum, or perineum. Infants with penoscrotal or perineal type or with glanular form and other genital anomalies or dysmorphic features should be evaluated to rule out disorders of sexual differentiation (Al Remeithi & Wherrett, 2015). Evaluation by a urologist may be required before circumcision.
Inguinal hernia	Scrotal mass caused by the presence of loops of intestines in the scrotal sac; arises from persistence of processus vaginalis, often associated with hydrocele.	On examination, the entire circumference of the testis is not palpable, and the scrotum cannot be transilluminated. Unless incarcerated, hernias are reducible (Cavaliere, 2019; Elder, 2016).
Micropenis/ microphallus	Abnormally short or thin penis.	Penis more than two standard deviations below the mean of length and width for age according to standard charts; frequently requires evaluation by an endocrinologist and a geneticist (Al Remeithi & Wherrett, 2015).
Phimosis	Intractable foreskin.	Must be differentiated from physiologic phimosis, a nonretractable foreskin that is a normal finding in neonates (Cavaliere, 2019).
Priapism	Constantly erect penis.	Abnormal finding in neonate (Broderick, 2016; Cavaliere, 2019).
Retractile testis	Normally descended testis that recedes into the inguinal canal because of activity of the cremaster muscle.	May not be seen in the newborn period because of lack of cremaster reflex in this age group; however, some newborns do demonstrate this response (Cavaliere, 2019; Elder, 2016).
Testicular torsion	Twisting of the testis or testes on the spermatic cord; manifests as a swollen, red or bluish-red scrotum; may be painful, but this is not a universal symptom in the neonate.	Urgent evaluation and management are required, because the blood supply to the testis is compromised, which results in irreversible ischemic damage to the testis; condition may occur in utero (Lissauer, 2015; Mangurten et al., 2015).
Musculoskeletal System		
Arachnodactyly	Unusually long, spiderlike digits.	Characteristic of, but not universally present in, Marfan syndrome and homocystinuria (Parikh & Mitchell, 2015).
Arthrogryposis	Persistent flexure or contracture of one or more joints.	May be associated with oligohydramnios or an underlying neuromuscular disorder (Parikh & Mitchell, 2015).
Brachydactyly	Shortening of one or more digits as a result of abnormal development of phalanges, metacarpals, or metatarsals.	Benign trait if an isolated finding; may be a component of skeletal dysplasias (achondroplasia) and syndromes (trisomy 21; Parikh & Mitchell, 2015).
Calcaneus foot	Abduction of the forefoot with the heel in valgus position (turned outward).	Associated with external tibial torsion; often caused by in utero positioning.

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
Camptodactyly	Congenital flexion deformity of the finger; bent finger.	Usually involves the little finger; can be a minor variant, familial trait, or part of a syndrome (Parikh & Mitchell, 2015).
Clinodactyly	Lateral angulation deformity of a finger with either radial or ulnar deviation.	Usually involves the little finger; may be a benign finding if occurring alone but can be associated with congenital syndromes (Parikh & Mitchell, 2015).
Crepitus	Crackling sensation produced by the presence of air in tissues (subcutaneous emphysema) or the movement of bone fragments (clavicular fracture).	
Genu recurvatum	Abnormal hyperextensibility of the knee allowing the knee to bend backward.	May be due to trauma, prolonged intrauterine pressure, or general joint laxity. May be a feature of other disorders (Ehlers-Danlos, Marfan syndromes; Son-Hing & Thompson, 2015; Walker, 2018).
Kyphosis	Round shoulder deformity; forward bending of the spine. Caused by congenital failure of formation of all or part of the vertebral body, with preservation of the posterior elements and failure of the anterior segmentation of the spine.	Severe deformities may be apparent at birth; less severe abnormalities may not appear until several years later; a progressive deformity can result in paraplegia (Parikh & Mitchell, 2015; Son-Hing & Thompson, 2015).
Lordosis	Exaggeration of the normal curvature in the cervical and lumbar spine.	Caused by a bony abnormality of the spine (Bennett & Meier, 2019).
Lymphedema	Puffiness of the dorsum of the hands or feet.	Characteristic of Noonan's or Turner's syndrome (Parikh & Mitchell, 2015).
Meningocele	Saclike protrusion of the spinal meninges through a congenital defect in the spinal column.	Herniated cyst is filled with cerebrospinal fluid but does not contain neural tissue; affected infants usually do not show neurologic deficits (Robinson & Cohen, 2015b).
Metatarsus valgus	Congenital deformity of the foot in which the forepart rotates outward away from the midline and the heel remains straight.	Fixed deformity of the foot, which cannot be brought into neutral position; compare with metatarsus adductus, a functional deformity in which the foot can be brought into neutral position (Grover, 2000b; Son-Hing & Thompson, 2015).
Metatarsus varus	Congenital bony abnormality of the foot in which the forepart rotates inward toward the midline and the heel remains straight.	Fixed deformity; the foot cannot be brought into neutral position. Compare with metatarsus adductus, a functional deformity in which the foot can be brought into neutral position (Son-Hing & Thompson, 2015).
Myelomeningocele	Defect identical to meningocele but with associated abnormalities in the structure and position of the spinal cord.	Affected infants usually show neurologic deficits below the level of the abnormality (Robinson & Cohen, 2015b).
Polydactyly	Presence of more than the normal number of digits; there may be a complete extra digit (preaxial) that is normal in appearance, or a skin tag (postaxial).	May be an isolated finding, inherited as an autosomal dominant trait, or may occur in a variety of syndromes (trisomy 13, Meckel–Gruber syndrome; Cooperman & Thompson, 2011; Parikh & Mitchell, 2015; Son-Hing & Thompson, 2015).
Rachischisis	Congenital fissure of the spinal cord in which the incompletely folded cord is splayed apart and exposed along the back.	Caused by incomplete neurulation; often accompanied by anencephaly (Fletcher, 1998; Gressens & Huppi, 2015).

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
Rocker bottom feet	Deformity of the foot in which the arch is disrupted, giving a rounded appearance (rocker bottom) to the sole.	Usually seen in conjunction with congenital syndromes (trisomies 13 and 18; Parikh & Mitchell, 2015; Son-Hing & Thompson, 2015).
Scoliosis	Failure of formation or segmentation of the vertebrae; manifests as lateral (side to side) curvature of the spine.	May be congenital or acquired; may occur as part of another condition or may be idiopathic (Son-Hing & Thompson, 2015).
Simian crease	Single transverse line in the palm.	May be benign, but when accompanied by other dysmorphic features (e.g., incurving fifth finger, epicanthal folds, low-set thumb), it may be a sign of trisomy 21 (Parikh & Mitchell, 2015).
Spinal dimple, dermal sinus	Pit or depression that occurs along the midline of the back, often at the base of the spinal cord in the lumbosacral area; may be accompanied by tufts of hair.	May be a benign finding, especially if the base of the defect can be visualized; however, defect can extend into the spinal cord, representing a neural tube defect and tethered spinal cord (Heaberlin, 2019; Liu & Thompson, 2015).
Syndactyly	Fusion of two or more digits; may involve only soft tissue (simple) or may include bone or cartilage (complex).	May occur as an isolated defect or as part of a syndrome (e.g., Cornelia de Lange's, Smith-Lemli-Opitz; Son-Hing & Thompson, 2015).
Talipes equinovarus	Clubfoot; congenital deformity of the foot and lower leg marked by adduction of the forefoot (turned inward and pointed medially), varus position of the heel (turned inward), and downward pointing of the toes.	May be congenital (isolated deformity), teratologic (associated with underlying neuromuscular disorder), or positional (normal foot held in equinovarus position in utero; Son-Hing & Thompson, 2015).
Tibial torsion	Abnormal rotation of the feet while the knees are pointing forward; may be internal (toes in) or external (toes out).	Often caused by in utero positioning; resolves spontaneously (Son-Hing & Thompson, 2015).
Torticollis	Shortening of the sternocleidomastoid muscle, resulting in head tilt toward the affected muscle and chin rotation toward the unaffected muscle; a palpable mass may appear during the first few weeks of life.	May be due to birth trauma, intrauterine malposition, muscle fibrosis, venous abnormalities in the muscle, or congenital cervical vertebral abnormalities (Liu & Thompson, 2015).
Neurologic Examination		
Brachial plexus injuries	Peripheral damage to the network of spinal nerves supplying the arm, forearm, and hand.	Multifactorial etiology; interaction between characteristics of the brachial plexus, maternal and fetal risk factors, and birth trauma (Liu & Thompson, 2015).
	Erb–Duchenne palsy (upper arm paralysis): Arm is adducted and internally rotated, with elbow extension, flexion of the wrist, and pronation of the forearm. The arm falls to the side of the body when passively abducted, and the Moro reflex is absent on the affected side but the grasp is intact.	Arises from injury to the fifth and sixth cervical roots; most common brachial plexus injury (Liu & Thompson, 2015; Mangurten et al., 2015).
	Klumpke palsy (lower arm paralysis): Hand is paralyzed, and voluntary movement of the wrist and grasp reflex *are* absent.	Rare; results from injury to the eighth cervical and first thoracic roots; usually Horner's syndrome (ptosis, miosis, and enophthalmos) is present on the affected side; delayed pigmentation of the iris may be seen (Liu & Thompson, 2015; Mangurten et al., 2015).

(*continued*)

TABLE 4.12

ABNORMALITIES AND VARIATIONS FOUND ON PHYSICAL EXAMINATION OF NEWBORNS AND INFANTS (*continued*)

Finding	Definition/Description	Comments
	Paralysis of the entire arm: Arm is completely motionless, flaccid, and powerless and hangs limply; all reflexes are absent, and sensory deficit may extend to the shoulder.	Liu & Thompson (2015).
Facial nerve palsy	Facial weakness or paralysis arising from compression of the seventh cranial nerve, caused by intrauterine position or forceps delivery; characterized by asymmetry of facial movement (most evident on crying), ptosis, and unequal nasolabial folds.	Mangurten et al. (2015).
Phrenic nerve injury	Cause of respiratory distress secondary to paralysis of the diaphragm; arises from upper brachial plexus injury.	Rarely occurs as an isolated phenomenon; accompanies signs and symptoms of Erb–Duchenne palsy (Mangurten et al., 2015).

CPAP, continuous positive airway pressure; GA, gestational age; GI, gastrointestinal; GU, genitourinary; LBW, low birth weight; OFC, occipitofrontal circumference.

HEALTH MAINTENANCE IN THE FIRST YEAR OF LIFE

The goal of health maintenance, or primary care, is to provide consistent preventive healthcare for the infant and education for the parents. In addition to the basic surveillance provided for all infants, high-risk infants have other needs that must be addressed. Primary care for these infants often requires a multidisciplinary approach, and the healthcare provider is responsible for coordinating medical, developmental, and social services. Because high-risk infants face the possibility of developmental delays, neurologic sequelae, and nutritional deficits, follow-up must include formal developmental, neurologic, and nutritional assessments in addition to routine screening tests. The healthcare provider may need to schedule longer and more frequent visits to evaluate the infant adequately and to assess the family's adjustment to caring for the child. The healthcare provider also is responsible for giving the parents comprehensive anticipatory guidance (Santos & Smith, 2014).

There are published guidelines for health supervision (Bellflower, 2017; Dunn, 2016; Hagan, Shaw, & Duncan, 2017). These guidelines indicate the elements that can be included in office visits for patients from birth to 18 years of age. They are intended to be used for those infants and children whose health needs are considered to be within the normal range. Although the guidelines were intended to be flexible and easily modified for follow-up of high-risk infants, there are specific resources available for chronic and disabling conditions (Allen, 2010; Stewart & Joselow, 2012). The reader is encouraged to consult these resources for assistance in planning health maintenance both for normal infants and those with special needs. In the current healthcare arena, information is updated rapidly and readers are encouraged to use the most recently updated guidelines.

Immunizations

Both the Centers for Disease Control and Prevention (CDC) and the AAP have published recommendations for routine childhood immunization through the first 18 years of age. The latest recommendations can be accessed at the following websites: https://www.cdc.gov/vaccines/schedules/downloads/child/0-18yrs-child-combined-schedule.pdf and https://pediatrics.aappublications.org/content/143/3/e20190065

It is beneficial to routinely check these websites for the most up-to-date information about immunizations rather than relying on journals or textbooks, which may not have been recently updated.

HEALTH MAINTENANCE FOR HIGH-RISK INFANTS IN THE FIRST YEAR OF LIFE

History

It is important for the primary care provider to review the infant's medical history, including a complete family history and the record of the hospital course (Table 4.13). In addition to providing routine healthcare maintenance and anticipatory guidance to the parents, the primary care provider must monitor the status of associated medical conditions and developmental sequelae.

Growth and Nutrition

Weight, length/height, and OFC are measured and plotted on the appropriate graphs. Expected increases in these parameters are summarized in Table 4.14. The parameters for premature infants must be corrected for preterm birth. Adjustments generally are made until 2 to 2½ years of age. Premature infants frequently show accelerated ("catch-up") growth, which first manifests in the head circumference. This may begin as early as 36 weeks postconceptional age or as late as 8 months adjusted age (Sifuentes, 2000). Increases in the OFC of more than 2 cm/week are worrisome and should be investigated, because they may signify a pathologic process (hydrocephalus) rather than catch-up growth (Kelly, 2010).

Weight gain is evaluated in grams per day. Many high-risk infants are placed on special diets (24 calories/oz) or feeding regimens (feedings every 2 hours or continuous feedings). It is important to review the necessity of continuing or modifying the feeding plan according to the adequacy of growth. The need

TABLE 4.13

RECORDED ELEMENTS OF THE HISTORY, MEDICAL COURSE, AND CURRENT NEEDS FOR NEONATES

Component	Elements
History	Prenatal and perinatal course Hospital course: Birth weight, gestation Illnesses, surgical procedures Radiographic studies Discharge examination Weight, head circumference, length
Nutrition information	Current diet and feeding schedule Feeding problems: GE reflux, feeding intolerance Dietary supplements: Vitamins, minerals, human milk fortifier Current deficiencies: Osteopenia/rickets, anemia
Medications	Doses Serum levels Oxygen requirements
Immunizations	Immunizations given in the hospital Respiratory syncytial virus prophylaxis
Laboratory data	Most recent values: Hemoglobin, hematocrit Bilirubin Pending laboratory studies Need for further testing Newborn screening results
Current problems and complications	Retinopathy of prematurity, ophthalmologic problems (e.g., strabismus) Hearing deficits Bronchopulmonary dysplasia/chronic lung problems GE reflux Intraventricular hemorrhage Developmental deficits Other

GE, gastroesophageal.

Source: Data from Santos, L. S., & Smith, L. A. (2014). Well-child care for the preterm infant. In C. D. Berkowitz (Ed.), *Berkowitz's pediatrics: A primary care approach* (e Version) (5th ed., Chapter 40). Philadelphia, PA: American Academy of Pediatrics. Retrieved from http://ebooks.aappublications.org/content/9781581108514/9781581108514

for dietary supplements (vitamins, minerals, human milk fortifier), medications (ranitidine, metoclopramide), and biochemical monitoring (e.g., for rickets or osteopenia) should also be addressed.

Physical Examination

A complete physical examination should be performed at each visit. Depending on the infant's history and needs, special attention may be required in certain areas, which are listed in Table 4.15.

TABLE 4.14

EXPECTED INCREASES IN WEIGHT, LENGTH/HEIGHT, AND HEAD CIRCUMFERENCE IN THE FIRST YEAR OF LIFE

Parameter	Age (months)	Expected Increase
Weight	Birth to 3	25–35 g/day
	3–6	12–21 g/day
	6–12	10–13 g/day
Length/height	Birth to 12	25 cm/year
OFC	Birth to 3	2 cm/months
	4–6	1 cm/months
	7–12	0.5 cm/months

OFC, occipitofrontal circumference.

Sources: Data from Grover, G. (2000). Nutritional needs. In C. D. Berkowitz (Ed.), *Pediatrics: A primary care approach* (2nd ed.). Philadelphia, PA: Saunders; Duffy, L. V. (2010). Hydrocephalus. In P. J. Allen, J. A. Vessey, & N. A. Schopira (Eds.), *Primary care of the child with a chronic condition* (5th ed., pp. 564–561). St. Louis, MO: Mosby.

TABLE 4.15

MONITORING FOR SUBSEQUENT CONDITIONS IN HIGH-RISK INFANTS

System	Condition	Comments
Ocular	ROP, strabismus, visual abnormalities	
Oropharyngeal	Palatal groove, high-arched palate, abnormal tooth formation	May develop secondary to intubation or may be due to congenital abnormalities
	Discolored teeth	Caused by high bilirubin levels
Thoracic/ respiratory	Retractions, wheezing, stridor, chest scars	Sequelae of chronic lung disease. Caused by chest tube placement
Cardiovascular	Hypertension	Blood pressure monitoring is especially important for an infant who had umbilical artery catheters in place
Abdominal	Hypoplastic umbilicus	Use of umbilical catheters and suturing frequently are the cause of this condition

(*continued*)

TABLE 4.15

MONITORING FOR SUBSEQUENT CONDITIONS IN HIGH-RISK INFANTS (*continued*)

System	Condition	Comments
Genitourinary	Hernias Cryptorchidism	Increased risk in preterm babies
Extremities	Developmental hip dysplasia Scars on heels or extremities	Sequelae of blood sampling, placement of IV lines, or extravasation of IV fluid
Neuromuscular	Abnormal tone, asymmetric movements and reflexes, persistence of primitive reflexes and fisting, sustained clonus, scissoring, poor suck-swallow coordination	Abnormalities must be identified as soon as possible and the patient and family referred to appropriate intervention services

IV, intravenous; ROP, retinopathy of prematurity.

Sources: Data from Allen, P. J. (2010). The primary care provider and children with chronic conditions. In P. J. Allen, J. Vessey, & N. Shapiro (Eds.), *Primary care of the child with a chronic condition* (5th ed., pp. 3–21). St. Louis, MO: Elsevier. Santos, L. S., & Smith, L. A. (2014). Well-child care for the preterm infant. In C. D. Berkowitz (Ed.), *Berkowitz's pediatrics: A primary care approach* (e Version) (5th ed., Chapter 40). Philadelphia, PA: American Academy of Pediatrics. Retrieved from http://ebooks.aappublications.org/content/9781581108514/9781581108514

Laboratory Tests and Monitoring Examinations

All standard screening tests required for healthy infants should be performed according to AAP recommendations. Other tests may be necessary for high-risk infants, such as periodic electrolyte determinations for babies receiving diuretics. Consideration should be given to measuring serum levels for such drugs as anticonvulsants, methylxanthines, and digoxin.

Repeat ophthalmologic examinations may be required to evaluate the extent and progression or regression of retinopathy of prematurity (ROP). Further follow-up may be indicated, because some infants are at risk for strabismus, myopia, amblyopia, glaucoma, and other visual deficits. The infant may need serial auditory evaluations (brainstem auditory evoked response [BAER] behavioral audiograms) and other studies, such as electroencephalography, electrocardiography, echocardiography, radiography, pneumography, and neuroradiologic imaging (CT or MRI). Infants receiving supplemental oxygen often benefit from periodic pulse oximetry (Kelly, 2010; Santos & Smith, 2014).

Immunizations

Vaccines are administered according to chronologic (postnatal) age, not GA. The standard doses and intervals are followed, as recommended by the AAP and/or CDC (see Immunizations section). Former premature infants have adequate serologic responses to immunizations without increased incidence of untoward effects. There is benefit derived from respiratory syncytial virus (RSV) prophylaxis for high-risk infants, especially premature infants with a history of respiratory distress syndrome (RDS) or RDS/BPD (RDS with bronchopulmonary dysplasia).

Box 4.1

CHARACTERISTICS OF VCS

- Exaggerated separation anxiety (both infant and parent)
- Sleep difficulties
- Overprotectiveness
- Overindulgence
- Lack of appropriate discipline
- Excessive parental preoccupation with infant's health

Psychosocial Needs

Families of high-risk infants require a great deal of support and anticipatory guidance. Healthcare providers must seek to understand parental expectations and legitimize their fears while providing support and encouragement. Parents should be given consistent, honest information and realistic appraisals of their infant's status and prognosis.

NICU graduates may be at risk for vulnerable child syndrome (VCS; Box 4.1). Because parents continue to perceive their child as vulnerable and fragile, abnormal parent–infant interactions develop. By assessing for early, subtle signs, healthcare providers may prevent progression of the disorder.

SUMMARY

The comprehensive history and physical assessment create the framework for identifying problems and planning interventions. Assessment allows the nurse to gather information and to evaluate and integrate that information as care of the newborn proceeds. Although careful attention to the obvious is important, subtle findings detected by an experienced practitioner also may play a crucial role in the continuing care of the infant and family.

CASE STUDY

■ **Identification of Patient Problem.** You are assessing a full-term female infant who was born 15 minutes previously via vaginal delivery. You note a firm but fluctuant cranial mass with ill-defined borders swelling across the suture lines to the ear and neck. The pinna appears to be protuberant.

■ **Assessment: History and Physical Examination.** Obtain detailed history to include:

- Maternal medications used during pregnancy (aspirin, ibuprofen, phenytoin)
- History of placental insufficiency or fetal asphyxia during delivery
- Length of time spent pushing
- If delivery was vacuum assisted, number of attempts and length of application
- Presentation of fetus at delivery

- Infant's Apgar scores
- History of previous child with clotting or bleeding disorder
- Family history of bleeding or clotting disorders
- Detailed examination (to be performed on open warmer): Observe general appearance of infant including color of skin and mucous membranes, overall perfusion, size and symmetry of head and face, obvious deformities or evidence of birth trauma
- Monitor vital signs (VS)

Assess state of alertness, tone, resting posture/position, and cry

- Note any arching or posturing with movement

Head

- Observe general appearance, size, and movement of head and neck
- Observe shape and symmetry of head, neck, and pinna bilaterally
- Inspect and palpate sutures and fontanelles
- Measure head circumference
- Observe hair growth patterns and check for signs of birth trauma or other anomalies
- Auscultate fontanelles

Face

- Observe for symmetrical movement of facial features
- Assess eyes, pupillary response to light, red reflex, and blink reflex in response to light
- Inspect for facial, head, and neck edema, and ecchymosis
- Assess gag, suck/rooting reflex, palate, color of mucous membranes, suck/swallow coordination, tongue, midline, moves freely, color, proportional size
- Observe for facial palsy

Ears

- Assess for any drainage or bleeding from the ear canals
- Inspect shape, placement, swelling, and position of ears
- Inspect ears for lesions, cysts, nodules
- Inspect nose: appearance, patency of nares

Neck

- Observe appearance, noting any abnormalities such as short, redundant skin, webbing
- Assess clavicles

Chest

- Assess color and perfusion prior to starting examination and note any changes throughout examination
- Palpate quality of pulses and compare upper to lower
- Observe for active precordium
- Assess capillary refill
- Auscultate lung sounds, noting any retractions, grunting, flaring, asymmetrical chest movement, or aeration
- Auscultate chest for murmurs, clicks, and rubs; PMI
- Assess for placement of breasts/nipples, presence of breast tissue, symmetry

Abdomen

- Observe color and size, shape, and symmetry of abdomen
- Auscultate abdomen for bowel sounds
- Palpate for loops, noting any tenderness and guarding with examination
- Palpate for hepatosplenomegaly

Genitourinary

- Inspect external genitalia and inguinal area/suprapubic area
- Inspect labia, clitoris, urethral meatus, and any bleeding or discharge
- Inspect for any discoloration/bruising or other signs of birth trauma
- Assess anus for patency and placement

Musculoskeletal

- Observe for spontaneous, symmetrical movement in all four limbs
- Inspect entire body for ecchymosis and petechiae or other signs of bleeding with careful documentation (mark borders if necessary)

Neurologic

- Assess reflexes: tonic neck reflex, Moro reflex, grasp reflex, Babinski reflex, and trunk incurvation

Differential Diagnosis

- Caput succedaneum, cephalohematoma, skull fracture, subgaleal hematoma

Diagnostic Tests

- Continuous monitoring: heart rate, respiratory rate, blood pressure, and pulse oximetry
- Blood gas to assess for metabolic acidosis
- Hematocrit, platelets, clotting factors, to assess for blood loss and/or coagulopathy
- Liver function studies, blood glucose level
- Skull radiograph to assess for skull fracture
- Depending on the results of the neurologic examination, a head CT may be necessary

Working Diagnosis

- Subgaleal hemorrhage

Development of Management Plan

- Admit to NICU for close observation
- Monitor VS closely and continuously (HR, RR, BP); pulse oximetry, observing closely for signs of hypovolemic shock (tachycardia, hypotension, respiratory distress)
- Monitor neurologic VS closely for possible deterioration in level of consciousness
- Monitor intake and output strictly

Blood work to be done:

- Blood gas (for baseline respiratory function)
- Complete blood count (for baseline hematocrit)
- Coagulation factors (for potential indication of massive bleeding and coagulopathy)
- Bilirubin level (for baseline: during resolution the breakdown of the blood may cause hyperbilirubinemia requiring treatment; thus, levels of bilirubin need to be followed closely as well)
- Blood urea nitrogen and creatinine (for baseline of kidney function and hydration)

- Keep the patient NPO for now
- Provide maintenance IV solution
- Blood products or normal saline (NS) boluses can be given as required for replacement of blood volume

Meet with parents: Careful preparation of the parents for the acute side effects and sequelae of subgaleal hemorrhage is important. Parents should be warned of the possibility of swelling and discoloration of the face, head, and neck. They should also know that spontaneous resolution usually occurs within 2 to 3 weeks and some infants require close long-term follow-up for sequelae.

■ Implementation and Evaluation of Effectiveness

Implement the previously noted plan with continuous monitoring for deterioration of infant's cardiovascular or neurologic status.

EVIDENCE-BASED PRACTICE BOX

Assessment

Although the 10-point Apgar score has been used to evaluate the physical condition of newly born infants since it was proposed by Virginia Apgar in 1952, its value has become controversial due to attempts to use it as a predictor of neurologic outcome. Casey, McIntire, and Leveno (2001) studied whether the Apgar scoring system remains relevant as a prognosticator of survival during the neonatal period, an intent for which it was originally developed. Based on their analysis, these investigators concluded that the Apgar system continues to be an important tool in the prediction of neonatal outcome.

However, more recently opposing evidence has emerged. Even a 5-minutes score of 0 to 3, although possibly a result of hypoxia, is limited as an indicator of the severity of the problem and in and of itself correlates poorly with future neurologic outcome (Stanley, 1994; Weiner, Zaichkin, & Kattwinkel, 2016). The prevailing opinion is that the Apgar score should not be used in isolation to predict morbidity or mortality for any particular neonate, but is intended to convey information about the newborn's response to resuscitation (Goldsmith, 2015).

CHAPTER 5

Normal Term Newborn

Cheryl Riley, Becky Spencer, and Lyn S. Prater

INTRODUCTION

The nurse caring for the newborn plays a unique role in not only providing care to the newborn but also in assisting in the integration of the baby into the family. Understanding of the newborn is optimized when information related to the mother and family is known. The information from the maternal history, which includes previous health issues, as well as prenatal, intrapartum, and postpartum histories, is critical for assessing adaptation to extrauterine life. This information gives insight into the environment from which the newborn has come and therefore helps determine the nurse's plan of care. Skills of assessment, analysis, planning, implementation, and evaluation of both mother and newborn are critical and must occur in synchrony for the nurse to assist the newborn's transition from birth to discharge. See Chapter 4, Assessment of the Newborn and Infant, for a list of the components of a comprehensive maternal and neonatal history.

ADMISSION

Providing the optimal environment for the newborn begins at birth. "Mothers and babies have a physiologic need to be together at the moment of birth and during the hours and days that follow." (Crenshaw, 2014, p. 211). The healthy, stable newborn should be placed directly on the mother's bare chest immediately after birth. Initial nursing interventions after birth, such as drying the infant, initial assessment, and Apgar scoring, should occur while the baby is skin to skin. Babies having difficulty with the transition from intrauterine to extrauterine life may be placed in the radiant warmer that provides warmth and an unobstructed view of the newborn infant for further evaluation. The admission nurse receives a comprehensive report from the labor and delivery nurse, which includes the maternal history and the delivery summary. Nursing interventions including birth weight, vitamin K, and ophthalmic antibiotic administration should be delayed to allow at least 1 hour of uninterrupted skin-to-skin contact (SSC) and breastfeeding attempts. Nurses should remain with the mother during this time and assist with breastfeeding positioning and latch. Crenshaw (2014) demonstrated through a quality improvement project that skin to skin in the operating room after a cesarean can safely occur and promote exclusive breastfeeding. Risk factors alerting the nurse for possible problems are identified, and a cursory visual assessment is done to assess for any signs of maladaptation to extrauterine life.

Vital Signs

A complete physical assessment of the newborn is done on admission (see Chapter 4, Assessment of the Newborn and Infant). Vital signs are taken during the initial physical assessment and are repeated periodically according to the institution's protocol. The vital signs include temperature, respiratory rate, heart rate, rhythm, and a four-point blood pressure (see Table 5.1). **Quality and Safety: Infants at risk for hypoglycemia would require a blood glucose level to be drawn no later than 2 hours after birth** (Wight & Marinelli, 2014).

The initial temperature gives the nurse a baseline from which to evaluate the thermoregulation ability of the newborn and is taken via the axillary route. The acceptable range of values is from 35.5°C to 37.5°C. The apical heart rate is counted for one full minute, and the acceptable range is from 100 to 160 beats/minute (bpm). The respiratory rate is also counted for one full minute, and the acceptable range of values is from 30 to 60 breaths/minute, although it is not uncommon to have respiratory rates as high as 80 to 100 breaths/minute within the first 20 minutes of life, which most likely represents normal transition to extrauterine life. A four-point blood pressure is taken, and the acceptable range values are systolic 60 to 80 mmHg and diastolic from 40 to 50 mmHg. Pain is assessed as the fifth vital sign by using a pain scale (Raeside, 2011). Blood glucose should be obtained within the first 2 hours of life and after the first feeding in all newborns that are identified as high risk for the development of hypoglycemia or any newborn with signs and symptoms of hypoglycemia.

Medications

Quality and Safety: The administration of vitamin K is given as a prophylaxis for hemorrhagic disease of the newborn by the intramuscular route using the vastus lateralis muscle.

Quality and Safety: As a prophylaxis against neonatal ophthalmia due to organisms such as gonorrhea and chlamydia, erythromycin ointment is applied by placing a ribbon of medication into each eye from the inner to the outer canthus. This practice is mandated by state law and is required in all states (Mabry-Hernandez & Oliverio-Hoffman, 2010).

TABLE 5.1

NORMAL RANGE FOR VITAL SIGNS

Temperature	Respiratory Rate	Heart Rate	Blood Pressure Systolic	Blood Pressure Diastolic
35.5°C–37.5°C	30–60 breaths/minute	100–160 beats/minute	60–80 mmHg	40–50 mmHg

After signed consent at the parents' request, hepatitis B (Hep B) vaccine will be given intramuscularly. Hep B is a serious viral disease that affects the liver. This virus is spread through contact with blood or other body fluids of an infected person. The vaccine can prevent Hep B and the serious complications associated with it that include liver cancer and cirrhosis. Routine hepatitis vaccination in the United States began in 1991. Since then, the reported incidence of Hep B in children has dropped more than 95%, and by 75% in all age groups. New recommendations call for three doses of Hep B. The first dose should be given shortly after birth, the second dose 1 through 2 months, and the third dose between 6 and 18 months of life. If the mother is Hep B positive, both Hep B vaccine and Hep B immune globulin should be given within 12 hours of birth (Centers for Disease Control and Prevention [CDC], n. d.).

Measurements

Measurements of the newborn provide information for comparisons to normal growth curves and help the nurse identify potential risk factors. The newborn's length is measured from the crown of the head to the heel with the leg fully extended; it is a more accurate measurement when the baby is placed on a calibrated length board than when using measuring tape. The average newborn length is 50 cm. Head circumference is measured placing the tape measure around the fullest part of the occiput. The average head circumference is 35.5 cm. Chest circumference is measured using the nipple line as a reference point and crossing the lower border of the scapulae. The average chest circumference is 33 cm and is usually 2 to 3 cm smaller than the head. The abdominal circumference is measured at just above the umbilicus. All measurements are documented in the medical record. These measurements are plotted on a growth chart to determine if the newborn is small for gestation age (SGA), appropriate for gestation age (AGA), or large for gestation age (LGA; Kaneshiro, 2011). Growth parameters for both male and female infants help providers assess subsequent growth, development, and risk of disease.

The First Bath

The first bath is given after the newborn has achieved thermal and cardiorespiratory stability, and no sooner than 6 hours after birth to promote maternal–newborn bonding and for skin protection. This delay in bathing is a change from the previous Association of Women's Health, Obstetrics, and Neonatal Nurses (AWHONN) guidelines and serves to promote transition to extrauterine life. Potential benefits to the baby with this change include a decreased risk for hypothermia and hypoglycemia. Additionally, the vernix that remains on the skin provides a mechanical barrier with antimicrobial properties that protect the infant from infection and will be absorbed into the skin over a 24-hour period. The amniotic fluid has similar components to colostrum and should not be wiped off the baby's hands to encourage rooting for the mother's breast and suckling in preparation for breastfeeding. Prior to bathing, ensure that the bath equipment is disinfected before and after each use. The bath water should be approximately 38°C (100°F) and the room temperature should be between 26°C and 27°C (79°F–81°F; Fort & Walker, 2015). It is important to keep the duration of the bath to a minimum. A mild pH-neutral cleanser may be used to remove blood and amniotic fluid (AWHONN, 2014). Dry the newborn with prewarmed towels or blankets and place in SSC with the mother or on a preheated radiant warmer if skin-to-skin placement is not possible.

Cord Care

During the first bath, clean the umbilical cord and surrounding skin to remove debris. Dry the cord with clean absorbent gauze and leave uncovered. Allow the cord to dry naturally. These means keep the umbilical cord area clean and dry without the routine use of topical agents. Keep the diaper folded down to leave the cord uncovered to help prevent contamination with urine and/or stool. The routine use of antimicrobial agents such as isopropyl alcohol, povidone-iodine, topical antibacterial agents, and triple dye is not recommended (AWHONN, 2014). If there is redness, swelling, or drainage, it may be a sign of infection and should be reported to the primary care provider.

SECURITY

Safety and security measures are important components of any environment that provides care to newborns. Institutions are required to have a safety and security system in place to ensure the infant's safety during its birth hospitalization. These systems also provide parents with the reassurance that their baby is safe not only from internal threats, but from external ones as well.

Identification bracelets are placed at birth with a printed number on each of the bracelets, along with the identifying information of the mother, including birth date, birth time, and gender. Typically, two bracelets are placed on the baby: one on the wrist and one on the leg. Another bracelet is placed on the mother, and the fourth bracelet is placed on the father or significant other. Wearing the matching bracelet means that the person is allowed the privilege of receiving the baby from the nursery nurse or taking the baby from the nursery. These bracelets are also used to match the baby with mother every time the baby is brought to the room or taken from the nursery. **Quality and Safety: This is an important policy that assures that the baby is always given to the correct mother, including upon discharge.**

Security sensors can be placed either on the umbilical cord via the cord clamp or on the leg with a strap. These sensors monitor the baby's location at all times and will send out a signal if the sensor passes too close to an open elevator or stairwell door. These tracking systems vary from institution to institution but are usually connected to the security systems of the hospital. **Emergency Alert: Whenever the alarm is set off or activated, a "Code Pink" is broadcasted throughout the hospital and security personnel**

are deployed to that area of the hospital for follow-up. The security sensors are then removed prior to discharge.

An *ID Badge* with the healthcare employee's picture and name are now required by most institutions while the employee is on duty. Many institutions also use a color-coded badge to identify which healthcare workers are allowed to transport the baby from the mother's room to the newborn nursery and back. This safety measure is in place to assure that only qualified employees care for the newborn infants.

Passwords are used at many institutions as another form of security to identify employees who are allowed to transport newborns. These passwords are typically changed daily, and the parents will be given the new password at the beginning of the nursing shift. Parents are requested to ask anyone who attempts to take their baby out of their room for the password of the day. If the transporter cannot tell them the correct password for the day, the parents should call the newborn nursery for help before allowing the newborn to be taken.

Teaching the parents how to use the *bulb syringe* to clear oral or nasal secretions is an important aspect of the newborn nurse's initial visit, along with showing the parents how to use the *emergency call button*. Demonstrating how to use these two safety measures along with requesting the mother to repeat the demonstrations helps assure the newborn nurse that the baby is in a safe environment.

BACK TO SLEEP

In 1994, the National Institute of Child Health and Human Development along with American Academy of Pediatrics (AAP) launched the Back to Sleep campaign in an effort to reduce the risk of sudden infant death syndrome (SIDS). There are approximately 3,500 infant sleep-related deaths annually, including SIDS, accidental strangulation, and suffocation, along with ill-defined deaths. After the initial decline of sleep-related deaths with the Back to Sleep campaign, there has been little reduction in recent years. In its 2016 update, the AAP recommends a safe sleep environment to reduce the risk of all sleep-related deaths (AAP, 2016). A safe sleep environment includes supine positioning, the use of a firm sleep surface, room sharing without bed sharing, and the avoidance of soft bedding and overheating. They further recommended the avoidance of exposure to smoke, alcohol, and illicit drugs and promoting breastfeeding, routine immunizations, and use of a pacifier (AAP, 2016).

In the newborn nursery, infants are placed on their backs in the cribs, and this practice is taught to parents as a part of the initial safety teaching protocol. Studies show that parents take their cues from the nurses in the nursery regarding the handling and positioning of their infant. This role-modeling behavior of nurses is a critical way for information to be transferred to parents (Carrier, 2009). Teaching the parents about a safe sleep environment is important due to the direct correlation between increased infant mortality and where and how infants sleep (AAP, 2016; Ibarra & Goodstein, 2011).

DAILY CARE

The daily care of the newborn includes obtaining the weight every 24 hours and documenting it in the medical record. If the newborn has lost more than 7% of his or her birth weight, the primary care provider should be notified.

Vital signs are obtained and documented at every shift. Any abnormal value should be reported, and more frequent assessments of vital signs may be required.

Reviewing the intake and output is an important parameter to measure the nutritional status of the newborn. Many times, this form is filled out by the parents and may require verification for any missing information.

The newborn should void within the first 24 hours of life and stool within the first 48 hours of life. If this does not occur, the primary care provider should be notified.

Lactation consultants should be available for all breastfeeding mothers.

A physical examination is completed every shift and documented in the medical record. Any abnormalities should be reported to the primary care provider.

Discharge teaching begins at admission and continues throughout the birth hospitalization.

CIRCUMCISION

The issue of circumcision has long been debated as to its medical necessity, and the newest task force statement on circumcision by the AAP in 2017 calls both providers and consumers to be educated on the risks and benefits of routine circumcisions to be able to make informed decisions. While neonatal circumcision is cited as one of the most commonly performed procedures in the United States today (Ahmed & Ellsworth, 2012), it is a topic that healthcare providers must be able to discuss with their patients. Whether parents decide to have their male infants circumcised, the decision should be made only after appropriate counseling by their primary healthcare provider so that they may make an informed decision.

The nurse caring for the newborn who is to be circumcised must ensure that the proper consent form has been signed by the parent, assemble necessary equipment for the procedure, and then participate in the "time-out" surgical protocol before the care provider initiates the surgical procedure. Because circumcision is a painful procedure, pain management techniques must be implemented before, during, and after the procedure. Before the procedure, it is common for the care provider to order a topical analgesic cream that should be applied 20 to 30 minutes before the surgical procedure. During the procedure, the newborn is swaddled in blankets with only the groin area exposed while being strapped to the circumcision board. This swaddling provides for tactile comfort and warmth while being securely strapped to the board. Giving the newborn an oral sucrose solution along with nonnutritive sucking has been shown to decrease the infant's pain during the circumcision (Hardcastle, 2010). Utilizing a dorsal penile block or ring block by the care provider in combination with the administration of sucrose and analgesic cream provides the best pain relief for the newborn during circumcision (AAP Policy Statement, 2012). **Emergency Alert: After the circumcision, it is important to monitor the newborn's pain response and treat with acetaminophen as necessary for the first 24 hours post procedure. It is also imperative that the nurse monitor for bleeding at the site as well as prevent infection.** Depending upon the type of circumcision device used, a petroleum jelly dressing should be applied to keep the wound from adhering to the diaper. This dressing should be changed after every void or stool to maintain cleanliness at the surgical site. Teaching the parents to care for the circumcised penis is important during hospitalization as well as in preparation for discharge. This should include cleansing the area with water at each diaper change, monitoring for signs and symptoms of infection, and refraining from tugging at the Plastibell ring until it falls off on its own.

There are basically three types of circumcision devices used in the United States today: the Gomco or Yellen clamp, the Plastibell,

and the Mogen clamp. The type chosen by the care provider is usually determined by which device was in use during their medical training program. The most important factor is that the healthcare professional performing the procedure is familiar with the equipment or device he or she is using (Angel, 2018). Whichever device is used, it is the nurse's responsibility to ensure that the equipment is sterile and in good working order and that appropriate sizes are available for use.

NEONATAL THERMOREGULATION

Thermoregulation is the ability to balance heat production and heat loss in order to maintain normal body temperature. The infant loses heat by evaporation, convection, conduction, and radiation. Evaporation is heat loss that occurs by the evaporation of water from the skin and respiratory tract. Convection is heat loss from cooler surroundings such as the delivery room. Conduction is heat loss to cooler objects that are in direct contact with the infant such as a cold bed. In contrast with conduction, radiation is heat loss to cooler objects where there is no direct contact. Evaporation of amniotic fluid from the infant's skin in the delivery room is the main source of heat loss in the initial newborn period. Normal adaptation to extrauterine life requires minimizing all the mechanisms for heat loss. The goal of care is to maintain a neutral thermal environment for the infant in whom heat balance is maintained (Ringer, 2013).

Nonshivering Thermogenesis

A thermogenic response begins within the first few minutes of life. There are two mechanisms for heat production. First, there is an increase in cellular metabolic activity primarily in the brain, heart, and liver; second, heat is produced by nonshivering thermogenesis (NST). NST is the primary source of heat production and entirely depends on brown adipose tissue. Brown adipose tissue is deposited after 28 weeks' gestation and is primarily found around the scapulae, kidneys, adrenals, neck, and axilla. Heat is produced by uncoupling adenosine triphosphate synthesis via the oxidation of fatty acids in the mitochondria, utilizing uncoupled protein (Ringer, 2013). Brown fat has an increased vascular and nerve supply that other fats do not. Significant lipid metabolic activity in the brown fat can warm the infant by increasing heat production by 100%. Brown fat stores are usually present for several weeks after birth, but are rapidly depleted in the presence of cold stress (Stavis & Mawr, 2017).

Cold Stress

The presence of cold stress increases metabolic and physiologic demands on all infants. When an infant has cold stress, there is an increase in oxygen consumption and energy is shifted from maintaining normal function of vital organs to thermogenesis for survival. If adequate oxygen tension cannot be maintained, there is vasoconstriction that can lead to increased pulmonary pressure. This causes a decrease in the partial pressure of arterial oxygen and blood pH. These changes may prevent the ductus arteriosus from closing and cause a right to left shunt. The basal metabolic rate also increases with cold stress; if cold stress is prolonged, it can lead to lactic acid production, which causes metabolic acidosis (Stavis & Mawr, 2017).

Management

In cases of mild hypothermia (36.0°C–36.4°C), the infant can be rewarmed by SSC in a warm room. This entails placing the infant with only a diaper directly on the mother's bare chest and covering them both with a blanket with the infant's head exposed. With moderate hypothermia (32.0°C–35.9°C), the infant should be placed on a radiant warmer or a preheated isolette set at 35.0°C to 36.0°C. In cases of severe hypothermia (<32°C), the infant should be rewarmed on a radiant warmer over several hours. Feeding should be continued to provide calories and fluid to prevent hypoglycemia, which is common in infants experiencing hypothermia.

Hyperthermia

Hyperthermia is less common than hypothermia but does occur and needs to be corrected. Hyperthermia is defined as a body temperature greater than 37.5°C. The most common cause for hyperthermia is excess environmental heat. It is important to differentiate hyperthermia from fever, which is a raised body temperature in response to infection and/or inflammation. Although it is not possible to distinguish between fever and hyperthermia based on the measurement of body temperature alone, infection should always be considered first. Assessment of the environmental factors such as the mode and temperature that the radiant warmer is set on and the number of blankets the infant is swaddled in is necessary. Steps should be taken to correct any environmental factors present. The clinical appearance of the infants often indicates the causative mechanism. Any signs and symptoms of infection should be reported to the healthcare provider.

GLUCOSE HOMEOSTASIS

Glucose provides the metabolic fuel for the developing fetus. While in utero, the fetus receives a constant supply of glucose from the mother by facilitated diffusion across the placenta. After birth, when the cord is cut, the supply of glucose stops, which requires the infant to begin to regulate the concentrations of insulin. Lower glucose levels are typically seen in healthy infants in the first 48 hours of life (Thompson-Branch & Havranek, 2018). This mechanism is present in all mammals, which may indicate normal adaptation to extrauterine life.

The infant requires a higher glucose infusion rate when compared to older children and adults primarily due to the larger brain-to-body mass ratio in infants. Therefore, it is important for the infant to maintain regular and frequent feeds every 2 to 3 hours during the first few days of life. If the infant is unable to meet the metabolic demand, it may lead to hypoglycemia. Severe and prolonged hypoglycemia may result in seizures and abnormal neurologic outcomes, though it is not known at what specific value of glucose these outcomes occur and the duration of the hypoglycemic event (Thompson-Branch & Havranek, 2018).

Management of low glucose levels in the first 48 hours of life is one of the most frequent issues encountered in the newborn. The screening and management of hypoglycemia is based on identified risk factors that include symptoms of hypoglycemia, LGA, perinatal stress including birth asphyxia, preeclampsia, intrauterine growth restriction (IUGR), meconium aspiration, erythroblastoma, polycythemia, hypothermia, preterm and post term, infant of a diabetic mother (IDM), family history and genetic disorders, and late-preterm infants born between 34 and 36 completed weeks of gestation. An expert panel convened by the National Institutes of Health (NIH) in 2008 concluded that there is not an evidence-based definition for clinically significant neonatal hypoglycemia, especially regarding how it relates to brain injury, which remains true even today. Blood glucose concentrations as low as 30 mg/dL are common in healthy infants by 1 to 2 hours after birth and are usually transient, asymptomatic,

and considered part of the normal adaptation to extrauterine life. Most infants will compensate for this physiologic hypoglycemia by producing alternate energy sources such as ketone bodies, which are released from fat. Clinically significant hypoglycemia, on the other hand, reflects an imbalance between the supply and use of glucose and alternative fuels (Adamkin, 2018).

Hypoglycemia is most common in infants that are SGA, IDM, and late-preterm infants. It remains unclear if otherwise healthy infants that are LGA are at risk for hypoglycemia because it is difficult to exclude maternal diabetes or maternal hyperglycemia with standard glucose tolerance tests. Therefore, screening should be reserved for the at-risk infants. Routine glucose screening is not necessary in healthy term newborns after a normal pregnancy and delivery. In any infant with signs and symptoms of hypoglycemia, blood glucose should be collected and sent to the laboratory as soon as possible. Breastfed infants have a lower concentration of serum glucose but a higher concentration of ketone bodies when compared to formula-fed infants. It is hypothesized that breastfed infants tolerate lower serum glucose concentrations without signs and symptoms because of the increased ketone levels (Adamkin, 2011).

Screening

IDMs may develop asymptomatic hypoglycemia as early as 1 hour after birth and up to 12 hours of age. While SGA or LGA infants may develop hypoglycemia as early as 3 hours of age, they may be at risk for up to 10 days. Because of this, decisions related to how often to obtain glucose levels are based on the infants' individual risk factors. Screening for the asymptomatic at-risk infants should be performed within the first few hours of life and continue through several feedings. SGA infants should be fed every 2 to 3 hours and have their glucose checked prior to each feed for the first 24 hours. After that, if the glucose checks before every feed may be discontinued. Due to the limitations of point of care monitoring, a blood or serum glucose must be confirmed by the laboratory. If there is a delay in processing the sample, it can give a falsely low value due to the metabolism of glucose by the erythrocytes. Treatment of low point of care results should not be delayed while waiting for laboratory results (Adamkin, 2018).

Currently, there is discussion between the AAP and the Pediatric Endocrine Society (PES) regarding the management of hypoglycemia and at what glucose level to treat. The AAP admits that the definition of hypoglycemia, a blood glucose of less than 47 mg/dL, is based on observational studies. The PES recommends treatment of glucose levels less than 50 mg/dL within the first 48 hours. The PES also suggests that if there is concern regarding a congenital hypoglycemia disorder, the threshold should be 60 mg/dL (Adamkin, 2018).

Management

Signs and symptoms of hypoglycemia include jitteriness, cyanosis, seizures, apneic episodes, tachypnea, weak or high-pitched cry, decreased tone, lethargy, poor feeding, and eye rolling. It is important to assess for underlying conditions such as sepsis. **Emergency Alert: Coma and seizures may occur with prolonged and repetitive hypoglycemia, usually less than 10 mg/dL.** Because of the risk of brain injury, special attention should be paid to neurologic signs and symptoms (Adamkin, 2018).

The recommendations shown in Figure 5.1 for the treatment of hypoglycemia are divided into two time periods that reflect the changing glucose levels within the first 12 hours of life. This algorithm provides a range of options for the treatment of hypoglycemia that include refeeding or giving intravenous (IV) glucose. The target glucose range is greater than or equal to 45 mg/dL prior to each feed. Infants that are at risk should be fed within the first hour of life and screened 30 minutes after the feeding. This recommendation is consistent with that of the World Health Organization (WHO). If the infant does not feed well, gavage feedings can be considered. LGA and IDMs should be screened prior to each feeding for 12 hours, with a goal of a glucose level greater than 40 mg/dL prior to each feed. SGA and late-preterm infants should be screened for the first 24 hours. Glucose levels should be stable for a minimum of three feedings prior to discharge (Adamkin, 2018).

New Therapies

In a benchmark study, the use of buccal glucose demonstrated lower neonatal intensive care unit (NICU) admission rates related to hypoglycemia and improved breastfeeding rates while keeping the mothers and their babies together (Rozance & Hay, 2016). Makker et al. (2018) reported using 40% glucose gel (200 mg/kg or 0.5 mL/kg) as a supplement to feeding at-risk infants in the newborn nursery, which reduced the need to transfer to the NICU and the administration of IV dextrose. Results of this study demonstrated a reduction in the need to transfer to a higher level of care from 8.1% in the first year to 3.7% in the second year. Exclusive breastfeeding rates increased from 6% to 19% in the two years.

HYPERBILIRUBINEMIA

Jaundice is the most common clinical diagnosis affecting approximately 80% of all newborns in the United States (Bhutani, Vilms, & Hamerman-Johnson, 2010; Ullah, Rahman, & Hedayati, 2016). Jaundice is caused by an elevation in unconjugated (indirect) and/or conjugated (direct) bilirubin levels. Bilirubin is an antioxidant in low levels and a potent neurotoxin in high levels. Elevations in bilirubin are either due to an increase in production (breakdown of heme-containing proteins) and/or a delay in the elimination of bilirubin as well as the reabsorption of bilirubin through the enterohepatic pathway (Bhutani et al., 2010).

Seventy-five percent of bilirubin comes from the breakdown of red blood cells and 25% from ineffective erythropoiesis in the bone marrow and breakdown of tissue heme and heme proteins by the liver (Dennery, Seidman, & Stevenson, 2001). Heme is degraded by heme oxygenase, resulting in the release of iron and the formation of carbon monoxide and biliverdin. Biliverdin is then reduced to bilirubin by biliverdin reductase. The bilirubin that is formed is taken up by the liver, bound to protein Y or ligandin, and conjugated in the smooth endoplasmic reticulum with glucuronides to form bilirubin monoglucuronide in a reaction catalyzed by uridine diphosphate and monophosphate glucuronosyltransferase. The now water-soluble bilirubin glucuronide is excreted into the intestinal lumen to be eliminated in stool. The conjugated bilirubin can be deconjugated by the intestinal enzyme beta-glucuronidase and reabsorbed into circulation intestinally. This process is known as the enterohepatic pathway (Bhutani et al., 2010; Ullah et al., 2016).

Physiologic Jaundice

Physiologic jaundice in the healthy term newborn follows a typical pattern and does not present within the first 24 hours of life. The average total serum bilirubin (TSB) usually peaks at 5 to 6 mg/dL on the third to fourth day of life, then declines over the first week of life. Bilirubin levels increase to 12 mg/dL in approximately 6.1% of healthy newborns and increase to 15 mg/dL in only 3% of healthy newborns (Bhutani et al., 2010; Blackwell, 2003; Ullah

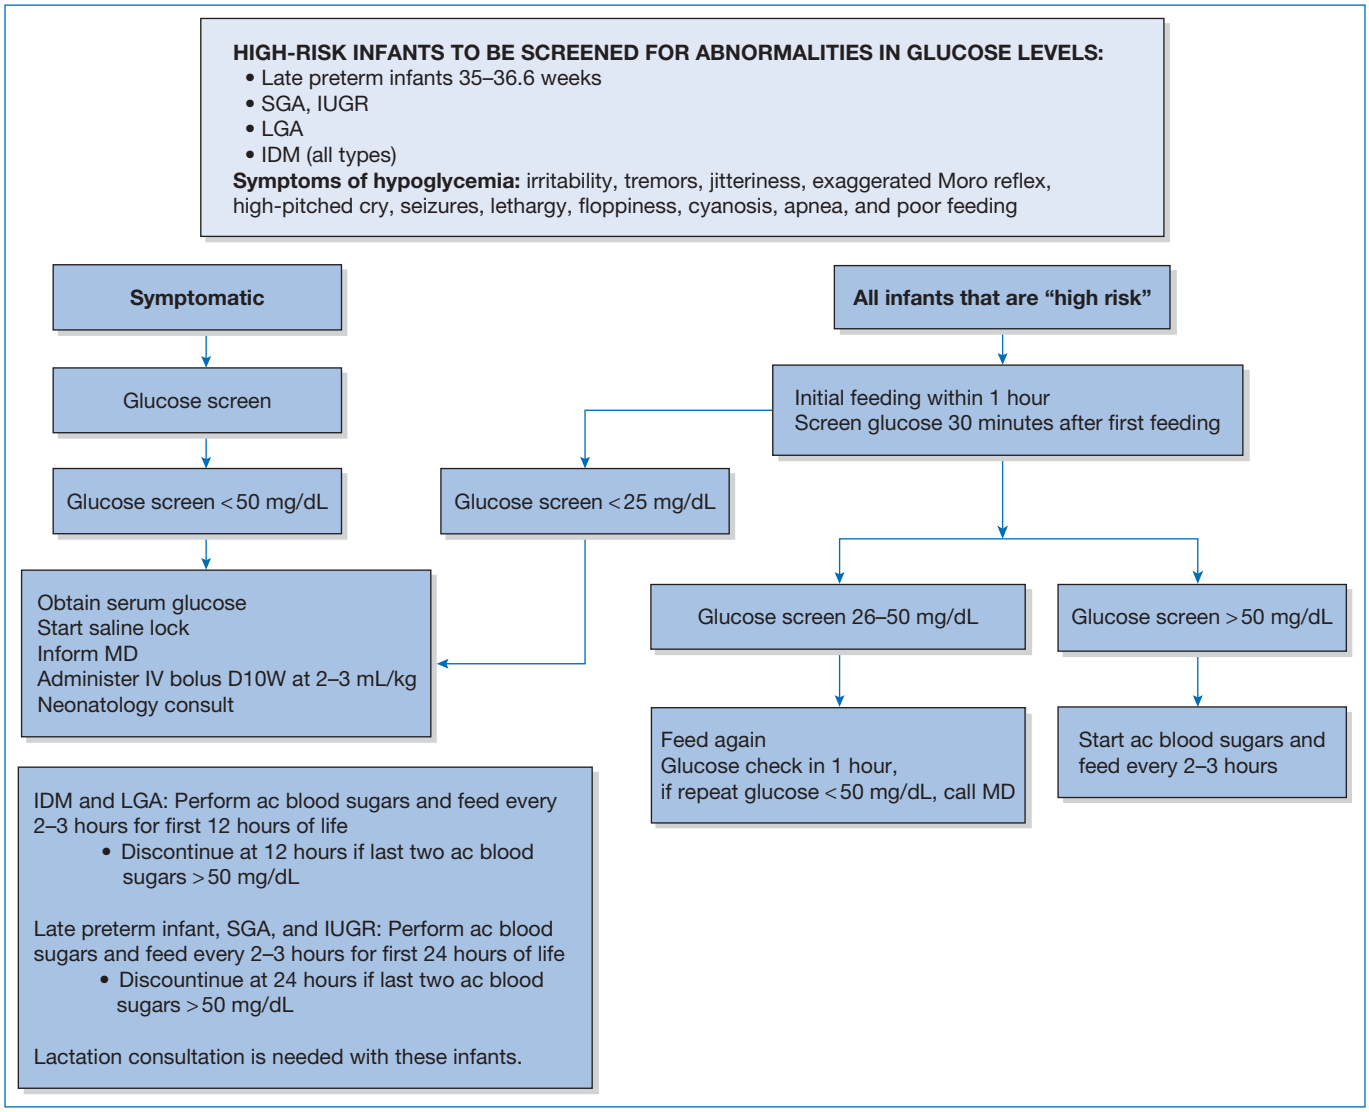

FIGURE 5.1 Screening and management of hypoglycemia.

Source: From Adamkin, D. H. (2011). Clinical report-postnatal glucose homeostasis in late-preterm and term infants. *Pediatrics, 127*(3), 575–579. doi:10.1542/peds.2010-3851

et al., 2016). Factors that contribute to the development of hyperbilirubinemia include relative polycythemia, shortened erythrocyte life span, immature hepatic uptake and conjugation processes, and increased enterohepatic circulation. Additional risk factors that increase the risk of hyperbilirubinemia are having a previous sibling with jaundice, advanced maternal age, diabetics, first trimester bleeding, prematurity, male sex, cephalohematoma or significant bruising, isoimmune or other hemolytic anemia, and Asian, American Indian, and Greek ethnicity (Khurshid & Medves, 2017).

Breastfeeding Jaundice

Breastfed newborns may be at an increased risk for developing early-onset jaundice due to decreased volume and frequency of feeding, which may result in mild dehydration and delayed passage of meconium. When compared to formula-fed newborns, breastfed newborns are 12% to 13% more likely to have peak serum bilirubin levels of 12 mg/dL. These newborns require frequent feeding, and mothers should be encouraged to breastfeed often. If there is significant (8%–10%) weight loss, decreased stooling, and decreased nutritional intake, supplementation with expressed breast milk or formula may be needed (Ullah et al., 2016).

Breast Milk Jaundice

Breast milk jaundice occurs later in the newborn period, and the incidence is 2% to 4% in term newborns. The bilirubin begins to rise around day of life 4 and continues to rise and may reach 20 mg/dL by day of life 14 and remain elevated for 2 weeks. The underlying cause of breast milk jaundice is unknown. The breast milk may have substances such as beta-glucuronidase and nonesterified fatty acids that may inhibit normal bilirubin metabolism. If breastfeeding is discontinued, there will be a rapid decline in bilirubin within 48 hours, confirming the diagnosis. During this time, it is important to encourage mothers to continue to pump their breast milk to enable continued breastfeeding. There is only a small increase in the bilirubin when breastfeeding is resumed. Mothers of newborns with breast milk jaundice have a 70% chance of this reoccurring with future pregnancies (Ullah et al., 2016).

Pathologic Jaundice

Pathologic jaundice in term infants is diagnosed if jaundice appears within the first 24 hours of life, after the first week of life, or lasts greater than 2 weeks. TSB that rises by greater than 5 mg/dL/day

or TSB greater than 18 mg/dL is also considered pathologic. Term infants who show signs and symptoms of underlying illness need further evaluation. Some of the most common pathologic causes of pathologic jaundice are immune and nonimmune hemolytic anemia, G6PD deficiency, hematoma resorption, sepsis, and hypothyroidism (Alkalay, Bresee, & Simmons, 2010; Alkalay & Simmons, 2005). Approximately 5% to 11% of term infants will develop severe hyperbilirubinemia, which is defined as a TSB greater than the 95th percentile for age in hours, and require phototherapy (Bhutani et al., 2010; Ullah et al., 2016).

Acute Bilirubin Encephalopathy and Kernicterus

Acute bilirubin encephalopathy (ABE) and kernicterus is a preventable form of neonatal bilirubin-related brain injury. ABE is a clinical central nervous system finding that is caused by bilirubin toxicity to the basal ganglia and various brainstem nuclei that is seen in the first few weeks of life. In the early stage of ABE, the severely jaundiced infant will become lethargic and hypotonic and have a poor suck. The next stage is characterized by moderate stupor, irritability, and hypertonia. The infant may also develop a fever and/or a high-pitched cry that may alternate with hypotonia and drowsiness. The hypertonia may present with arching of the neck and trunk. There is evidence that an exchange transfusion at this stage can reverse the central nervous system changes. The advanced stage is characterized by probable permanent central nervous system damage, pronounced retrocollis, opisthotonos, shrill cry, inability to feed, apnea, fever, deep stupor to coma, seizures, and death (CDC, 2016a).

Kernicterus is the chronic form of ABE in surviving infants. It is characterized by some or all of the following: athetoid cerebral palsy, auditory dysfunction, dental enamel dysplasia, paralysis of upward gaze, and occasional intellectual and other handicaps. The hallmark sign of kernicterus is the icteric staining of the basal ganglia, which is usually found at autopsy. Injury occurs when the TSB levels exceed the infant's neuroprotective defenses and result in neuronal damage. Risk factors for kernicterus are late-preterm birth, plethora, hemolytic disease, and genetic abnormalities as well as complications from dehydration, sepsis, acidosis, poor feeding, and hypoalbuminemia (Bhutani et al., 2010; CDC, 2016a; Ullah et al., 2016).

Assessment

Assessment of hyperbilirubinemia should be done through diagnostic testing and screening and not by visual inspection alone. Screening tests for hyperbilirubinemia consist of assessing clinical risk factors and measuring bilirubin levels either by serum or transcutaneously (TcB), and plotting them on an age in hour-specific bilirubin nomogram (see Figure 5.2). This range of TSB levels rather than one specific level provides the threshold for the onset of neurotoxicity. Predischarge assessment by either a TSB or TcB measurement that is plotted on an age in hour-specific nomogram that identifies risk zones should be done on all infants. This provides a simple and accurate method of identifying the risk that a newborn will develop hyperbilirubinemia that requires treatment after discharge. The AAP Subcommittee on Hyperbilirubinemia (2004), Canadian Paediatric Society (2007), National Association of Neonatal Nurses Board of Directors (2011), and Okwundu et al. (2017) recommend the following clinical practices:

- Successful breastfeeding should be promoted and supported to decrease the incidence of severe hyperbilirubinemia.
- Nursery protocols for the identification and evaluation of hyperbilirubinemia should be established.
  - Hospitals should adapt facility-wide policies and procedures that maintain an adequate standard of care for all newborns in order to prevent ABE and kernicterus.
  - Bilirubin levels should be carefully monitored in infants found to be jaundiced in the first 24 hours of life.
  - Jaundice should be assessed regularly at least every 8 to 12 hours, and nurses should have independent authority to obtain a TSB or TcB level.
- Education for healthcare providers must emphasize that visual inspection is not reliable as the sole method for assessing jaundice.
- Bilirubin levels must be interpreted according to the infant's age in hours.
- Closer surveillance of infants with a gestational age of less than 38 weeks is necessary because of their higher risk for severe hyperbilirubinemia.
- All infants should be assessed for adequacy of breastfeeding and for the risk of severe hyperbilirubinemia before discharge. Universal discharge screening should be combined with an assessment of clinical risk factors (of which gestational age and exclusive breastfeeding are the most important) and a targeted follow-up.
- Parents should receive written and verbal information about jaundice.
- Follow-up care should be based on time of discharge and risk assessment.
- Phototherapy and exchange transfusion are to be used for treatment when indicated.
  - All nurseries should have the equipment to provide intensive phototherapy.
  - Breastfeeding should be encouraged for the infant receiving phototherapy or nutritional supplementation.
- Directive that bilirubin levels must be evaluated according to the infant's age in hours, not days.
- Underscoring of the increased risk of hyperbilirubinemia in infants less than 38 weeks' gestation.
- Directive that risk assessment must be included in the evaluation of all newborns (Bhutani et al., 2010; Okwundu et al., 2017).

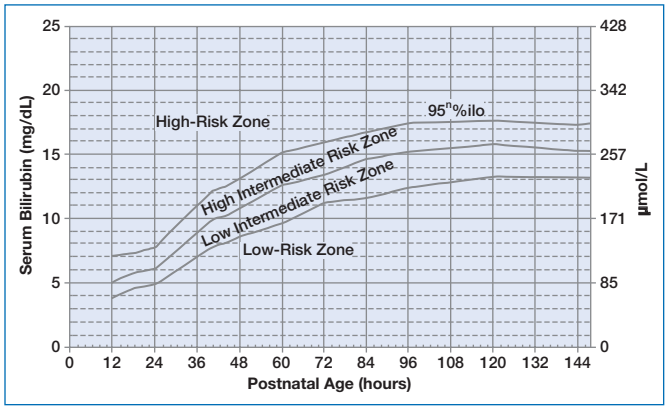

FIGURE 5.2 Nomogram for designation of risk in 2,840 well newborns at 36 or more weeks' gestational age with birth weight of 2,000 g or more or 35 or more weeks' gestational age and birth weight of 2,500 g or more based on the hour-specific serum bilirubin values.

Management

Phototherapy is used to decrease the TSB level and prevent the accumulation of bilirubin in the brain. The photoisomerization of bilirubin begins as soon as the light is turned on. The light causes the bilirubin molecules to undergo quick photochemical reactions that form nontoxic, excretable isomers. These isomers have different shapes when compared to the conjugated bilirubin. They can be excreted into the bile without conjugation or special transport carriers. This effective process has almost eliminated the need for exchange transfusions and is one of the most effective treatments to prevent severe hyperbilirubinemia (Stokowski, 2011).

Factors that affect the dose of phototherapy include the spectral qualities of the light source, the intensity of the light, the distance between the light and the infant, and the amount of surface area exposed. The blue, green, and turquoise lights are considered the most effective. With regard to the number of devices used, phototherapy can be ordered as single, double, triple, or quadruple. Fiberoptic blankets may also be used. The pad containing fiberoptic fibers can be placed against the skin and remains cool. Due to the spectral power of the pad alone, it is commonly used in combination with overhead lights (Muchkoswski, 2014; Stokowski, 2011).

Opaque eye shields are required during phototherapy to protect the eyes from retinal damage. During the assessment of the infant, the phototherapy lights should be turned off and the eye shields removed to assess the eyes for drainage, edema, and redness. Complications of eye shields include eye irritation, corneal abrasion, blocked tear ducts, and conjunctivitis. Eye care is important and should include cleaning the eyes with sterile water or saline. A separate cleaning pad should be used for each eye and should be cleaned from the inner canthus outward. Sterile gloves should be worn while providing eye care. Some phototherapy units produce heat, and the infant's temperature must be monitored to avoid overheating. Phototherapy can also cause diarrhea and water loss in stools. It is important to monitor for skin breakdown in the perianal area and use protective barriers if needed (Muchkowski, 2014; Stokowski, 2011).

During phototherapy, the infant is separated from the mother, which has the potential to interfere with lactation. As long as the hyperbilirubinemia is not severe, the phototherapy can be interrupted to allow for breastfeeding and skin-to-skin care. Eye shields can be removed during this time (Muchkowski, 2014; Stokowski, 2011).

FEEDING THE HEALTHY NEWBORN

Human milk provides optimal nutrition for infants. The AAP Policy Statement on Breastfeeding and the Use of Human Milk (Eidelman & Schanler, 2012) recommends exclusive breastfeeding for 6 months and continued breastfeeding through the first year of life with the introduction of solid foods. Breastfeeding beyond 1 year of age is also supported if mother and baby so desire. Many health benefits for infants and children have been attributed to breastfeeding and are confirmed through systematic literature reviews and meta-analyses. Breastfeeding is associated with the following:

- Protection against necrotizing enterocolitis (NEC) for preterm infants (Holman et al., 2006; Ip et al., 2007; Quigley, Henderson, Anthony, & McGuire, 2007)
- Protection against SIDS; exclusive breastfeeding provides the strongest protection against SIDS (Hauck et al., 2011; Ip et al., 2007; Thompson et al., 2017; Vennemann et al., 2009)
- Protection against respiratory infections and reduced risk of hospitalization and mortality when compared with formula-fed infants (Horta & Victora, 2013; Ip et al., 2007)
- Protection against gastrointestinal infections and diarrhea (Duijts, Jaddoe, Hofman, & Mall, 2010; Horta & Victora, 2013; Ip et al., 2007)
- Protection against acute otitis media (AOM): children who are breastfed longer than 4 to 6 months had a significant reduced risk for incidence of AOM (Bowatte et al., 2015; Duijts et al., 2010; Ip et al., 2007)
- Protection against dental caries: longer duration of breastfeeding increases protection against dental caries (Avila, Pordeus, Paiva, & Martins, 2015; Tham et al., 2015)
- Protection against malocclusions: the longer infants were breastfed, the less likely they were to have malocclusions later in childhood (Peres, Cascaes, Nascimento, & Victora, 2015)
- A reduced risk of developing childhood leukemia: specifically, breastfeeding for 6 months or longer was associated with a reduced risk of acute lymphocytic leukemia (Amitay & Keinan-Boker, 2015; Ip et al., 2007)
- Possible protection against developing asthma later in childhood (Ip et al., 2007; Peres et al., 2015)
- Possible protection against developing type 1 and/or type 2 diabetes (Horta, Loret de Mola, & Victora, 2015; Ip et al., 2007)
- Possible protection against obesity later in life (Horta et al., 2015; Ip et al., 2007)

Breastfeeding also has an economic impact on the health. Bartick and Reinhold (2010) conducted a breastfeeding cost analysis related to the following pediatric diseases: NEC, otitis media, gastroenteritis, hospitalization for lower respiratory tract infections, atopic dermatitis, SIDS, childhood asthma, childhood leukemia, type 1 diabetes, and childhood obesity. The authors calculated a $13 billion per year savings in healthcare costs if 90% of mothers would breastfeed their infants exclusively for 6 months. A cost analysis of suboptimal breastfeeding rates was conducted and revealed that $14.2 billion was attributed to infant premature death from SIDS and NEC and maternal premature death from heart disease, breast cancer, and diabetes (Bartick et al., 2017).

All healthcare professionals who provide care to women of childbearing age and their children have an obligation to recommend, promote, and educate women and their support persons about breastfeeding. In 1991, the WHO and United Nations Children's Fund (UNICEF) created the Baby Friendly Hospital Initiative (BFHI) to offer recognition to hospitals and birthing centers worldwide that provide the optimal environments for breastfeeding initiation. Hospitals and birthing centers can receive the Baby Friendly designation when they fully implement and demonstrate the *Ten Steps to Successful Breastfeeding* as outlined by WHO and UNICEF (2018). To date, over 19,000 hospitals and birthing centers worldwide have achieved the Baby Friendly designation. In the United States, 527 hospitals and birthing centers are currently designated Baby Friendly (Baby Friendly USA, 2018). A systematic review of 58 experimental and quasi-experimental studies that examined the impact of the BFHI 10 steps on breastfeeding intention, duration, and exclusivity was conducted in 2016 (Pérez-Escamilla, Martinez, & Segura-Pérez, 2016). The authors found that hospitals who adhered to the BFHI 10 steps had mothers who breastfed longer, and there was a dose–response between the number of 10 steps implemented in hospitals and improved breastfeeding outcomes. In 2018, WHO and UNICEF updated the *Ten Steps to Successful Breastfeeding* to include improved guidance for implementation within healthcare facilities (Table 5.2).

TABLE 5.2

WHO/UNICEF BABY FRIENDLY HOSPITAL INITIATIVE

Ten Steps to Successful Breastfeeding (Revised 2018)	
Critical management procedures	1a. Comply fully with the *International Code of Marketing of Breast-Milk Substitutes* and relevant World Health Assembly resolutions.
	1b. Have a written infant feeding policy that is routinely communicated to staff and parents.
	1c. Establish ongoing monitoring and data management systems.
	2. Ensure that staff have sufficient knowledge, competence, and skills to support breastfeeding.
Key clinical practices	3. Discuss the importance and management of breastfeeding with pregnant women and their families.
	4. Facilitate immediate and uninterrupted skin-to-skin contact and support mothers to initiate breastfeeding as soon as possible after birth.
	5. Support mothers to initiate and maintain breastfeeding and manage common difficulties.
	6. Do not provide breastfed newborns any food or fluids other than breast milk, unless medically indicated.
	7. Enable mothers and their infants to remain together and to practice rooming-in 24 hours a day.
	8. Support mothers to recognize and respond to their infants' cues for feeding.
	9. Counsel mothers on the use and risks of feeding bottles, teats, and pacifiers.
	10. Coordinate discharge so that parents and their infants have timely access to ongoing support and care.

NURSING INTERVENTIONS THAT PROMOTE SUCCESSFUL BREASTFEEDING

Skin to Skin

Providing the optimal breastfeeding environment begins at birth. The healthy, stable newborn should be placed directly on the mother's bare chest immediately after birth. Initial nursing interventions after birth including drying the infant, initial assessment, and Apgar scoring should occur while the baby is skin to skin with the mother. Nursing interventions including birth weight, vitamin K, and ophthalmic antibiotic administration should be delayed to allow at least 1 hour of uninterrupted SSC and breastfeeding attempts. Nurses should remain with the mother during this time and assist with breastfeeding positioning and latch. SSC should also be maintained when possible during painful procedures including heelsticks, venous puncture, and injections because SSC during painful procedures reduces the neonates' pain response (Johnston et al., 2014).

The 2016 Cochrane Review (Moore, Bergman, Anderson, & Medley) regarding early SSC of mothers and healthy infants revealed empirical evidence that early and frequent SSC promotes stability of the cardiorespiratory system in the neonate and higher blood glucose levels. Neonates who received SSC had similar body temperature when compared to infants who did not receive SSC. Women who experienced SSC after vaginal birth reported longer durations of and exclusive breastfeeding compared to women who did not experience SSC. SSC in the operating room after a cesarean can safely occur and promote exclusive breastfeeding (Berg & Hung, 2011; Stone, Spencer, & Prater, 2014). Earlier onset of lactogenesis II (milk production), increased oxytocin release, and increased milk production as a result of frequent SSC are also suggested in the literature (Chen, Nommsen-Rivers, Dewey, & Lonnerdal, 1998; Cong et al., 2015; Gordan, 2015; Hemachandra, Puapornpong, Ketsuwan, & Imchit, 2016). Frequent SSC between mother and baby should be encouraged throughout the postpartum hospital stay and after discharge to home. Infants should be undressed (diaper only) and placed directly on the mother's bare chest. Mother and baby should then be covered with a blanket with the infant's head exposed.

Maternal–Infant Separation Only When Medically Necessary

Healthcare professionals should recommend 10 to 12 feedings at breast per 24-hour period in the first 3 to 5 days after birth. Milk production is the result of lactogenesis I and II. Lactogenesis I begins around the 10th to 22nd week of pregnancy and is hormonally mediated. During lactogenesis I, growth of glandular tissue occurs, and the mammary secretory cells, lactocytes, are formed. Lactogenesis II, the onset of milk production, begins with the separation of the placenta from the uterus at birth, which results in a drop in mother's serum progesterone. Lactogenesis II depends on frequent suckling at the breast. When the infant suckles at the breast, prolactin is released from the mother's anterior pituitary gland, and oxytocin is released from the posterior pituitary gland. Prolactin is responsible for milk production in the mammary gland, and oxytocin is responsible for the milk ejection reflex, which allows the release of the milk from the mammary gland to the milk ducts (Wambach & Riordan, 2016).

The longer the infant is separated from the mother in the hospital, the less opportunity for breastfeeding occurs. In the first few days after birth, several attempts at latching at the breast may be necessary before a good sustained latch is achieved; therefore, mothers need uninterrupted time together with their infants to learn to identify hunger cues and have adequate practice and assistance with breastfeeding. Parents need to be educated in the identification of their infant's hunger cues and to offer the breast when the infant expresses early rather than late hunger cues. Early hunger cues include movement of arms and legs, rooting, lip smacking, and fingers or fist to mouth movement. Early hunger cues may occur while the infant is in a light sleep state with eyes closed. Later hunger cues include restlessness, intermittent or full cry, and inconsolable screaming (Wambach & Riordan, 2016).

Mothers should be encouraged to room in (keep their infants with them continuously through the day and night) to promote quicker response to hunger cues and identification of infant needs. Infant assessments by all providers can and should occur in the mother's hospital room rather than in the nursery. Increased maternal sleep or perceived rest has not been substantiated in the literature when infants are separated from the mother or sent to the nursery (Doan, Gardiner, Gay, & Lee, 2007; Keefe, 1987, 1988; Waldenström & Swenson, 1991). The breastfeeding mother–infant dyad should only be separated when medically necessary.

Pacifier Use

Pacifier use in the healthy term breastfed infant is a somewhat controversial topic. Pacifier use has been associated with shorter breastfeeding duration (Howard et al., 2003; Nelson, Yu, & Williams, 2005) and decreased exclusive breastfeeding (Vogel, Hutchison, & Mitchell, 2001). Long-term pacifier use beyond 6 months of age has been associated with increased risk of otitis media (Niemelä, Pihakari, Pokka, & Uhari, 2000) and dental malocclusion (Peres, Barros, Peres, & Victora, 2007). WHO and UNICEF (2018) through the *Ten Steps to Successful Breastfeeding* recommend educating parents on the possible risks of pacifier use.

However, the AAP has identified pacifier usage to potentially decrease the incidence of SIDS (Hauck, Omojokun, & Siadaty, 2005; Li et al., 2006) and serve as a method of effective pain control in combination with sucrose for infants undergoing painful procedures, for example, heelsticks or circumcision (Stevens, Yamada, & Ohlsson, 2010). The specific recommendations of the AAP regarding pacifier use and breastfeeding infants are to avoid pacifier use in the neonatal period until breastfeeding is well established. The AAP encourages pacifier use in infants undergoing painful procedures and during nap and sleep times as a potential protection against SIDS (Eidelman & Schanler, 2012). One further recommendation is to discourage the use of pacifiers to rule out hunger or delay a feeding; breastfeeding should occur before offering a pacifier. Parents must be educated on all the risks and benefits of pacifier use in the breastfed infant, so they can make an informed decision that best suits their needs and parenting philosophy.

Adequacy of Breastfeeding

The three main indicators of adequate breast milk transfer are audible swallowing by the infant, adequate urine and stool output, and weight gain. All healthcare professionals who care for breastfeeding mother–infant dyads in the neonatal period must demonstrate competence in assessing an adequate transfer of breast milk. At least one complete breastfeed from latch to satiety should be observed, preferably once per shift after birth, but at least once before discharge. Mothers need education on positioning the infant during breastfeeding and on how to achieve a deep latch. The football hold, cross-cradle hold, and the side-lying position are common ways to hold the infant to promote a deep latch. The mother should be taught to support the infant's head with one hand and her breast with the other hand during latching. The mother should hold her breast so that her fingers do not cover her areola. The mother should be taught to hand-express drops of breast milk from her nipple and place on the infant's lips to entice a wide mouth gape. Once the infant has a wide mouth gape, it should be brought quickly to the breast. The infant needs to feel the nipple on its palate to elicit the sucking reflex. The infant should take in most of the mother's areola, and lips should be flanged on the breast.

Once latched and sucking, the healthcare provider should listen for audible swallowing by the infant. In the first few days of breastfeeding, the infant will take 5 to 10 sucks before a swallow will be heard as a soft "k" sound. As the mother's milk begins to come in, swallowing will become more frequent and more audible. An adequate breastfeed is sustained sucking and swallowing for at least 10 to 15 minutes on at least one breast. If the infant detaches from the first breast, the mother can continue feeding on the other breast. Encourage the mother to alternate which breast she starts on with each feeding. Length of feedings in minutes is a less important measure of adequate breastfeeding than sustained audible swallowing followed by signs of satiety, including slowing of sucking, falling asleep, and self-detaching (Wambach & Riordan, 2016). Several breastfeeding assessment tools have been developed and tested in an effort to measure the adequacy of breastfeeding in the early days after birth. The LATCH assessment tool by Jensen, Wallace, and Kelsay (1994) is one such tool that evaluates five different indicators of breastfeeding adequacy (Table 5.3). Each assessment is scored from 0 to 10, with a higher score indicating

TABLE 5.3

LATCH BREASTFEEDING ASSESSMENT TOOL

	0	1	2
Latch	Too sleepy or reluctant No latch achieved	Repeated attempts Hold nipple in mouth Stimulate suck	Grasps breast Tongue down Lips flanged Rhythmic sucking
Audible swallowing	None	A few with stimulation	Spontaneous and intermittent <24 hours old Spontaneous and frequent more than 24 hours old
Type of nipple	Inverted	Flat	Everted (with stimulation)
Comfort of mother	Engorged Cracked/ bleeding/ large blisters or bruises Severe discomfort	Filling Reddened/ small blisters or bruises Mild/ moderate discomfort	Soft Nontender
Hold or positioning	Full assist (staff holds infant at breast)	Minimal assist Teach one side; mother does other Staff holds and then mother takes over	No assist from staff Mother able to position/hold infant

Source: From Jensen, D., Wallace, S., & Kelsay, P. (1994). LATCH: A breastfeeding charting system and documentation tool. *Journal of Obstetric, Gynecologic, and Neonatal Nursing, 23*, 27–32. doi:10.1111/j.1552-6909.1994.tb01847.x

adequate latch and transfer of milk as well as relative comfort of the mother.

The second indicator of adequate breastfeeding is the amount of urine and stool output. Breastfed infants should have one wet diaper the first day of life and increase by one wet diaper for each day of life up to five to six wet diapers per day. Diapers should feel heavier when wet rather than just damp. The urine should be light in color and have slight to no odor. It is normal for breastfed neonates to have reddish colored urine in the first few days of life and this is not an indicator of dehydration (Kernerman & Newman, 2009). Neonates should have at least one stool on the first and second days of life that is green to black and a tarry consistency. By the third and fourth day of life, the neonate should have one to three stools per day that begin to change to a green looser stool as the mother's milk begins to come in. By the fourth to seventh days of life, the neonate should have one to four stools per day that are yellow, loose, and seedy in consistency. By the end of the second week of life, the neonate should have three to five stools per day that are the same consistency, but the volume of the stool will increase as the volume of milk intake from the mother increases. It can be normal for infants to have no stool on an occasional day (Wambach & Riordan, 2016). If a neonate does not have adequate output as previously described, the healthcare professional should assess a breastfeeding for adequate transfer of milk and frequency of breastfeedings and assess the neonate for jaundice and signs and symptoms of dehydration. Healthcare professionals should refer mothers to a lactation consultant for breastfeeding difficulties.

The third indicator of adequate breastfeeding is weight gain. Some weight loss is expected in the healthy term neonate. A weight loss up to 5% of birth weight in the first 3 days is considered normal and can be partially attributed to evaporative loss after birth. At 7% weight loss, the healthcare provider should assess breastfeeding as previously described and also assess urine and stool output. **Emergency Alert: A neonate with a greater than 7% weight loss who is having adequate breastfeeding and output could have been fluid overloaded as a result of large quantities of intravenous fluids given to the mother during labor** (Lawrence & Lawrence, 2015). If a 10% weight loss occurs in the first 3 days of life, intervention is necessary to assist the mother's body with lactogenesis II and to assist the baby in adequate transfer of milk. Mothers should be educated and encouraged to pump both breasts after a feeding with a hospital-grade breast pump for 10 to 15 minutes at least eight times per day. This will provide extra stimulation and assist with onset of milk. The mother should feed any expressed breast milk to the baby via cup, finger feeding, or at breast using a Supplemental Nursing System™, or a feeding tube inserted at the corner of the infant's mouth while nursing. Mothers and support persons must be educated by a nurse or a lactation consultant on safety and use of supplemental feeding methods.

If the mother is unable to pump adequate volumes of breast milk, the neonate's urine and stool output is not adequate, and the baby is unable to consistently transfer milk from the breast, then supplementation with formula may be necessary. Formula supplementation in the first 24 to 48 hours after birth should be limited to 10 to 15 mL per feeding given after a breastfeeding attempt (Wambach & Riordan, 2016). At greater than 48 hours of birth, formula supplementation should be limited to 30 mL per feeding and should be given after breastfeeding attempts. Supplementation should only continue until mother's milk is established.

Breastfeeding Follow-Up After Discharge

Breastfed neonates should be seen by a healthcare provider within 3 to 5 days after discharge from the hospital stay to assess breastfeeding adequacy, the onset of mother's milk, presence of jaundice or elevated bilirubin levels, and weight gain. Neonates with weight loss should gain back to birth weight by 14 days of age. Breastfeeding should be assessed at all subsequent infant healthcare provider visits to include not only the baby's health and growth, but also the mother's support systems and motivation to continue breastfeeding. Exclusive breastfeeding should be encouraged and promoted throughout the first six months of the infant's life with continued breastfeeding and addition of solid foods through the first year of life and beyond if mother and infant desire. Formula supplementation should be avoided unless medically indicated.

Formula Feeding

If a mother chooses not to breastfeed or breastfeeding is contraindicated (maternal infection with HIV, active TB, human T-cell lymphotropic virus, untreated brucellosis, or treatment with chemotherapeutic agents) and banked milk is not available or feasible, then formula feeding is the most available alternative (Eidelman & Schanler, 2012). Commercially prepared cow's milk-based formulas are all relatively similar in their composition of nutrients, vitamins, minerals, proteins, carbohydrates, and fat. Three other types of formula are soy-based formulas, casein or whey-hydrolysate formulas, and amino acid formulas. Soy formulas are generally recommended to mothers whose infants have a cow's milk intolerance, galactosemia, and hereditary lactase deficiency. Casein or whey-hydrolysate formulas are recommended to children who cannot tolerate cow's milk or soy-based formulas.

Formulas come in many forms and concentrations, for example, concentrate, ready to feed, or powder. Parents and caregivers need to be educated on how to prepare the formula correctly according to product package instructions. Improperly prepared formula can lead to infant malnutrition, electrolyte imbalance, and even death (Walker, 1993). Formula or breast milk should never be heated in a microwave because of uneven heating and the potential for burns. Energy requirements for normal growth and activity of infants is approximately 108 kcal/kg/day from birth to 6 months of age and approximately 98 kcal/kg/day from 6 to 12 months of age (Kleinman, 2008). Newborns receiving formula should be fed 1 to 2 oz per feeding every 3 to 4 hours for the first week, and advanced to 2 to 4 oz per feeding around 1 week of age. A general volume recommendation is 2.5 oz/lb per day. For example, a 10-lb baby would receive 25 oz of formula per day divided into approximately six to eight feedings (every 3–4 hours) of 3 to 4 oz per bottle (Blum-Kemelor & Leonberg, 2009). Prepared formula cannot sit at room temperature for more than 2 hours. After 2 hours at room temperature, bacteria growth begins to proliferate (WHO, 2007). Any formula that the baby does not consume from a bottle should be thrown away and not refrigerated. Prepared formula can be refrigerated for 24 hours prior to consumption.

DISCHARGE SCREENING

Hearing Screening

Hearing loss is one of the most common congenital anomalies, occurring in approximately 2 to 4 infants per 1,000 (American Speech-Language-Hearing Association, 2018; Delaney et al., 2012). Prior to implementation of universal newborn screening (NBS), testing was only done on infants who met the criteria of the high-risk register. Unfortunately, about 50% of infants born with hearing loss have no known risk factors (American Speech-Language-Hearing Association, 2018; Delaney et al., 2012).

The ability to hear during the first few years of life is critical for the development of speech, language, and cognition. Early identification and intervention can prevent severe psychosocial,

educational, and linguistic repercussions. Infants with hearing loss who are not identified by 6 months of age will likely have delays in speech and language development. Intervention at or before 6 months of age promotes the ability of a child with hearing loss to develop normal speech and language development (Delaney et al., 2012).

The two methods used in most universal hearing-screening programs are the otoacoustic emissions (OAEs) and automated auditory brainstem response (AABR). OAEs are used to assess cochlear integrity and are physiologic measurements of the response of the outer hair cells to acoustic stimuli. When using the OAE method, a probe is placed in the ear canal and click stimuli are delivered causing the OAEs to be generated by the cochlea, which are then measured with a microphone (American Speech-Language-Hearing Association, 2018; Delaney et al., 2012). The presence of the OAE responses indicates that hearing is in the normal to near-normal range.

AABR is an electrophysiologic measurement that is used to assess auditory function from the eighth nerve through the auditory brainstem (Delaney et al., 2012). This is done by placing disposable electrodes high on the forehead, on the mastoid, and on the nape of the neck. The click stimulus is delivered to the infant's ear with small disposable earphones. Most AABR systems compare an infant's waveform with a control that was developed from normal ABR infant data (American Speech-Language-Hearing Association, 2018; Delaney et al., 2012). A pass or fail response is determined from this comparison. Infants who do not pass the universal hearing screening at birth should have follow-up testing within 1 month. This follow-up appointment allows for additional testing and medical diagnosis.

Newborn Screening

NBS tests the newborn for many hormonal, genetic, and metabolic disorders. This screening is done with a simple blood test that allows for early detection of preventable life-threatening disorders. There are 31 disorders that have been identified for routine screening. Current standards are determined at the state level, and most states screen for the majority of the recommended disorders, though there is some variation from state to state on the specific disorders tested (CDC, 2016b; National Newborn Screening and Genetic Resource Center, 2014).

Without proper screening and treatment, infants and children can suffer mental retardation, physical disability, or even death. With early treatment shortly after birth, many affected infants and children can lead normal healthy lives (AWHONN, 2011). There is a need for the development of national standards to ensure that all states screen for all of the recommended disorders.

In April 2008, the Newborn Screening Saves Lives Act (Public Law 110–204, 2008) was signed into law, but this law recommends rather than mandates states to increase the number of disorders they test for.

In 1999, the AAP developed a task force that recommended greater uniformity among states. In response, the American College of Medical Genetics issued guidelines for state NBS programs that recommended all states test for a core panel of 29 disorders (AAP Newborn Screening Authoring Committee, 2008). Then, in 2010, the Advisory Committee for Heritable Disorders in Newborns and Children agreed to include severe combined immunodeficiency in the panel (AWHONN, 2011). The following is a complete list of the disorders:

Organic acid metabolism disorders

- Isovaleric acidemia
- Glutaric acidemia
- 3-OH 3-CH3 glutaric aciduria
- Multiple carboxylase deficiency
- Methylmalonic acidemia due to mutase deficiency
- Methylmalonic acidemia (Cbl A, B)
- 3-Methylcrotonyl-CoA carboxylase deficiency
- Propionic acidemia
- Beta-ketothiolase deficiency

Fatty acid oxidation disorders

- Medium chain acyl CoA dehydrogenase
- Very long chain acyl CoA dehydrogenase deficiency
- Long chain l-3-OH acyl CoA dehydrogenase deficiency
- Trifunctional protein deficiency
- Carnitine uptake defect

Amino acid metabolism disorders

- Phenylketonuria
- Maple syrup urine disease
- Homocystinuria due to cystathionine beta synthase (CBS) deficiency
- Citrullinemia
- Argininosuccinic acidemia
- Tyrosinemia type 1

Hemoglobinopathies

- Sickle cell anemia (Hb SS)
- Hemoglobin S/beta-thalassemia (Hb S/Th)
- Hemoglobin S/C (Hb S/C)

Others

- Congenital hypothyroidism
- Biotinidase deficiency
- Congenital adrenal hyperplasia due to 21-hydroxylase deficiency
- Classic galactosemia
- Hearing loss
- Cystic fibrosis
- Severe combined immunodeficiency

March of Dimes Foundation developed a recommendation for all states to test for these 30 conditions, grouping them into five categories:

- Amino acid metabolism disorders
- Organic acid metabolism disorders
- Fatty acid oxidation disorders
- Hemoglobinopathies
- Others, please see https://www.marchofdimes.org/baby/newborn-screening-tests-for-your-baby.aspx for more specific information

All states collect blood samples from newborns during their birth hospitalization; these samples are usually referred to as blood spots (see Figure 5.3). Some states discard the blood samples when the NBS is complete, and others store the blood spots for future research. Genetic privacy, parental consent, and security must be incorporated into any blood storage system and there needs to be a mechanism in place that addresses parents' rights with regard to storage and future uses with the blood spots (AWHONN, 2011).

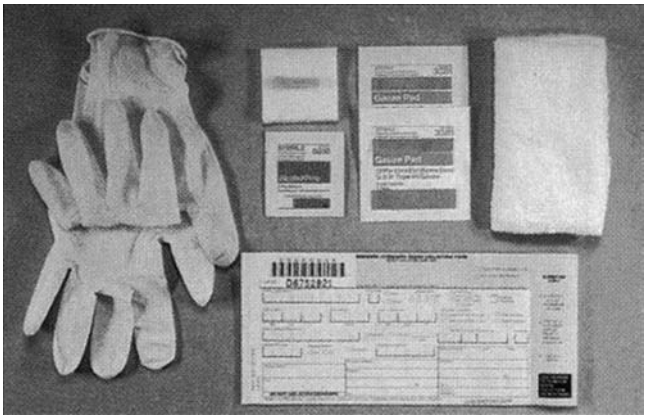

FIGURE 5.3 Newborn screen blood specimen collection and handling procedure.

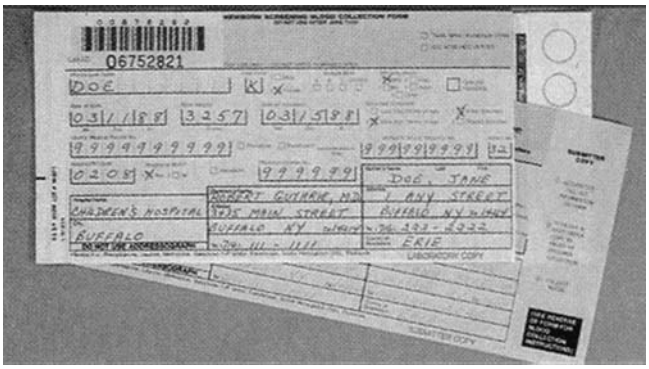
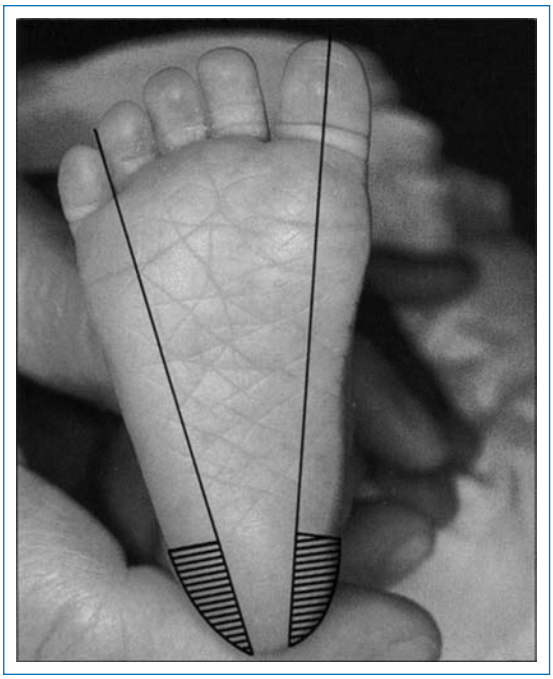
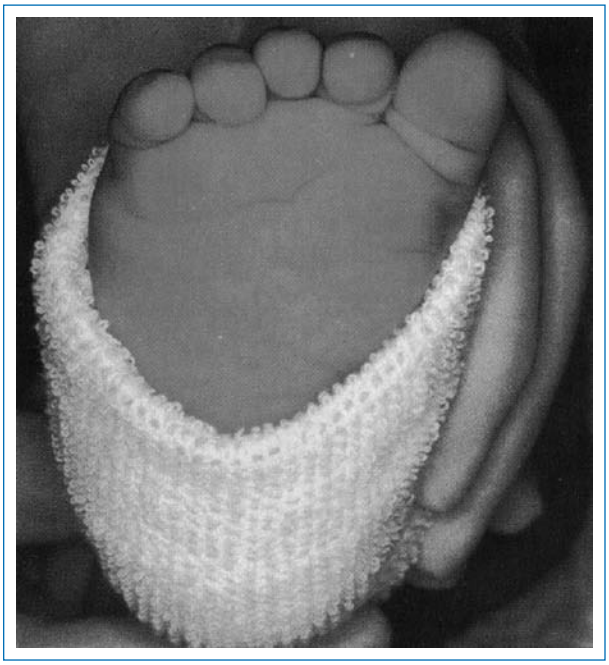
1. Equipment: Sterile lancet with tip less than 2.4 mm, sterile alcohol prep, sterile gauze pads, soft cloth, blood collection form, gloves.



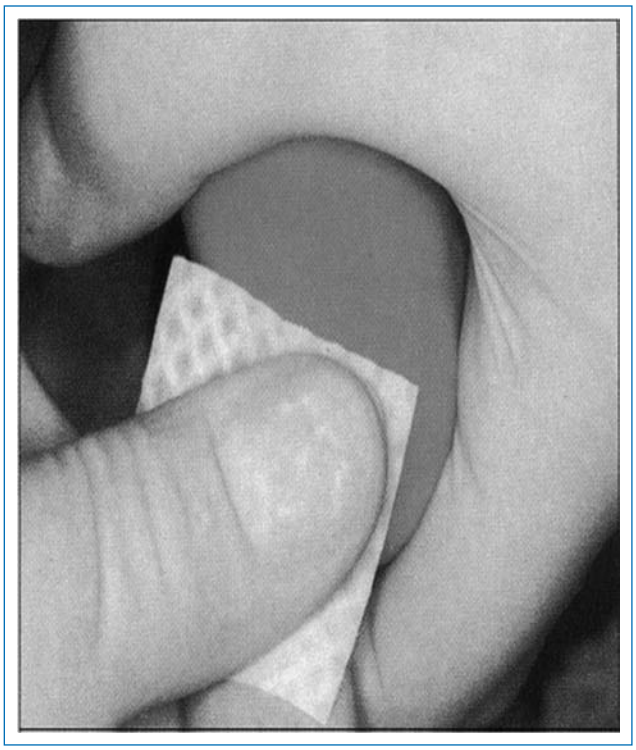
2. Complete all information. Do not contaminate filter paper circles by allowing the circles to come in contact with spillage or by touching before or after blood collection.



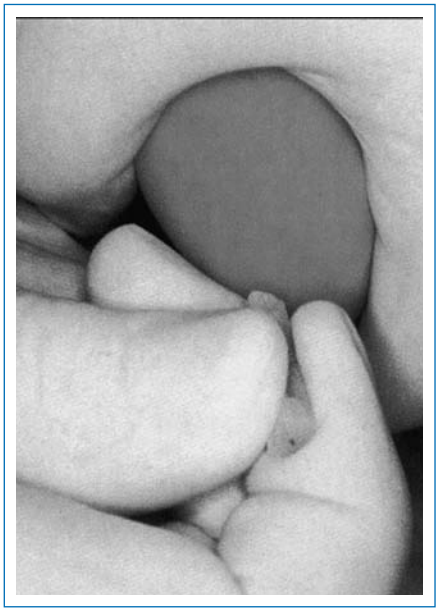
3. Hatched area indicates safe areas for puncture site.



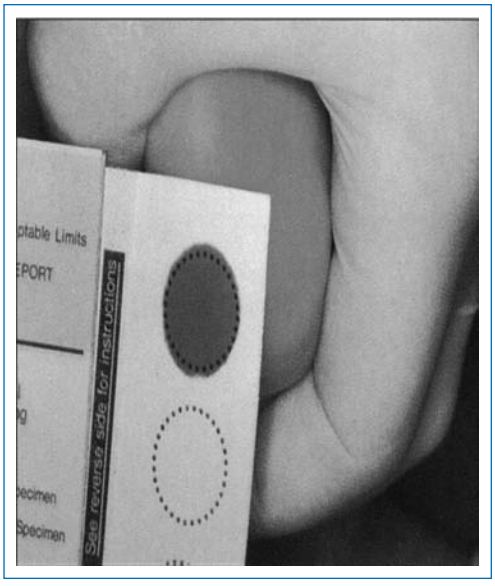
4. Warm site with soft cloth, moistened with warm water or a heel warmer for 3 to 5 minutes.



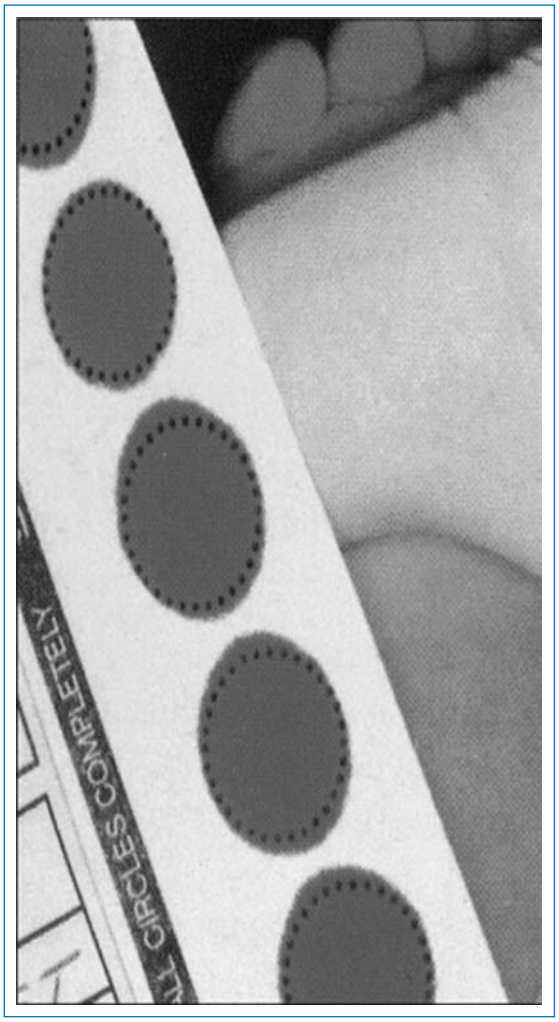
5. Cleanse site with alcohol prep. Wipe dry with sterile gauze pad.



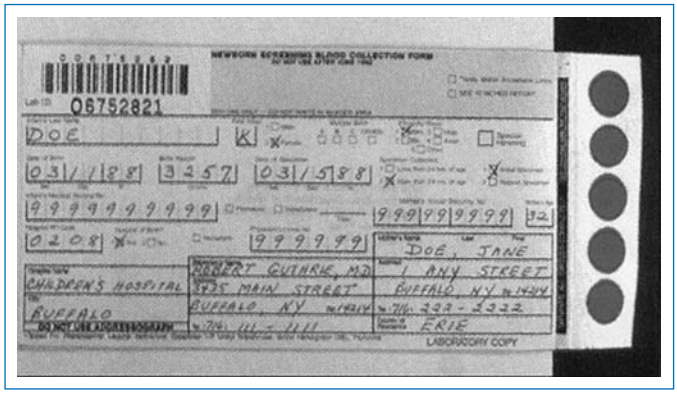
6. Puncture heel. Wipe away first blood drop with sterile gauze pad. Allow another large blood drop to form.



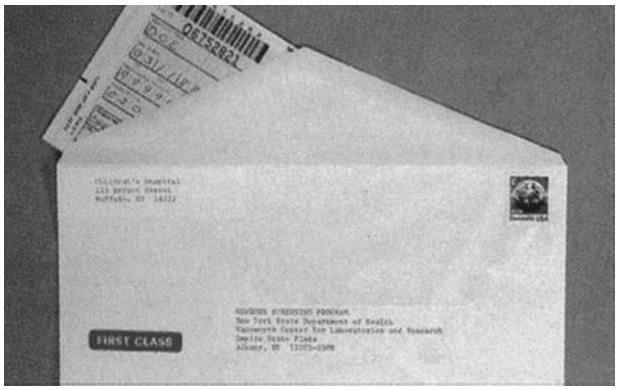
7. Lightly touch filter paper to large blood drop. Allow blood to soak through and completely fill circle with single application to large blood drop. (To enhance blood flow, very gentle intermittent pressure may be applied to area surrounding puncture site.) Apply blood to one side of filter paper only.



8. Fill remaining circles in the same manner as in step 7, with successive blood drops. If blood flow is diminished, repeat steps 5 through 7. Care of skin puncture site should be consistent with your institution's procedures.



9. Dry blood spots on a dry, clean, flat nonabsorbent surface for a minimum of 4 hours.



10. Mail completed form to testing laboratory within 24 hours of collection.

CRITICAL CONGENITAL HEART DISEASE SCREENING

Pulse oximetry screening (POS) of the newborn is an effective, noninvasive, and inexpensive tool that is beneficial in detecting critical congenital heart disease (cCHD) in newborns (Riede et al., 2010). Congenital heart defects are the most common serious birth defects, affecting approximately 8 of every 1,000 newborns, and cCHDs affect 2 to 3 per 1,000 live births. The seven defects classified as cCHDs are hypoplastic left heart syndrome, pulmonary atresia (with intact septum), tetralogy of Fallot, total anomalous pulmonary venous return, transposition of the great arteries, tricuspid atresia, and truncus arteriosus. Babies with one of these cCHDs are at significant risk for death or disability if their heart defect is not diagnosed and treated soon after birth. These seven cCHDs potentially can be detected using POS, which is a test to determine the amount of oxygen in the blood and pulse rate. Certain hospitals routinely screen all newborns using POS. However, POS is not currently included in NBS in most states (AAP, 2018; CDC, 2018). Prenatal ultrasound and physical examination alone

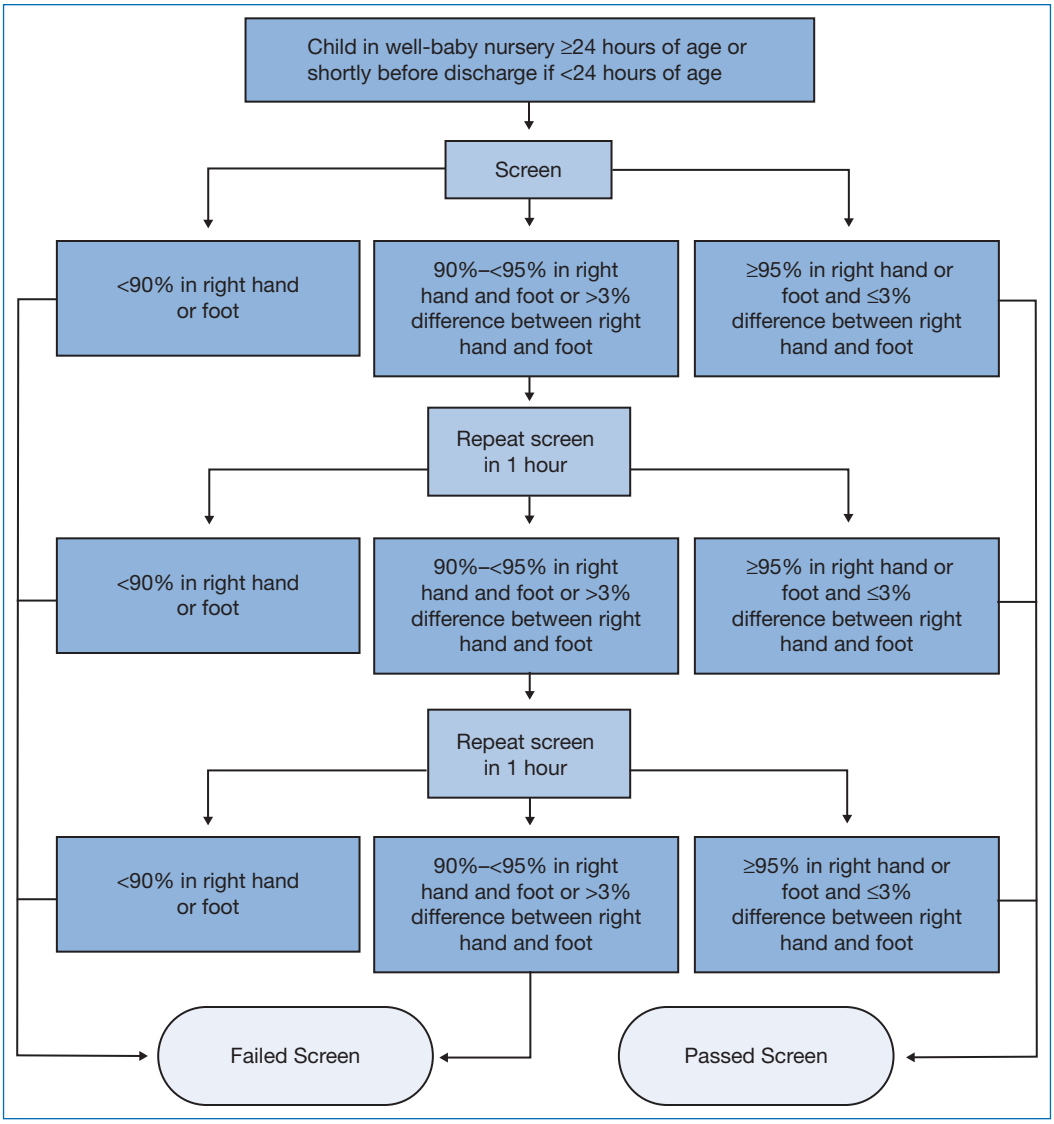

FIGURE 5.4 Newborn screening algorithm for critical congenital heart defects.

Note: Percentages refer to oxygen saturation as measured by pulse oximeter.

Source: Centers for Disease Control and Prevention. (2018). *Congenital heart defects information for healthcare providers.* Retrieved from https://www.cdc.gov/ncbddd/heartdefects/hcp.html

can miss cCHDs because symptoms may not appear until after discharge when the ductus arteriosus closes. Heart murmurs may be absent or misleading due to underlying anatomy, prolonged decline of pulmonary vascular resistance, or reduced ventricular function (Riede et al., 2010). Diagnosis may be further complicated by trends to discharge early. It has been estimated that at least 280 infants with an unrecognized cCHD are discharged each year from newborn nurseries in the United States (CDC, 2018). These babies are at risk for having serious problems within the first few days or weeks of life and often require emergency care.

The first signs of acute cCHD may be circulatory collapse requiring the need for cardiopulmonary resuscitation or death. Delays in diagnosis have been associated with significant morbidity and mortality. The current incidence of serious compromise resulting in undiagnosed cCHD has been estimated to be 1 per 15,000 to 1 per 26,000 live births (Riede et al., 2010). These data have led to a broad consensus that screening for cCHD is warranted.

Pulse oximetry can detect mild hypoxemia, which is a sign for many types of cCHD that may not be recognized by physical examination. This was first reported in 1995, and since then many studies have shown that screening with pulse oximetry is an effective tool for the detection of cCHD (Riede et al., 2010). Once identified, babies with a cCHD can be seen by cardiologists and can receive specialized care and treatment that could prevent death or disability early in life. Treatment can include medications and/or surgery.

When to Screen

Screening is done when a baby is 24 to 48 hours of age. If the baby is to be discharged from the hospital before he or she is 24 hours of age, screening should be done as late as possible before discharge. If the results are "negative" (in-range result), it means that the baby's test results did not show signs of a cCHD. This type of screening test does not detect all cCHDs, so it is possible to still have a critical or other heart defect with a negative screening result. If the results are "positive" (out-of-range result), it means that the baby's test results showed low levels of oxygen in the blood. This can be a sign of a cCHD. This does not always mean that the baby has a cCHD. It just means that more testing such as an echocardiogram is needed. The algorithm in Figure 5.4 shows the steps on how to complete the screening.

A screen is considered positive if (1) any oxygen saturation measure is less than 90% (in the initial screen or in repeat screens); (2) oxygen saturation is less than 95% in the right hand and foot on three measures, each separated by 1 hour; or (3) a greater than 3% absolute difference exists in oxygen saturation between the right hand and foot on three measures, each separated by 1 hour. Any screening that is less than or equal to 95% in the right hand or foot with a less than or equal to 3% absolute difference in oxygen saturation between the right hand or foot is considered a negative screen, and screening would end.

Any infant with a positive screen should have a diagnostic echocardiogram, which would involve an echocardiogram within the hospital or birthing center, transport to another institution for the procedure, or use of telemedicine for remote evaluation. The infant's healthcare provider should be notified immediately, and the infant might need to be seen by a cardiologist for follow-up.

False positives are decreased if the infant is alert, and timing cCHD screening around the time of the newborn hearing screening improves efficiency. POS should not replace taking a complete family medical and pregnancy history and completing a physical examination, which sometimes can detect cCHD before the development of hypoxia.

DISCHARGE

Planning for discharge should begin at the time of admission. Every interaction with the parents should be a teaching moment. Discharge instructions for the parents should be given by both the nurse caring for the newborn and the primary care provider and should include early follow-up appointment with the pediatrician or primary care provider within 72 hours of discharge from the birth hospitalization, feeding schedules, routine bathing, home care needs, umbilical cord care, signs and symptoms of infection, when to call your primary care provider, voiding and stooling patterns, and infant safety.

SUMMARY

This chapter has outlined the basic information for assessing, managing, and discharging the normal newborn. There is growing evidence to support the need for neonatal nurses to have a better understanding of the normal newborn as they care for the sick and/or preterm infant.

CASE STUDY

■ **Identification of the Problem.** A term male infant presented at birth with 2 to 5 mm pustules covering his face, chest, trunk, and scrotum.

■ **Assessment: History and Physical Examination.** A term male infant, 39 + 4 weeks' gestation, weighing 3.6 kg, was born via a cesarean section for failure to progress. Apgars were 8 and 9 at 1 and 5 minutes, respectively. The mother was a 33-year-old G1 P0. The pregnancy was uncomplicated, mother's blood type is A+, syphilis screen was negative, hepatitis screen was negative, HIV screen was negative, and Rubella was immune. Group B strep culture was negative. Mother received prenatal care. Medications during the pregnancy included prenatal vitamins. Complications during labor included failure to progress, requiring a cesarean section.

■ **Physical Examination on Admission to the Newborn Nursery**

- General: AGA term male infant in no distress with pustules covering his body. On admission to the newborn nursery, the infant was placed on a radiant warmer. Vital signs were stable: temperature 98.2°F, heart rate 158, respirations 48, blood pressure 72/48 mmHg, $m = 52$; blood sugar was 86.
- HEENT: mild caput, anterior fontanelle soft and flat, sutures approximated and mobile, palate intact, and ears appropriately placed; eyes normally spaced with red reflex bilaterally, pupils reactive, no hemorrhage noted. Ears with ready recoil and symmetric
- RESP: bilateral breath sounds clear and equal, no grunting or retractions
- CV: regular rate and rhythm, good perfusion, brisk cap refill, normal pulses × 4 extremities, and no murmur
- ABDOMEN: soft, flat, and nontender. Active bowel sounds and no hepatomegaly
- GU: normal male genitalia, testes descended bilaterally, rugae present, and anus patent
- NEURO: awake and active, tone AGA. Good suck and gag reflex

- SPINE: spine straight and intact, no dimple and neck supple, no masses
- EXTREMITIES: moving all extremities well with symmetric extremities; no hip clicks or clunks
- SKIN: warm and dry. Moderate nonerythematous pustule approximately between 1 and 4 mm on the face, chest, trunk, scrotum, and thighs. Vesicle appears to contain milky, purulent exudate. The pustules rupture easily. Some appear superficial and wiped off easily with vernix.

■ Differential Diagnosis

- Acropustulosis
- Candidiasis
- Erythema toxicum
- Herpes simplex virus infection
- Milia
- Miliaria
- Neonatal pustular melanosis
- *Staphylococcus aureus* infection

■ **Diagnostic Tests.** If the appearance is typical of transient neonatal pustular melanosis, no further workup is indicated. If appearance is not typical, potassium hydroxide preparation, Gram stain, and Wright-Giemsa stain can be obtained to support other diagnoses in the differential. Bacterial and viral cultures can be done from the pustule. If there is a clustering of pustules, a polymerase chain reaction to identify possible herpes simplex should be considered.

■ **Working Diagnosis.** Transient neonatal pustular melanosis.

This is a benign, self-limiting rash of unknown etiology. In the United States, incidence has been reported to be 2.2% in white infants and as high as 4.4% in black infants and infants with darker pigmentation.

The rash starts in utero, so eruptions are always present at birth but the clinical appearance can vary. At first, the pustules appear as uniform, round, 2- to 4-mm nonerythematous pustules that rupture easily. There is a thin white scale that is left around the perimeter of each denuded pustule. After a few hours, a central pigmented brown macule appears. This is smooth and has distinct borders that look like a freckle. The hallmark of this rash is the hyperpigmented spot that remains after the pustule has resolved. They may be profuse or sparse and typically are found under the chin and on the neck, upper chest, back, and buttocks. Occasionally, the palms, soles, and scalp are affected.

■ **Management.** No treatment is indicated. Parents will be anxious when they see pustules covering their baby and will need reassurance that neonatal pustular melanosis is a benign finding and that it fades and disappears over a period of months.

EVIDENCE-BASED PRACTICE BOX

Early SSC in the Healthy Term Newborn

SSC between mother and baby at birth has been associated with numerous physiologic and psychological benefits, including temperature, heart rate, and respiratory rate stabilization of the newborn, less crying, decreased pain with procedures, and less incidence of hypoglycemia in the newborn (Bergman, Linley, & Fawcus, 2004; Christensson et al., 1992; Christensson, Cabrera, Christensson, Unvas Moberg, & Winberg, 1995; Johnston et al., 2014; Nolan & Lawrence, 2009). Breastfeeding initiation and duration is also positively impacted by SSC. Mothers who engaged in SSC with their newborns at birth were more likely to have a successful breastfeed, post birth, than mothers who did not engage in SSC (Carfoot, Williamson, & Dickson, 2004, 2005; Karimi & Khadivzadeh, 2012). Mothers who engaged in SSC were also more likely to be exclusively breastfeeding at 6 weeks, 3 and 6 months post birth (Anderson et al., 2009; Gouchon et al., 2010; Sharma, 2016; Vaidya, Sharma, & Dhungel, 2005). Mothers who engage in SSC also have reported less pain (Nolan & Lawrence, 2009; Wagner, Lawrence, Xu, & Melsom, 2018), state less anxiety 3 days post birth (Shiau, 1997), report higher self-efficacy with breastfeeding at 1 month post birth (Aghdas, Talat, & Sepideh, 2014), and report less postpartum depressive symptoms and physiologic stress (Bigelow, Power, MacLellan-Peters, Alex, & McDonald, 2012).

Moore, Bergman, Anderson, and Medley (2016) conducted a meta-analysis of 46 randomized controlled trials regarding SSC and concluded that women who experienced SSC were significantly more likely to be breastfeeding at 1 to 4 months after birth, and were more likely to exclusively breastfeed than women who did not experience SSC. Moore et al. (2016) also found that infants who experienced SSC had greater stability of the cardiorespiratory system and higher glucose levels than infants who did not experience SSC. The authors found no significant difference in infant temperature between infants who did or did not experience SSC. Johnston et al. (2014) conducted a meta-analysis of 25 randomized controlled trials regarding SSC and procedural pain. The authors found that infants who received SSC during painful procedures had less crying and lower heart rate than infants who did not receive SSC.

The AAP Policy Statement (2012), the Academy of Breastfeeding Medicine (2010), the AWHONN (Dabrowski, 2007), and the BFHI (2018) all have position statements and recommendations for policy regarding the implementation of SSC at birth. All healthy term infants are recommended to be placed skin to skin immediately after delivery for at least 1 hour. Newborns should be placed naked or with diaper only, and prone on the mother's chest. Mother and baby should be covered with a warm blanket. From this position, the infant can be dried, Apgar scores assigned, initial assessment completed, and identification bracelets placed on mother and newborn. Newborn care and measurements/weight and length, including bathing, vitamin K, and erythromycin administration, should be delayed to allow uninterrupted SSC and optimal opportunity for the initial breastfeed within the first hour after birth.

Stevens, Schmied, Burns, and Dahlen (2014) conducted a review of the literature on SSC in the operating room (OR) after cesarean delivery. The authors not only concluded, based on the literature, that SSC in the OR with healthy term newborns was feasible, but also that SSC in the OR promotes breastfeeding initiation, reduced formula supplementation in the hospital, increased bonding and maternal satisfaction, promoted more stable temperature, and reduced newborn stress. While the evidence for SSC is strong, barriers to implementation do exist. Haxton, Doering, Gingras, and Kelly (2012) discussed challenges including overcoming staff concerns, modifying unit order sets, and adapting electronic medical records to allow for documentation

(*continued*)

EVIDENCE-BASED PRACTICE BOX (*continued*)

and tracking of SSC. While overcoming these challenges took time and coordination, the authors express that the outcome of increasing breastfeeding initiation rates from 74% to 84% within a 6-month time frame was worth their effort.

While SSC has been safely implemented in hospitals across the United States and the world, some rare adverse events have been documented. Andres et al. (2011) reviewed six cases of apparent life-threatening events (ALTEs) that occurred with infants in SSC within two hours after birth. In all six cases, the ALTE occurred with no apparent cause, and all six infants were born at term and were otherwise healthy. The common risk factors identified among the six cases were that the mothers were primiparous, in SSC with the infant in a prone position on the mother's chest, and the mother and infant were left alone in the delivery room. To improve safe SSC practice, Feldman-Winter and Goldsmith (2016) suggest that continuous observation by staff and obtaining frequent vital signs of the newborn occur throughout SSC. The authors also suggest safe positioning of the newborn during SSC including making sure the infant's face is visible with mouth and nose not covered and the infant's head in the sniffing position and turned to one side with a straight neck. The infant's shoulders and chest should face the mother and the infant's legs should be flexed.

PARENT VOICES

Jennifer Canvasser, MSW

My spouse and I struggled with infertility for 3 years before finding out we would be welcoming twins to the world. Despite our planning and best efforts, our twins, Micah and Zachary, were born at 27 weeks' gestation. Zachary spent 91 days in the NICU, while our son Micah was hospitalized for a total of 299 days due to developing NEC. Tragically, Micah died from complications of NEC when the twins were 11 months old.

Three years after Micah and Zachary were born, we welcomed our rainbow baby, Elijah, to the world. Elijah was born weighing almost 9 lb at over 41 weeks' gestation. Thankfully, it was a healthy term pregnancy, yet I was constantly terrified and anxious of giving birth prematurely. It was most helpful when nurses would validate my feelings and recognize them as normal, given my past experience. Writing served as a helpful outlet for me during my pregnancy with Elijah, and I even wrote about it here: www.huffingtonpost.com/entry/5-ways-to-support-a-family-expecting-a-rainbow-baby_b_7222608.html

Number 3 in the blog really stands out for me as a bereaved mother: Get the birth order right. Death does not change birth order, simple as that.

Pregnancy after giving birth prematurely—or after a loss—is unique and these mothers deserve an empathetic, responsive care team tuned in to their needs and experiences.

Heather McKinnis

Our first baby came so early that deciding to give our micropreemie a sibling was a difficult decision. Each of our pregnancies after our preemie was emotionally and physically draining. Progesterone injections, countless ultrasounds, some bedrest, and early full-term scheduled C-sections became our normal. I had panic attacks, anxiety, and nightmares, although these decreased with each pregnancy. We never discovered the reason my first son came so early and each pregnancy was filled with the unknown. In the end, we were able to deliver three more beautiful babies close to full term. I was able to experience their deliveries, hear their cries, breastfeed, and hold them skin to skin. I finally felt like I was able to experience motherhood like everyone else around me. All those moments that my son's extremely premature delivery stole from us were given back three times over and I'll be forever grateful. After everything we went through with our 25-weeker, these experiences were incredibly healing.

Tracy Pella

We gave birth to our twins at 23 + 4 weeks and one of our sons passed away the same day and our other son spent 134 days in the NICU. Post-NICU was filled with very much a "23-weeker life," including appointments, medications, and isolation. When our surviving twin was 4 years old, we were blessed to give birth to our daughter at 37 weeks during a planned C-section. Her birth may have been "normal" by standards of the baby world, but it was far from our normal. Remember, our normal was the 23-weeker life. Our first birth included saying goodbye to one of our sons and watching the other fight for his life for several months. That was our normal!

Being able to plan her arrival and the anticipation was exhausting. I often found myself waiting for the floor to drop from under me. It was almost like we wouldn't allow ourselves to believe we could have a normal delivery. Anxiety took over when I realized she wouldn't be monitored 24/7. I understood she was healthy, but it was more natural to think we wouldn't be able to take her home with us. Visitor after visitor commented that we must be elated she arrived full-term and healthy. Yes, we were happy, but we needed everyone to understand that this was new territory for us. We had put our defenses up and we had to get used to the idea that we got to leave the hospital doors with a baby. It was like experiencing birth and parenthood for the first time.

Unit III: Systems Assessment and Management of Disorders

CHAPTER 6

Respiratory System

Samuel Gentle, Colm Travers, and Waldemar A. Carlo

INTRODUCTION

The mechanisms that bring about normal pulmonary function are complex. The clinician must fully comprehend the physiologic processes associated with neonatal respiratory diseases. Only through advanced knowledge can the clinician efficiently assess and evaluate the newborn's respiratory status. Systematic use of these assessment skills allows the clinician, as part of the collaborative team, to positively affect patient outcome.

EMBRYOLOGIC DEVELOPMENT OF THE LUNG

Pulmonary development of the embryo proceeds along a predetermined sequence throughout gestation (Greenough & Milner, 2005). Pulmonary development begins with the formation of an outpouching of the embryonic foregut during the fourth week of gestation. Sequential branching of the lung bud, which appears at about 4 weeks and is complete by the sixth week, marks the embryonic phase of lung development. Weeks 7 to 16, the pseudoglandular phase, are marked by the formation of conducting airways by branching of the aforementioned lung buds. This phase ends with completion of the conducting airways. The canalicular phase follows through week 28, when gas exchange units, known as acini, develop. Surfactant-producing type II pneumocytes begin to form during the latter part of this phase. Mature, vascularized gas exchange sites form during the saccular phase, which spans the 29th through 35th weeks. During this phase, the interstitial space between alveoli thins, so respiratory epithelial cells tightly contact developing capillaries. The alveolar development phase, marked by expansion of the gas exchange surface area, begins at 36 weeks and extends into the postnatal period. Additional alveoli continue to develop well into childhood, perhaps as late as the seventh year of life (Table 6.1). The alveolar wall and interstitial spaces become very thin, and the single capillary network comes in close proximity to the alveolar membrane. No firm boundaries separate the phases of lung development, and gas exchange, albeit inefficient, is possible relatively early in gestation, even before mature, vascularized gas exchange sites form. Lung development is a continuum that is marked by rapid structural changes. Interference at any time by premature birth or by disease introduces the possibility of inducing lung injury.

TABLE 6.1

STAGES OF NORMAL LUNG GROWTH

Phase	Timing	Major Event
Embryonic	Weeks 4–6	Formation of proximal airway
Pseudoglandular	Weeks 7–16	Formation of conducting airways
Canalicular	Weeks 17–28	Formation of acini
Saccular	Weeks 29–35	Development of gas exchange sites
Alveolar	Weeks 36 through postnatal life	Expansion of surface area

NEWBORN PULMONARY PHYSIOLOGY AND THE ONSET OF BREATHING

The fetal lung is fluid filled, underperfused, and dormant with regard to gas exchange. The fetal lung receives only approximately 10% of the cardiac output (CO). Because the placenta is the gas exchange organ in fetal life, high blood flow is preferentially directed toward it rather than to the lungs. The pulmonary vasculature maintains a high vascular resistance. Consequently, most of the right ventricular output is shunted from the pulmonary artery across the ductus arteriosus into the aorta, bypassing the pulmonary circulation.

Within moments after the umbilical cord is clamped, the newborn undergoes a transformation from a fetus floating in amniotic fluid to an air-breathing neonate. When normal breathing occurs after birth, the ensuing chain of events converts the fetal circulation to the adult pattern of circulation. Lung fluid is absorbed and replaced with air, thus establishing lung volume and allowing for normal neonatal pulmonary function. The process of fetal lung fluid absorption begins before birth when the rate of alveolar fluid secretion

declines. Reabsorption speeds up during labor. Animal data suggest that as much as two-thirds of the total clearance of lung fluid occurs during labor due to the cessation of active chloride secretion into the alveolar space. Perinatal fluid clearance is also related to epithelial sodium channels (ENaC) induced by the increase in serum cortisol after delivery (Janér, Pitkänen, Helve, & Andersson, 2011). Oncotic pressure favors the movement of water from the air space back into the interstitium and into the vascular space. With the onset of breathing and lung expansion, water moves rapidly from the air spaces into the interstitium and is removed from the lung by lymphatic and pulmonary blood vessels. Since a large proportion of the clearance of lung fluid occurs during the labor process, neonates born without labor after a scheduled cesarean section are at particularly high risk for delayed absorption of fetal lung fluid and thus for transient tachypnea of the newborn (TTN). Late preterm infants whose mothers received betamethasone have lower rates of TTN presumably due to the influence of corticosteroids on upregulation of ENaC channels (Gyamfi-Bannerman et al., 2016). Birth prior to 38 weeks by elective scheduled cesarean section is especially associated with an increased risk of respiratory disorders and an increase in mortality risk (Tita et al., 2009).

Several cardiac changes must take place to complete the process of transition from the intrauterine to extrauterine environment. With the onset of breathing, highly negative intrathoracic pressures are generated with inspiratory efforts, filling the alveoli with air. Replacing alveolar fluid with air causes a precipitous decrease in hydrostatic pressure in the lung, leading to a decrease in pulmonary artery pressure. The resultant decrease in right atrial pressure and increase in pulmonary blood flow leads to an increase in alveolar oxygen tension (Pa_{O_2}) which causes constriction of the ductus arteriosus, which normally shunts right ventricular blood away from the lungs. Clamping of the umbilical cord removes the large, low-resistance, placental surface area from the circulation. This change in resistance causes an abrupt increase in systemic arterial pressure, reflected all the way back to the left atrium. As left atrial pressure rises, the flap valve opening between the atria, known as the foramen ovale, is pushed shut. This closure prevents blood from bypassing the lungs by eliminating the shunt across the foramen ovale from the right atrium to the left atrium. These simultaneous changes wherein the systemic vasculature resistance exceeds that of the pulmonary vasculature allow physiologic closure of both the foramen ovale and ductus arteriosus. The infant successfully converts from the pattern of fetal circulation to neonatal circulation when blood coming from the right ventricle flows in its new path of least resistance (lower pressure) to the lungs, instead of shunting across the foramen ovale to the left atrium or across the ductus arteriosus from the pulmonary artery to the aorta.

Understanding normal breathing and ventilation enables the clinician to assess the infant in respiratory distress and devise strategies for management. The respiratory system is composed of the following: (a) the pumping system (the chest wall muscles, diaphragm, and accessory muscles of respiration), which moves free gas into the lungs; (b) the bony rib cage, which provides structural support for the respiratory muscles and limits lung deflation; (c) the conducting airways, which connect gas-exchanging units with the outside but offer resistance to gas flow; (d) an elastic element, which offers some resistance to gas flow but provides pumping force for moving stale gas out of the system; (e) air–liquid interfaces, which generate surface tension that opposes lung expansion on inspiration but supports lung deflation on expiration; and (f) the abdominal muscles, which aid exhalation by active contraction.

Limitations in the respiratory system predispose the newborn to respiratory difficulty. The circular, poorly ossified rib cage, with a flat instead of angular insertion of the diaphragm, is less efficient at generating negative intrathoracic pressure during inhalation. The highly compliant chest wall often moves in a contrary manner to the desired flow of air. Small muscles and a relative paucity of type I muscle fibers hinder the strength and endurance of respiratory muscles. The newborn has a relatively low functional residual capacity (lung volume at the end of exhalation) because the comparatively floppy chest wall offers little resistance to collapse, even when a normal amount of functional surfactant is present.

Surface tension is the force that arises from the interaction among the molecules of a liquid. Molecules in the interior of the liquid bulk are attracted to each other, but molecules on the surface of the liquid are attracted to other molecules in the interior of the liquid, which results in the movement of the surface molecule toward the bulk of the liquid. This explains why a droplet of water over a surface tends to adopt a given size and not continuously expand. If we think of the alveolus as a soap bubble, the molecules of the wall of the bubble are attracted to each other, which tend to collapse the bubble. The higher the surface tension, the faster the bubble collapses. The pressures across the wall of the bubble act against the surface tension and avoid the collapse of the bubble. The relationship between the surface tension and the distending pressures and the pressure across the wall of the bubble are described by Laplace's law, as shown in the following equation:

$$P = \frac{2ST}{r}$$

where P is pressure, ST is surface tension, and r is radius of the alveolus. It is difficult to inflate a small or collapsed alveolus because it has a very small diameter. As its volume increases, the pressure needed to continue inflation becomes progressively less—that is, compliance of the alveolus and thus compliance of the lung have improved. Coating the alveoli with an agent that decreases surface tension reduces the effort required to inflate the lungs from a low volume.

An alveolar cell known as the type II pneumocyte produces pulmonary surfactant. Surfactant is a mixture of proteins and phospholipids that naturally coats the mature alveoli, preventing alveolar collapse and loss of lung volume during expiration—that is, as expiration ensues and the lung deflates, the alveolar diameter becomes smaller. Surfactant coating of the alveolus reduces surface tension so that collapse is prevented and less pressure is required to reinflate it with the next inspiration. Neonates with respiratory distress syndrome (RDS) have surfactant deficiency. In the absence of surfactant, surface tension is high, and the tendency is toward collapse of alveoli at end expiration and resulting microatelectasis.

Compliance is the elasticity, or distensibility, of the lung. It is expressed as the change in volume caused by a change in pressure as follows:

$$CL = \frac{V}{P}$$

where CL is compliance of the lung, V is volume, and P is pressure. The higher the compliance, the larger the volume delivered to the alveoli per unit of applied inspiratory pressure. Surface tension and compliance are particularly important in the preterm infant with RDS. Surface tension is a force that opposes lung expansion. Surfactant deficiency leads to increased surface tension in the alveoli. Lungs with higher surface tension are more difficult to inflate. During expiration, some alveoli collapse. This results in a decreased lung volume at the end of expiration (low functional residual capacity). Clinically, the presence of retractions and other signs of respiratory distress such as nasal flaring and grunting manifest the effects of this increased surface tension. Respiratory muscles contract to inflate the lungs against the surface tension that acts in the opposite direction. The negative pleural pressure easily deforms

the floppy thoracic wall of the preterm infant. When a preterm infant with RDS is intubated, a high peak inspiratory pressure (PIP) is required to expand the thorax (i.e., tidal volume is obtained only with a high change in pressure). After surfactant is administered, chest expansion increases with the same PIP. This effect (increased compliance) is due to a decrease in surface tension (i.e., a smaller force opposing lung distention). Thus the tidal volume obtained with the same PIP is increased. Before surfactant is administered, it is very difficult to inflate the lung because compliance is low. After surfactant is administered, surface tension decreases, and it becomes easier to inflate the lung (i.e., compliance is improved).

Resistance is a term used to describe the characteristics of gas flow through the airways and pulmonary tissues. Resistance can be thought of as the capacity of the lung to resist airflow. The principal component of resistance is determined by the small airways. Pressure is required to force gas through the airways (airway resistance) and to overcome the forces of the lung and chest wall, which work to deflate the respiratory system (tissue resistance). At a specific flow rate, resistance is described by the following equation:

$$R = \frac{P1 - P2}{V}$$

where $P1$ and $P2$ are pressures at opposite ends of the airway, and V is the flow rate of gas (volume per unit of time). Resistance increases as airway diameter decreases. Because the infant has airways of relatively small radius, the resistance to gas flow through those airways is high. Poiseuille's law recognizes that resistance to flow through a cylindrical object is inversely proportional to the fourth power of the radius.

$$R = \frac{8\eta L}{2\pi r^4}$$

In other words, if the radius of the airway is decreased by half, the resulting resistance to flow through the airway is increased 16-fold.

The time constant is the time necessary for airway pressure to partially equilibrate throughout the respiratory system and equals the mathematic product of compliance and resistance. In other words, the time constant is a measure of how quickly the lungs can inhale or exhale. It takes approximately five time constants to complete inhalation and exhalation. The time constant (K_t) is directly related to both compliance (C) and resistance (R). This relationship is described by the following equation:

$$K_t = C \times R$$

An infant with RDS has decreased compliance, so the time constant of the respiratory system is relatively short. In such an infant, little time is required for pressure to equilibrate between the proximal airway and alveoli, so short inspiratory and expiratory times may be appropriate during mechanical ventilation. This allows the child with RDS to be ventilated with higher rates than would commonly be tolerated in most other populations. When compliance improves (increases), however, the time constant becomes longer. If sufficient time is not allowed for expiration, the alveoli may become overdistended due to gas trapping, and an air leak may result.

Blood Gas Analysis and Acid–Base Balance

Oxygen diffuses across the alveolar-capillary membrane, moved by the difference in oxygen pressure between the alveoli and the blood. In the blood, oxygen dissolves in the plasma and binds to hemoglobin. Thus, arterial oxygen content (Cao_2) is the sum of dissolved and hemoglobin-bound oxygen, as is shown by the following equation:

$$Cao_2 = (1.37 \times Hb \times Sao_2)\ (0.003 \times Pao_2)$$

where Cao_2 is arterial oxygen content (mL/100 mL of blood), 1.37 is the milliliters of oxygen bound to 1 g of hemoglobin at 100% saturation, Hb is hemoglobin concentration per 100 mL of blood (g/100 mL), Sao_2 is the percentage of hemoglobin bound to oxygen (%), 0.003 is the solubility factor of oxygen in plasma (mL/mmHg), and Pao_2 is oxygen partial pressure in arterial blood (mmHg).

In the equation for arterial oxygen content, the first term—$(1.37 \times Hb \times Sao_2)$—is the amount of oxygen bound to hemoglobin. The second term—$(0.003 \times Pao_2)$—is the amount of oxygen dissolved in plasma. Most of the oxygen in the blood is carried by hemoglobin. For example, if a premature infant has a Pao_2 of 60 mmHg, an Sao_2 of 92%, and a hemoglobin concentration of 14 g/100 mL, then Cao_2 is the sum of oxygen bound to hemoglobin $(1.37 \times 14 \times 0.92) = 17.6$ mL, plus the oxygen dissolved in plasma $(0.003 \times 60) = 0.1$ mL. In this typical example, only less than 1% of oxygen in blood is dissolved in plasma; more than 99% is carried by hemoglobin. If the infant has a sudden decrease in the hemoglobin concentration to 10.5 g/dL but Pao_2 and Sao_2 remain the same, then Cao_2 $(1.37 \times 10.5 \times 0.92) + (0.003 \times 60)$ equals 13.4 mL/100 mL of blood. Thus, without any change in Pao_2 or Sao_2, a 25% decrease in hemoglobin concentration (from 14 to 10.5 g/dL) reduces the amount of oxygen in arterial blood by 24% (from 17.6 to 13.4 mL/100 mL of blood). This is an important concept for clinicians who care for patients with respiratory disease. Sao_2 and hemoglobin should be monitored and, if low, corrected to maintain adequate tissue oxygenation. Besides Sao_2 and hemoglobin, CO is the other major determination of oxygen delivery to the tissues.

The force that loads hemoglobin with oxygen in the lungs and unloads it in the tissues is the difference in partial pressure of oxygen. In the lungs, alveolar oxygen partial pressure is higher than capillary oxygen partial pressure, so that oxygen moves to the capillaries and binds to the hemoglobin. Tissue partial pressure of oxygen is lower than that of the blood, so oxygen moves from hemoglobin to the tissues. The relationship between partial pressure of oxygen and hemoglobin is better understood with the oxyhemoglobin dissociation curve (Figure 6.1). Several factors can affect the affinity of hemoglobin for oxygen. Alkalosis, hypothermia, hypocapnia, and decreased levels of 2,3-diphosphoglycerate (2,3-DPG) increase the affinity of hemoglobin for oxygen (as shown in Figure 6.1 by a left shift of the curve). Acidosis,

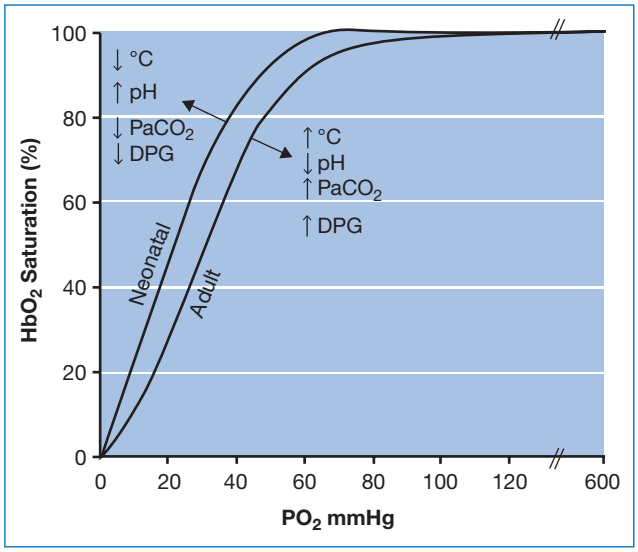

FIGURE 6.1 Oxyhemoglobin equilibrium curves of blood from term infants at birth and from adults (at pH 7.40).

hyperthermia, hypercapnia, and increased 2,3-DPG have the opposite effect, decreasing the affinity of hemoglobin for oxygen, so that the hemoglobin dissociation curve shifts to the right. This characteristic of hemoglobin facilitates oxygen loading in the lung and unloading in the tissue, where the pH is lower and alveolar carbon dioxide tension ($Paco_2$) is higher. Fetal hemoglobin, which has a higher affinity for oxygen than adult hemoglobin, is more fully oxygen-saturated at lower Pao_2 values. This is represented by a leftward shift on the hemoglobin oxygen dissociation curve.

Once loaded with oxygen, the blood should reach the tissues to transfer oxygen to the cells. Oxygen delivery to the tissue depends on CO and Cao_2, as described in the following equation:

$$\text{Oxygen Delivery} = CO \times Cao_2$$

In the case of the infant discussed previously, increased CO compensates for the decrease in Cao_2 that results from anemia. The key concept is that when a patient's oxygenation is assessed, more information than just Pao_2 and Sao_2 should be considered. Pao_2 and Sao_2 may be normal, but, if hemoglobin concentration is low or CO is decreased, oxygen delivery to the tissues is decreased. With this approach, the clinician should be able to better plan the interventions needed to improve oxygenation.

As in the adult, the acid–base balance in the neonate is maintained within narrow limits by complex interactions between the pulmonary system (which eliminates carbon dioxide) and the kidneys (which conserve carbon dioxide and eliminate metabolic acids). Carbon dioxide elimination, which is more efficient than oxygenation across the alveolar-capillary membrane, is usually not as problematic as oxygenation. Carbon dioxide has a high solubility coefficient, so cellular diffusion is efficient and no measurable partial pressure gradient exists between venous blood and the tissues. Therefore, elevated carbon dioxide tension (Pco_2) values in arterial blood samples nearly always indicate ventilatory dysfunction. Dissolved carbon dioxide moves rapidly across cell membranes of peripheral chemoreceptors, thereby making them sensitive to changes in ventilation. Increased intracellular Pco_2 elevates the cellular hydrogen ion concentration as carbon dioxide combines with water to form carbonic acid. This stimulates neural impulses to the medulla, which in turn stimulates respiration. However, excessively high Pco_2 levels and acidosis can depress ventilation. Acid–base balance is controlled by homeostatic mechanisms and is expressed by the Henderson–Hasselbalch equilibrium equation:

$$pH = 6.1 + \frac{\log HCO_3^-}{0.03 \times Pco_2}$$

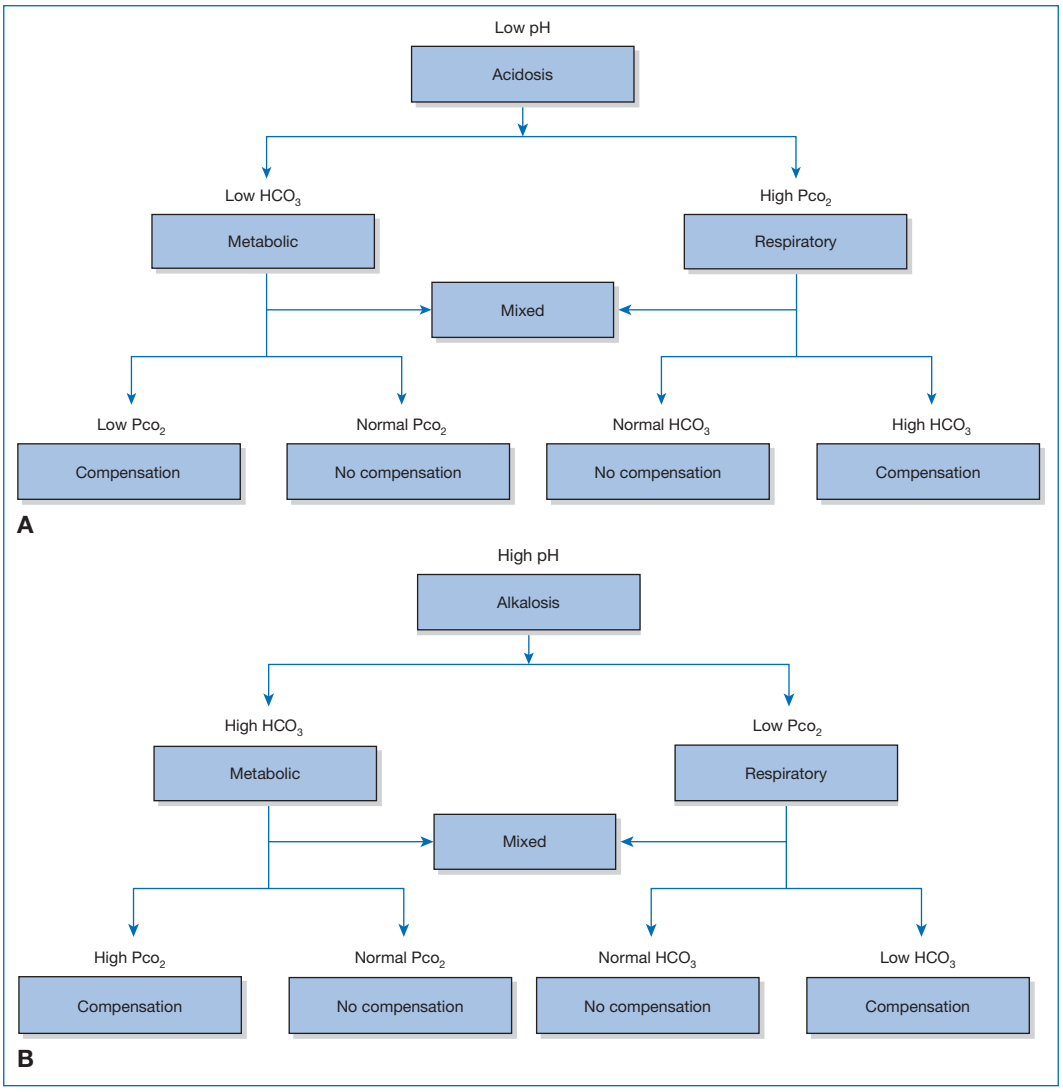

FIGURE 6.2 Acid–base balance: diagnostic approach. (A) Low pH. (B) High pH.

It can be seen from this mathematical relationship that acid–base balance depends on the interplay of bicarbonate ion (HCO_3^-) and carbon dioxide (CO_2). Low pH (in other words, acidosis) can contribute to vasoconstriction and can result in worsening hypoxemia caused by extrapulmonary shunt across the ductus or foramen ovale. A pH of 7.20 or higher is generally considered safe in preterm infants with RDS (SUPPORT Study Group et al., 2010). A pH of less than 7.0 is not well tolerated and is associated with a poor survival rate in these patients.

If $Paco_2$ rises above normal, as in hypoventilation, pH declines and the patient suffers from respiratory acidosis. The patient with a chronic respiratory acidosis may retain bicarbonate, thus self-inducing a compensatory metabolic alkalosis. A patient who is hyperventilated with a low $Paco_2$ has respiratory alkalosis. Depressed bicarbonate ion concentration (less than approximately 20 mmol/L in plasma) is called metabolic acidosis and can be associated with any cause of anaerobic metabolism, such as poor CO from congenital heart disease—for example, hypoplastic left heart syndrome or severe aortic coarctation—or from myocardial ischemia, myocardiopathy, myocarditis, hypoxia, necrotizing enterocolitis, or septic shock. Metabolic acidosis that results from renal bicarbonate wasting commonly develops in extremely premature infants. Less common causes for prolonged and severe metabolic acidosis are the inborn errors of metabolism, including urea cycle defects and aminoacidopathies.

The clinician should become proficient at interpreting blood gas data. With knowledge of the accepted normal values and definitions of the simple blood gas disorders and their compensatory mechanisms, the clinician can examine data in light of the disease process and interpret blood gas values in a fairly straightforward manner. Normally, the body does not overcompensate for a pH above or below the normal range. Therefore, when presented with an abnormal pH, the clinician should rapidly determine whether acidosis (Figure 6.2A) or alkalosis (Figure 6.2B) exists. An examination of $Paco_2$ and HCO_3^- determines whether the process is respiratory, metabolic, or mixed. The clinician should determine which derangement occurred first. For example, an acidotic, acutely ill hypoxemic infant with a high $Paco_2$ and depressed HCO_3^- is usually hypoventilating and suffering metabolic acidosis secondary to anaerobic metabolism. The infant with a low $Paco_2$ is hyperventilating, either spontaneously or secondary to overzealous mechanical ventilation. A concomitantly low pH and low $Paco_2$ indicate that the infant is compensating for metabolic acidosis with hyperventilation in an effort to normalize the pH. A pure metabolic alkalosis with high pH can be caused by bicarbonate administration, loop diuretics such as furosemide, or gastric losses due to pyloric stenosis or gastric suctioning. Infants with bronchopulmonary dysplasia (BPD) usually have a compensated respiratory acidosis, with an elevated $Paco_2$ and concomitantly elevated HCO_3^-. The pH may be in the normal range or slightly acidotic. A severely depressed pH usually indicates acute decompensation.

ASSESSMENT OF THE NEONATE WITH RESPIRATORY DISTRESS

The assessment of a neonate with respiratory distress should always begin with the compilation of a detailed perinatal history. In some cases, the history is difficult to obtain, especially when the infant has been transferred from one center to another, often with incomplete records. Even so, every effort should be made to obtain as much pertinent information as possible. The clinician is often able to gain important supplemental information from the father or visiting relatives at the bedside. A review of the maternal–perinatal history and a complete physical examination, combined with a limited laboratory and radiologic evaluation, leads to a timely diagnosis in most circumstances. Many neonatal diseases, including many with nonpulmonary origins, may manifest with signs of respiratory distress. Therefore, a comprehensive differential diagnosis must be considered (Figure 6.3).

History

In most situations, data from a patient's history can direct the clinician to the correct diagnosis of neonatal respiratory distress. The prenatal record should be reviewed carefully for possible causes of the infant's difficulties. The mother's age, gravidity, parity, blood

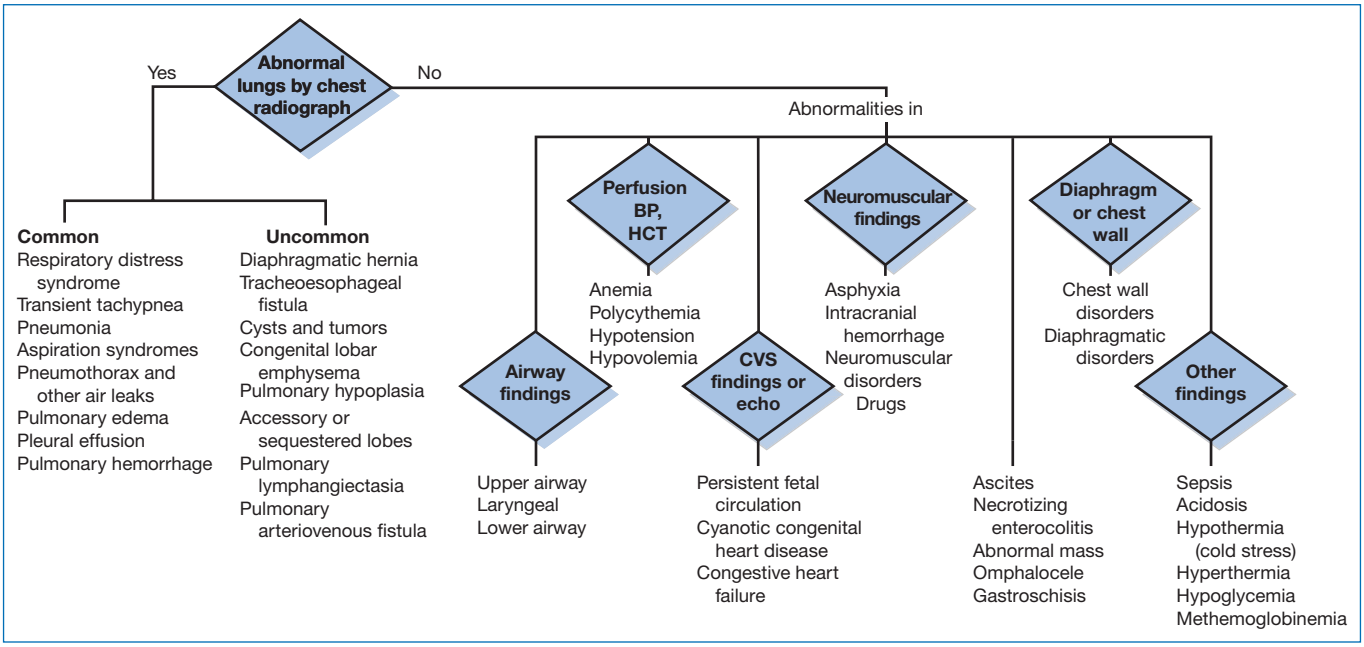

FIGURE 6.3 Diagnostic algorithm for the neonate with acute respiratory distress.

BP, blood pressure; HCT, hematocrit.

type, and Rh status should be recorded. The obstetrician's best estimate of gestational age should be documented as determined by first-trimester ultrasound or last menstrual period. Ultrasonography often provides information related to anomalies and amniotic fluid volume, which is useful in the anticipation of required support at birth. Historical information such as previous preterm birth is relevant, as it is often associated with an increased risk of premature delivery in subsequent pregnancies. Because excessive maternal weight gain occurs with diabetes, multiple gestation, or polyhydramnios, prepregnancy weight and total gain should be noted. The clinician is often alerted to the possibility of gestational diabetes with abnormal glucose tolerance screening results, which again should be reflected in the prenatal record.

The duration of membrane rupture or oligohydramnios, the presence of maternal fever with or without accompanying chorioamnionitis, and the presence of meconium-stained amniotic fluid are important pieces of information that may help in the differential diagnosis of a newborn with respiratory distress. Additionally, antepartum and intrapartum administration of certain medications may affect respiratory outcomes. **Quality and Safety: Administration of steroids to the mother reduces the likelihood that RDS will develop in the infant; administration of narcotics to the mother close to delivery may result in poor respiratory effort by an otherwise normal infant.** The use of magnesium sulfate for either neuroprotection or for tocolysis does not result in cardiorespiratory depression or need for increased resuscitation (De Jesus et al., 2015; Johnson et al., 2012).

Physical Examination of the Respiratory System

One or more of the major signs of respiratory difficulty (e.g., cyanosis, tachypnea, grunting, retractions, and nasal flaring) are usually present in neonates with both pulmonary and nonpulmonary causes of respiratory distress. Observation of the distressed infant with the unaided eye and ear is the clinician's first step in the physical assessment. Cyanosis may be central, as caused by pulmonary disease and cyanotic heart disease, or peripheral, as occurs in conditions with impaired CO. However, pulse oximetry more accurately detects hypoxemia as considerable interobserver variability has been reported in clinical detection of cyanosis (O'Donnell et al., 2007). Acrocyanosis, or cyanosis noted in the extremities, is a common normal finding in newborns during the first few days after birth. Tachypnea typically manifests in infants with decreased lung compliance, such as RDS, whereas patients with high airway resistance (e.g., airway obstruction) usually have deep but slow breathing. Grunting is produced by an adduction of vocal cords during expiration. Grunting holds gas in the lungs throughout expiration, which helps maintain lung volume and avoid alveolar collapse. At the end of expiration, the gas is released and rapidly propelled, causing an audible grunt. Grunting is more typical of infants with decreased functional residual capacity, such as preterm infants with RDS. Chest wall retractions occur more often in very premature infants because of the highly compliant chest wall (Carlo & Di Fiore, 2011). When the infant is intubated, observation of the chest gives important information. Careful observation of chest wall excursions produced by the ventilator allows the clinician to adjust the magnitude of the ventilator pressure so that optimal gas exchange is achieved while risk of volutrauma is minimized. The chest of an intubated infant should move the same or only slightly less than that of a healthy spontaneously breathing infant. The clinician should assess the appropriateness of the magnitude of the chest expansion in ventilated patients. **Emergency Alert: A reported abrupt decrease in the chest rise may indicate atelectasis, a plugged endotracheal tube, a pneumothorax, a leak in the circuit, or ventilator failure. Slow decreases in the chest rise over hours may indicate a deteriorating lung compliance or gas trapping. An overinflated thorax, as determined from radiographs, is a sign of gas trapping. In the intubated infant, this observation should prompt the clinician to decrease the positive end-expiratory pressure (PEEP) or expiratory time so that gas trapping and air leakage are prevented. An anguished intubated infant with cyanosis and gasping efforts may have endotracheal tube obstruction.**

Careful attention should be given to the sounds that emanate from the respiratory tract, as variations in quality often aid in localization of the source of respiratory distress. Stridor is common in neonates with upper airway and laryngeal lesions. Inspiratory stridor occurs most often with upper airway and laryngeal lesions, whereas expiratory stridor suggests lower airway problems. Hoarseness is a common sign of laryngeal disorders. Forced inspiratory efforts may indicate upper airway or laryngeal involvement, whereas expiratory wheezes suggest a lower airway disease. Congenital airway disorders that may cause respiratory distress in the neonate are included in Figure 6.3.

Auscultation of the chest further aids the examiner. Because infants with RDS have low lung volumes, breath sounds are faint, usually without rales. In comparison, the infant with pneumonia may have rales indicative of alveolar filling. Auscultation allows the clinician to detect the presence of secretions in the airway and to evaluate the response to physiotherapy and suctioning. Rhonchi may be heard in neonates with airway disease, such as meconium aspiration syndrome (MAS). **Emergency Alert: Unequal breath sounds may be due to a pneumothorax or to one of the many causes of diminished ventilation to a lung lobe (e.g., atelectasis, mainstem bronchial intubation, and pleural effusion). A shift of the apex of the heart can occur with a pneumothorax, diaphragmatic hernia, unilateral pulmonary interstitial emphysema, pleural effusion, dextrocardia, or atelectasis, which may be differentiated by transillumination of the chest and chest imaging. Dullness to percussion may be due to a pleural effusion or solid mass. Muffled heart tones suggest a pneumopericardium or a pericardial effusion.** Respiratory distress may occur in many chest wall disorders that restrict rib cage movements. Increased oral secretions and choking with feedings are common in neonates with a tracheoesophageal fistula. Because newborns are obligate nasal breathers, those with choanal atresia typically improve with crying and have worsening respiratory distress at rest or with feeding. Characteristic Potter facies, bell-shaped chest, and other compression deformities and contractures may be present in neonates with hypoplastic lungs secondary to oligohydramnios.

Examination of the cardiovascular system and assessment of peripheral perfusion yield many clues toward a diagnosis. Pallor and poor perfusion may indicate anemia, hypotension, or hypovolemia. Polycythemia with plethora may also cause respiratory distress. Cardiovascular signs of congestive failure (e.g., hyperactive precordium, tachycardia, and hepatomegaly), poor CO, pathologic murmurs, decreased femoral pulses, and non-sinus rhythm suggest a primary cardiac cause for the respiratory distress.

When hypotonia, muscle weakness, or areflexia accompanies respiratory distress, a neuromuscular cause should be considered (Box 6.1). In such cases, an accompanying history of less frequent fetal movement and polyhydramnios is often present. Sometimes a history of muscular disease exists in the family. Brachial plexus injury or fracture of a clavicle may accompany phrenic nerve injury and diaphragm paralysis.

Abnormalities found on abdominal examination enlighten the examiner to other causes of respiratory difficulty. Abdominal distention that results from causes such as ascites, necrotizing

Box 6.2

CAUSES OF LATE RESPIRATORY DISTRESS IN THE NEONATE

- BPD
- Pneumonia (bacterial, viral, or fungal)
- Congestive heart failure
- Recurrent pneumonitis or aspiration
- Upper airway obstruction
- Wilson–Mikity syndrome
- Idiopathic pulmonary fibrosis (Hamman–Rich syndrome)
- Pulmonary lymphangiectasia
- Cystic fibrosis
- Immature lungs

BPD, broncho-pulmonary dysplasia.

enterocolitis, abdominal mass, ileus, or tracheoesophageal fistula can cause respiratory distress, whereas a scaphoid configuration of the abdomen suggests a diaphragmatic hernia.

Other nonpulmonary disorders such as sepsis, metabolic acidosis, hypothermia, hyperthermia, hypoglycemia, and methemoglobinemia may also cause respiratory distress in the neonate.

Radiographic and Laboratory Investigation. Radiographic examination is often the most useful part of the laboratory evaluation and may serve to narrow the differential diagnosis. An anteroposterior view is usually sufficient, but a lateral chest radiograph may be useful when fluid, masses, or pneumothorax is suspected. Other diagnostic imaging techniques (ultrasonography, fluoroscopy, computed tomography, or magnetic resonance imaging) may be helpful in selected patients. Bronchoscopy allows direct visualization of the upper airway. This technique, albeit invasive and technically difficult, may in selected cases be a great aid in the differential diagnosis and treatment of patients with a suspected airway lesion.

Much can be learned from a relatively small battery of laboratory tests. In the neonatal intensive care unit (NICU) setting, the clinician is often required to collect specimens for and interpret the results of physiologic testing. Considerable skill is required in sampling both venous and arterial blood from small patients who are at substantial risk for iatrogenic anemia and vascular damage. Ideally, the hospital laboratory is equipped to do most routine tests on microliter quantities of blood. The clinician must monitor total quantities of blood sampled from the infant and be alert to the development of iatrogenic anemia.

Analysis of arterial blood for pH and gas tensions is perhaps one of the most common tasks of the clinicians caring for the infant with respiratory illness. Noninvasive methods to assess gas exchange, such as transcutaneous blood gas measurements or oxygen saturation, are very useful. Because oxygen delivery to the tissues so intimately depends on circulating red blood cell volume, a hematocrit should be performed.

COMMON DISORDERS OF THE RESPIRATORY SYSTEM

A large variety of respiratory disorders occur in neonates, the most common of which are discussed here. Figure 6.3 lists both pulmonary and nonpulmonary disorders that cause respiratory symptoms in the newborn infant. Several diseases have their roots in the neonatal period and extend into infancy (Box 6.2). The most common is BPD, a chronic lung disease that affects newborns, mainly premature infants exposed to mechanical ventilation for RDS or other respiratory problems.

Respiratory Distress Syndrome

RDS, formerly known as hyaline membrane disease (the term *hyaline membrane disease* originated from the histological observation of alveolar space lined by an eosinophilic membrane formed by cellular debris), is the most common cause of respiratory distress in premature neonates (Hamvas, 2011). RDS is common in preterm infants. Most children born extremely premature have RDS, and the incidence increases as gestational age decreases. The incidence decreases from 98% at 23 weeks to 86% at 28 weeks. Approximately 97% of 23 week infants are treated with surfactant. This decreases to 65% at 28 weeks (Stoll et al., 2010). In rare cases, RDS develops in full-term infants born to mothers with diabetes or in full-term infants with perinatal asphyxia.

Antenatal Steroids. Acceleration of lung maturation with antenatal steroids is now the standard of care in women with preterm labor of up to 34 weeks. Antenatal corticosteroid therapy to the mothers of preterm fetuses of up to 34 weeks significantly reduces the incidence of RDS with odds ratios of around 0.5 and decreases mortality, with odds ratios of around 0.6 (Roberts, Brown, Medley, & Dalziel, 2017). Subgroup analyses confirm that these benefits occur regardless of race and gender. No adverse effects have been reported with the usual single course of antenatal steroids. There are also other nonrespiratory benefits of steroid administration to mothers, including reductions in intraventricular hemorrhage and necrotizing enterocolitis. The current guidelines recommend giving steroids to mothers between 23 and 34 weeks' gestation; however, emerging data at the limits of viability show benefits to giving steroids to infants as early as 22 weeks' gestation with a lower mortality at every gestational age between 23 and 27 weeks' gestation (Carlo et al., 2011). Improved survival is additionally seen when infants only receive a partial steroid course (Carlo et al., 2011; Travers et al., 2018).

Treatment. The lungs of infants with RDS are deficient in pulmonary surfactant, the surface tension–reducing agent that prevents alveolar collapse and loss of lung volume at end expiration. Surfactant-deficient lungs develop progressive atelectasis,

which leads to intrapulmonary shunting, owing to perfusion of unventilated lung, and subsequent hypoxemia. The radiograph displays a characteristic ground glass, reticulogranular appearance with air bronchograms. When the lung inflation is poor due to stiff noncompliant lungs, the arterial blood gas analysis usually reveals respiratory acidemia as well as hypoxemia.

Therapy is directed toward improving oxygenation as well as maintaining optimal lung volume. Continuous positive airway pressure (CPAP) or PEEP is applied to prevent volume loss during expiration. In severe cases, mechanical ventilation via tracheal tube is required. Treatment with surfactant is the standard of care for preterm infants who require intubation for RDS. Exogenous surfactants (artificial and natural), which are available for intratracheal instillation, improve survival and reduce some of the associated morbidity of RDS. Earlier clinical trials indicated that prophylactic surfactant administration to extremely premature infants in the delivery room is more effective than waiting for the treatment after development of RDS (Soll & Morley, 2001). However, several subsequent trials, including the large SUPPORT trial in which prophylactic surfactant was compared to CPAP started at birth with rescue surfactant, showed equivalence, though many of the infants in the early CPAP arm ultimately required surfactant administration (Finer et al., 2010; Stetson, Brocklehurst, & Tarnow-Mordi, 2011). The most recent Cochrane review of the topic did not recommend routine administration of prophylactic surfactant administration, as there was less risk of BPD or death at 36 weeks when using early CPAP with selective surfactant administration for infants requiring intubation (Rojas-Reyes, Morley, & Soll, 2012). Prophylactic high-frequency ventilation for treatment of RDS has mixed results with limited evidence to support routine use (Cools, Offringa, & Askie, 2015), but these modes of ventilation should be considered as alternatives to conventional mechanical ventilation in specific circumstances such as in infants with air leaks including pulmonary interstitial emphysema or bronchopleural fistula. Infants greater than 34 weeks who have RDS and respiratory failure unresponsive to ventilatory management have responded favorably to extracorporeal membrane oxygenation (ECMO; Thome, Carlo, & Pohlandt, 2005).

Nursing care for infants with RDS is demanding; the most unstable infants often require a one-to-one, nurse-to-patient ratio. The nurse must monitor the quality of respirations and observe the degree of difficulty that the infant is experiencing. Worsening retractions may signal progressive volume loss and impending respiratory failure. **Quality and Safety: Arterial blood gas tensions and pH should be measured frequently, and continuous noninvasive monitoring of oxygenation, and carbon dioxide if available, may allow early identification of gas exchange problems.** The risk of pneumothorax and right mainstem intubation is high, and the symmetry of breath sounds must be verified regularly. A crying infant loses airway pressure when the mouth is open and therefore must be kept calm when receiving nasal CPAP. The intubated infant must be monitored for appropriate endotracheal tube position and patency. Suctioning of the airway should be done carefully. The suction catheter should be passed only as far as the end of the endotracheal tube because overzealous suctioning can denude the tracheal epithelium (Cordero, Sananes, & Ayers, 2000). Lung volume can be lost during prolonged disconnection from the ventilator. Rapid loss of lung volume can precipitate hypoxemia, so disconnection time should be minimized. Any sudden decompensation should alert the nurse to investigate for ventilator failure, pneumothorax, or tracheal tube plugging (Figure 6.4). The infant should also be closely monitored for changes in pulmonary compliance, especially after surfactant administration.

BPD is a common outcome in infants after RDS. BPD generally refers to a chronic lung disease in preterm infants characterized by pulmonary fibrosis, bronchiolar metaplasia, emphysema, and interstitial edema. It is most commonly seen in survivors of extreme prematurity who were diagnosed with RDS, but extremely low birth weight infants may develop BPD without a history of RDS. According to the National Institute of Child Health and Human Development (NICHD) consensus, infants with mild BPD are those who continue to require oxygen supplementation for a total of at least 28 days, while those with moderate or severe BPD require oxygen supplementation and/or ventilatory support at 36 weeks of postmenstrual age and for more than 28 days (Jobe & Bancalari, 2001). The incidence of BPD increases as gestational age decreases. Among infants less than or equal to 1,000 g at birth, 77% develop mild BPD, while 46% develop moderate BPD and 16% develop severe BPD (Ehrenkranz et al., 2005). Of survivors to 36 weeks corrected gestational age, 85% of infants born at 22 weeks had an oxygen requirement as opposed to 22% for infants born at 28 weeks (Stoll et al., 2010). Pulmonary morbidities and adverse neurodevelopmental outcomes at 18 to 22 months were more prevalent with an increased severity of BPD.

Several therapies reduce the incidence of BPD in preterm infants. A meta-analysis of the administration of vitamin A, an important mediator of pulmonary growth, showed a reduction in the incidence of BPD by 13% (Darlow & Graham, 2011). The administration of caffeine in the Caffeine for Apnea of Prematurity (CAP) trial found a reduction in BPD by 36% in infants who received caffeine compared with those receiving placebo. The administration of systemic corticosteroids after the first week of life reduces the incidence of BPD or BPD/death without causing any significant neurodevelopmental impairment (Doyle, Cheong, Ehrenkranz, & Halliday, 2017a), whereas giving steroids earlier (before 7 days of life) reduces BPD but with an increase in the incidence of cerebral palsy (Doyle, Cheong, Ehrenkranz, & Halliday, 2017b).

Air Leaks. Air leaks frequently complicate RDS and other neonatal respiratory disorders. Air leaks are characterized by air

in an ectopic location (Box 6.3). Many air-leak syndromes begin with at least some degree of pulmonary interstitial emphysema, which is the result of alveolar rupture from overdistention, usually concomitant with mechanical ventilation at lower rates and longer inspiratory times (Greenough, Murthy, Milner, Rossor, & Sundaresan, 2016) or CPAP (Morley et al., 2008). Pulmonary interstitial emphysema occurs most commonly in preterm infants but may be seen in infants of any gestational age. Lung compliance is nonuniform, and areas of poor aeration and alveolar collapse may be interspersed with alveoli of normal or near-normal compliance. The more normal lung units (those with better compliance) become overdistended and eventually rupture. Air is forced from the alveolus into the loose tissue of the interstitial space and dissects toward the hilum of the lung, where it may track into the mediastinum—causing a pneumomediastinum—or into the pericardium—causing a pneumopericardium. **Emergency Alert: The astute clinician may notice that an infant's chest becomes barrel-shaped with overdistention and that breath sounds become distant on the affected side.** In contrast, the infant who suffers a pneumothorax usually becomes unstable, with development of cyanosis, oxygen desaturation, and carbon dioxide retention. The infant may become hypotensive and bradycardic because the high intrathoracic pressure impedes venous return. A tension pneumothorax, in which the free pleural air compresses the lung, is a medical emergency, and prompt relief by thoracentesis or tube thoracostomy is indicated. There are infants who are medically stable with a pneumothorax who can be managed expectantly without decompression (Litmanovitz & Carlo, 2008). However, it is important to ensure that these infants truly are medically stable and, if they deteriorate, to intervene when needed to relieve the pneumothorax.

Transient Tachypnea of the Newborn

TTN occurs typically in infants born by cesarean section, particularly in the absence of labor or in those infants born vaginally but who delivered precipitously. The cause of the disorder is thought to be transient pulmonary edema that results from decreased absorption of pulmonary alveolar fluid. The chest radiograph may show increased perihilar interstitial markings and small pleural fluid collections, especially in the minor fissure. In contrast to infants with RDS, infants with transient tachypnea tend to have a normal or low P_{CO_2}. Oxygenation can usually be maintained by supplementing oxygen with a hood, although some infants benefit from a short course of positive pressure support. The infant usually recovers in 24 to 48 hours. Restricting fluid intake may also help reduce the duration of respiratory support (Stroustrup, Trasande, & Holzman, 2012).

Pneumonia

Pneumonia may be of bacterial, viral, or other infectious origin (Table 6.2). Pneumonia may be transmitted transplacentally, as has been shown with group B *Streptococcus*, or via an ascending bacterial invasion associated with maternal chorioamnionitis and prolonged rupture of the membranes. The usual causative organisms of pneumonia are group B *Streptococcus*, *Escherichia coli*, *Haemophilus influenzae*, and, less commonly, *Streptococcus viridans*, *Listeria monocytogenes*, and anaerobes.

A strong association exists between bacterial pneumonias and premature birth, which may be due to a developmental deficiency of bacteriostatic factors in the amniotic fluid. Alternatively, the infection may be a precipitating factor in preterm labor. Chorioamnionitis can occur even in the presence of intact membranes. Blood cultures and other diagnostic tests are necessary to help

direct specific antimicrobial therapy. The clinician should be attuned to the labor history. Were membranes ruptured for more than 12 to 24 hours? Did the mother have fever before delivery? Did the mother receive intrapartum antibiotics if risk factors for group B *Streptococcus* sepsis were present? Elements of the maternal history that delineate isolated maternal fever from a suspected intraamniotic infection include maternal leukocytosis, purulent cervical discharge, and fetal tachycardia (Committee on Obstetric Practice, 2017). The full-term infant who exhibits tachypnea, grunting, retractions, or temperature instability should be evaluated carefully. Although blood counts may be helpful as low white blood cell counts, low neutrophil counts, and high immature to total neutrophil ratios are associated with a higher odds of infection, these are imperfect predictors and should not solely be used to rule out infection (Hornik et al., 2012). Infection should be considered in any newborn with respiratory distress or more than transient oxygen requirements. Tracheal aspirates obtained within 8 hours of birth and that show both bacteria and white blood cells on Wright's stain are highly predictive of pneumonia.

Pending culture results, treatment is usually begun with broad-spectrum antibiotics, typically a penicillin and aminoglycoside or cephalosporin. A lumbar puncture may be undertaken or may be postponed until results of blood culture are obtained. When cultures result in the identification of the organism, the study of antibiotic sensitivity allows the clinician to identify the most effective antibiotic or combination of antibiotics for the causative agent. Antibiotic treatment for up to 10 to 14 days may be necessary.

Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension of the newborn (PPHN), or persistent fetal circulation, is a term applied to the combination of pulmonary hypertension (high pressure in the pulmonary artery), subsequent right-to-left shunting through fetal channels (the foramen ovale or ductus arteriosus) away from the pulmonary vascular bed, and a structurally normal heart. The syndrome may be idiopathic or, more commonly, secondary to another disorder—such as MAS, congenital diaphragmatic hernia (CDH), RDS, asphyxia, sepsis, pneumonia, hyperviscosity of the blood, or hypoglycemia (Walsh-Sukys et al., 2000). Idiopathic causes may be related to maternal late trimester nonsteroidal anti-inflammatory drug use or maternal use of selective serotonin reuptake inhibitors (Dhillon, 2011).

The neonatal pulmonary vasculature is sensitive to changes in Pa_{O_2} and pH and, during stress, can constrict to cause increased pressure against which the neonatal heart cannot force blood flow to the lungs. If the pulmonary artery pressure is higher than systemic pressure, blood flows through the path of least resistance, away from the lungs through the foramen ovale and the ductus arteriosus. The infant becomes progressively hypoxemic and acidemic, which accentuates the problem of increased pulmonary vascular resistance.

Management of infants with PPHN demands high vigilance. Because the pulmonary vasculature is unstable, almost any event can precipitate severe hypoxemia, including routine procedures such as endotracheal tube suctioning, weighing, positioning, and diaper changes. Under these circumstances, minimal stimulation is usually practiced.

Occasionally, sedation, and even muscle paralysis, is necessary to prevent spontaneous episodes of hypoxemia or deterioration associated with procedures (e.g., suctioning and position changes). Mild alkalosis—either with bicarbonate infusion or by mild hyperventilation—often relaxes the pulmonary vascular bed and allows better pulmonary perfusion and thus oxygenation. The approach to therapy should be directed toward preventing hypoxemia and acidosis. The critical pH necessary for overcoming pulmonary vasoconstriction seems to be unique to the individual. High applied ventilator pressures predispose the lung to air-leak syndromes, further increasing the risk of sudden destabilization. Vasopressor therapy with dopamine and dobutamine is often used in conjunction with hyperventilation, but controlled data are not available. Presumably, they act both to improve contractility of the stressed myocardium, which improves CO, and to raise systemic arterial pressure above pulmonary artery pressure to reduce right-to-left shunting.

When conventional therapies fail, high-frequency ventilation may be attempted. Approximately 30% to 60% of patients who fail conventional mechanical ventilation respond to high-frequency ventilation. However, the exact role of high-frequency ventilation in mortality or in preventing the need for ECMO needs further evaluation. Since the early 1990s, inhalation of nitric oxide—alone and in association with high-frequency ventilation—has been shown to be an effective therapy for PPHN (Davidson et al., 1998; Finer & Barrington, 2006; The Neonatal Inhaled Nitric Oxide Study Group, 1997).

When oxygenation cannot be accomplished despite the use of conventional mechanical ventilation, high-frequency ventilation, or nitric oxide, ECMO has proven to be an effective therapy (UK Collaborative ECMO Trial Group, 1996). Neonatologists disagree about the exact indications for ECMO, and some centers report impressive survival statistics without the use of ECMO (Mok, Yates, & Tasker, 1999). However, ECMO often is the only treatment that improves the outcome of some infants who fail less invasive therapies.

Meconium Aspiration Syndrome

MAS is the most common aspiration syndrome that causes respiratory distress in neonates. The role of meconium in the pathophysiology of aspiration pneumonia has become controversial. It is unclear whether the material itself causes pneumonitis severe enough to lead to hypoxemia, acidosis, and pulmonary hypertension or whether the presence of meconium in the amniotic fluid is merely a marker for other events that may have predisposed the fetus to severe pulmonary disease. The severely ill infant with MAS typically comes from a stressed labor and has depressed cord pH from metabolic acidosis. These infants are often postmature and exhibit classic signs of weight loss, skin peeling, and deep staining of the nails and umbilical cord. Pharyngeal suctioning at the time of birth does not reduce MAS (Vain et al., 2004). Guidelines for the resuscitation of non-vigorous infants with meconium-stained fluid were revised in 2015 and no longer include rapid intubation and suctioning of the airway (Wyckoff et al., 2015). This change in clinical practice was due to concerns for the potential for delay in bag mask ventilation in these infants without any known benefit and possible harm of endotracheal suctioning as randomized controlled trials showed no benefit of routine endotracheal suctioning in non-vigorous newborns (Chettri, Adhisivam, & Bhat, 2015; Nangia, Sunder, Biswas, & Saili, 2016). Additionally, suctioning the mouth and nose provides no benefit compared to wiping the mouth as part of routine resuscitation (Kelleher et al., 2013).

Pulmonary disease in infants with MAS arises from chemical pneumonitis, interstitial edema, small airways obstruction, and from concomitant persistent pulmonary hypertension. The infant may have uneven pulmonary ventilation with hyperinflation of some areas and atelectasis of others, leading to ventilation–perfusion mismatching and subsequent hypoxemia. The hypoxemia may then exacerbate pulmonary vasoconstriction, leading to deeper hypoxemia and acidosis. Infants with MAS may have evidence of

lung overinflation with a barrel-chested appearance. Auscultation reveals rales and rhonchi. The radiograph shows patchy or streaky areas of atelectasis and other areas of overinflation.

As with other cases of pulmonary hypertension, nursing care of infants with MAS centers on maintenance of adequate oxygenation and acid–base balance and on the avoidance of cold stress, which contributes to acidosis. A high incidence of air leaks exists in these infants, and positive pressure ventilation is best avoided if the patient can be adequately oxygenated, even at very high-inspired oxygen concentrations. Antibiotics are often used, particularly in critically ill infants, at least until a bacterial infection is ruled out, but antibiotic therapy may not be necessary. The infant is often exquisitely sensitive to environmental stimuli and should be treated in as quiet an environment as possible. Interventions should be preplanned to maximize efficiency of handling the infant. Infants with very severe respiratory failure and MAS improve with the administration of exogenous surfactant as aspiration may lead to secondary surfactant deficiency (El Shahed, Dargaville, Ohlsson, & Soll, 2007).

Although aspiration of meconium is most common, the neonate may become symptomatic as a result of the aspiration of blood, amniotic fluid, or gastrointestinal contents. The history is important in the differential diagnosis because radiographs are nondiagnostic.

Pulmonary Hemorrhage

Pulmonary hemorrhage is rarely an isolated condition and usually occurs in an otherwise sick infant. RDS, asphyxia, congenital heart disease, aspiration of gastric content or maternal blood, and disseminated intravascular coagulation and other bleeding disorders may play a role in the cause of pulmonary hemorrhage. The presence of a patent ductus arteriosus increases the risk for a clinically significant pulmonary hemorrhage that requires increased respiratory support and/or blood products. The administration of prophylactic indomethacin reduces the risk for clinically significant pulmonary hemorrhage by 35% (Alfaleh et al., 2008). The risk for pulmonary hemorrhage is increased by approximately 5% in infants receiving either natural or artificial surfactant. Massive bleeding may also occur as a complication of airway suction secondary to direct trauma of the respiratory epithelium.

Pulmonary hemorrhage is manifested by the presence of bloody fluid from the trachea. **Emergency Alert: When massive, it may be heralded by a sudden deterioration with pallor, shock, cyanosis, or bradycardia.** Attention must be given to maintenance of a patent airway because an obstructed endotracheal tube requires emergency replacement. However, replacing an occluded airway in the context of a massive pulmonary hemorrhage should be undertaken with caution as the bleeding can make visualization of the trachea difficult. Although studies have been reported describing the benefits of administration of surfactant in neonates with pulmonary hemorrhage, there are no high level of evidence studies to support its use (Aziz & Ohlsson, 2012). Suctioning must be done with great care to avoid precipitation of further bleeding. Clotting factors can be consumed rapidly, and the nurse should be alert to signs of generalized bleeding.

Pleural Effusions

Pleural effusions may be caused by accumulation of fluid between the parietal pleura of the chest wall and the visceral pleura enveloping the lung. A pleural effusion may also be due to chylothorax (lymphatic fluid) or hemothorax (blood). Lymphatics drain fluid that filters into the pleural space. Fluid accumulates in the pleural space as a result of either increased filtration or decreased absorption. An increase in filtration pressure, as seen with increased venous pressure in hydrops fetalis or congestive heart failure, leads to pleural effusion. The rate of filtration into the pleural space also increases if the pleural membrane becomes more permeable to water and protein, as occurs with infection.

Pleural effusion with high glucose content in an infant who is receiving parenteral nutrition via a central venous catheter should raise the suspicion of catheter perforation into the pleural space. If the infant is also receiving lipid infusion, the fluid may appear milky and be confused with chylothorax.

Chylothorax may be either congenital or acquired. Congenital chylothorax frequently presents at delivery or shortly after with respiratory distress. Chylothorax can also be acquired as a surgical complication of repair of diaphragmatic hernia, tracheoesophageal fistula, or congenital heart defect. Congenital chylothorax may be suspected in the infant who cannot be ventilated in the delivery room. Breath sounds are difficult to hear, and chest movement with ventilation is minimal. Bilateral thoracenteses may be lifesaving. The typical pleural fluid in a chylothorax—opalescent and rich in fat—is present only if the infant has been fed. Therefore, the fluid aspirated in the delivery room or shortly after birth in a child with congenital chylothorax often has a low triglyceride level.

Pleural effusions that impede respiratory function typically require drainage by thoracentesis or tube thoracostomy. It may be necessary for chest tubes placed for chylothorax and thoracic duct injury to remain in place for extended periods while the infant is given total parenteral nutrition, receiving nothing by mouth, thus minimizing thoracic duct flow. Somatostatin administration (such as octreotide) has been associated with a reduction in need for ventilator support (Yin et al., 2017). Several commercial formulas containing a higher percentage of medium-chain triglycerides that bypass the lymphatic system are also available for infants transitioning off parenteral nutrition. Due to the loss of lymphocytes and immunoglobulins through chylous drainage, these infants may also become immunocompromised and may benefit from immunoglobulin replacement.

Apnea

Apnea is the common end product of a myriad of neonatal physiologic events. Hypoxemia, infection, anemia, thermal instability, metabolic derangement, drugs, and intracranial disease can cause apnea. These causes should be considered before idiopathic apnea of prematurity is diagnosed.

Apnea is observed in more than half of surviving premature infants who weigh less than 1.5 kg at birth. The respiratory control mechanism and central responsiveness to carbon dioxide is progressively less mature the lower the gestational age. In contrast to adults, infants respond to hypoxemia with only a brief hyperpneic response followed by hypoventilation or apnea. In any infant who has apnea, hypoxemia should always be ruled out before the clinician embarks on any other workup or institutes therapy.

Care of the infant experiencing apneic episodes requires close observation. Obstructive apnea cannot be detected with the impedance respiratory monitor because normal or pronounced respiratory excursions of the chest wall exist. Prompt tactile stimulation for mild "spells" is often sufficient to abort the episode of apnea, obviating the need for further therapy. Infants with apneic episodes accompanied by profound bradycardia need prompt attention to their immediate needs as well as more aggressive diagnostic and therapeutic intervention.

Sensory stimulation with waterbeds or other means can sometimes be used to manage these infants, particularly those with mild apnea. Many apneic neonates respond to nasal CPAP at low pressures because the majority of apneic episodes have an obstructive component. Pressure support may also stimulate pulmonary stretch receptors, thus stimulating respiration. Nursing care that is directed toward promoting a neutral thermal environment, normoxia, optimal airway maintenance, and prevention of aspiration is essential in the care of neonates at risk for apnea.

Use of methylxanthines, such as caffeine and aminophylline, has markedly simplified the treatment of apnea in some premature infants. Xanthines appear to exert a central stimulatory effect on brainstem respiratory neurons and often markedly decrease the frequency and severity of apneic episodes. The clinician must be attuned to the toxicities of xanthines, including tachycardia, excessive diuresis, and vomiting. Caffeine may be associated with a lower risk of adverse effects (Schmidt et al., 2006). The timing of caffeine initiation as well as optimal dosing in preterm infants remains controversial. Little evidence supports early administration of caffeine (within 36 hours of birth) with the possibility of harm. The use of higher caffeine doses later on (i.e., in the setting of extubation) may confer neurodevelopmental benefit (Gentle, Travers, & Carlo, 2018; Gray, Flenady, Charles, & Steer; Caffeine Collaborative Study Group, 2011).

CONGENITAL ANOMALIES THAT AFFECT RESPIRATORY FUNCTION

Diaphragmatic Hernia

CDH occurs at a frequency of 1 in 2,500 live births and may be unsuspected until birth. Herniation of abdominal contents into the chest cavity early in gestation is accompanied by ipsilateral pulmonary hypoplasia. By mechanisms that are not well understood, there is often some degree of pulmonary hypoplasia on the contralateral side as well. Most infants are symptomatic at birth, with severe respiratory distress in the delivery room. The affected newborn's abdomen is usually scaphoid, and breath sounds are absent on the side of the defect (a left-sided defect occurs in 90% of cases). Bowel sounds may be heard in the chest, and heart sounds may be heard on the right side because the herniated abdominal contents push the mediastinum to the right.

Quality and Safety: As soon as the diagnosis is suspected, bag and mask ventilation should be avoided because it fills the herniated intestinal contents with gas, which can lead to further lung compression and worsening ventilation. When CDH has been diagnosed prenatally, the infant should be intubated and mechanical ventilation should be initiated immediately after birth. An orogastric tube should be placed to aid in decompression of the herniated abdominal viscera. Ventilation should be attempted with a rapid rate and low inflation pressure while tolerating hypercapnia. Symptomatic neonates often have pulmonary hypertension and progressive right-to-left shunting. Hypotension is common, and, when adequate intravascular volume is established, dopamine infusion may be helpful. Studies of inhaled nitric oxide have shown limited evidence for effectiveness in the treatment of diaphragmatic hernia (Finer & Barrington, 2006). Although evidence of surfactant deficiency in these newborns exists, surfactant administration does not appear to improve their clinical course or outcome (Colby et al., 2004).

The use of ECMO, more commonly required in infants with liver herniation or smaller lung volumes, may not lead to improvement in survival (Zalla, Stoddard, & Yoder, 2015). Surgery to repair the defect is indicated. Controversy regarding the urgency of the procedure exists among pediatric surgeons, and some prefer to stabilize the patient with mechanical ventilation, vasopressors, and correction of acidosis before undertaking surgical intervention; others perform surgical repair while the patient is maintained on ECMO.

Congenital Heart Disease

Congenital heart disease commonly manifests with signs of respiratory distress. Neonates with congenital heart disease who demonstrate right-to-left shunting and decreased pulmonary blood flow (e.g., tetralogy of Fallot, pulmonary valve atresia, and tricuspid valve atresia or stenosis) usually present with profound cyanosis unresponsive to oxygen supplementation. Neonates with congenital heart disease who demonstrate increased pulmonary blood flow or obstruction to the left outflow tract (e.g., transposition of the great vessels, total anomalous pulmonary venous return, atrioventricular canal, hypoplastic left heart syndrome, and critical coarctation of the aorta) may transiently improve with oxygen supplementation. However, oxygen supplementation in some conditions such as hypoplastic left heart syndrome can worsen systemic flow and make the child worse. Neonates with noncyanotic lesions such as patent ductus arteriosus and ventricular septal defect may present with signs of congestive heart failure (see Chapter 7, Cardiovascular System).

Choanal Atresia

Choanal atresia causes upper airway obstruction in the neonate. The choanae, or nasal passages, are separated from the nasopharynx by a structure known as the bucconasal membrane, which normally perforates during gestation. Failure of this developmental event results in an obstructed airway, occurring bilaterally in 50% of cases. Most affected infants are female and half of the affected infants have associated anomalies such as CHARGE (coloboma, heart defects, atresia of the choanae, retardation of growth and development, genital and urinary abnormalities, and ear abnormalities and/or hearing loss) syndrome. Because newborns are obligate nasal breathers, they have chest retractions and severe cyanosis (particularly during feeding), and paradoxically turn pink when crying. Diagnosis can be made via nasal endoscopy; however, CT imaging is also typically performed. Emergency treatment consists of tracheal intubation or placement of an oral airway. Surgical correction is indicated, though the ideal surgical intervention remains unclear (Cedin, Atallah, Andriolo, Cruz, & Pignatari, 2012). In cases where atresia is bilateral, surgery usually occurs in the first week after birth.

Cystic Hygroma

A variety of space-occupying lesions can impose on the airway of the newborn (Box 6.4). Most are derived from embryonic tissues. Cystic hygroma, derived from lymphatic tissue, is the most common lateral neck mass in the newborn. It is multilobular, multicystic, and, when large, obstructs the airway. Surgery is curative, although it is sometimes technically difficult. The clinician must always be mindful of the airway and its patency. Many of these lesions are of great cosmetic concern and cause great distress in the parents. A care plan should address these parental concerns. It is sometimes helpful to facilitate contact with parents of other children with similar problems who can share similar experiences.

Pierre Robin Sequence

The major feature of Pierre Robin sequence is micrognathia (a small mandible). The tongue is posteriorly displaced into the oropharynx, thus obstructing the airway. Sixty percent of affected patients also

have a cleft palate. Obstructive respiratory distress and cyanosis are common and may be severe. In an emergency, as with all airway obstructions (obstructive apnea), tracheal intubation should be undertaken. Infants with Pierre Robin sequence are nursed in the prone position to prevent the tongue from falling backward. Nasogastric tube feedings are usually required in the neonatal period. With good care, the infant has a good prognosis for survival; the mandible usually grows; and the problem resolves by 6 to 12 months of age. Some infants will require surgical intervention if positioning changes do not enable an infant to successfully feed by mouth or prevent apneic symptoms. Surgical correction includes mandibular distraction or tongue to lip adhesion, both of which have reduced or eliminated the need for tracheostomy (Khansa et al., 2017).

COLLABORATIVE MANAGEMENT OF INFANTS WITH RESPIRATORY DISORDERS

Supportive Care

Supportive care of the infant in respiratory distress requires attention to detail. The clinicians' primary goals are to minimize oxygen consumption and carbon dioxide production. These goals are accomplished by maintaining a neutral thermal environment. The nurse must be skilled in physical assessment to interpret signs and symptoms, such as cyanosis, gasping, tachypnea, grunting, nasal flaring, and retractions. By understanding the pathophysiology of breathing, the nurse knows that the infant with retractions has decreased lung compliance and that the cyanotic infant has poor tissue oxygenation.

Excellent communication is needed between the neonatal nurse and the rest of the neonatal team. Acutely ill neonates with respiratory disease are often unstable and their condition can deteriorate rapidly, so astute observation skills are necessary. Assessment is a continuous process, and effective communication among nurses, respiratory therapists, physicians, and support staff is necessary for proper delivery of intensive care. The nurse, who is the primary bedside caregiver, is the gatekeeper for all interactions between the patient and the environment. The nurse who is caring for an unstable patient should be the patient's advocate, whether such a role involves regulating the timing of a physical examination by the physician or venipuncture for laboratory investigation.

Technical competence is an important facet of the nurse's repertoire. The nurse is responsible for maintaining intravenous lines and tracheal tube patency, accurately measuring volumes of intravenous intake as well as urinary output, and operating advanced electronic machinery. Moreover, the nurse must also be adept at interpreting arterial blood gas and laboratory data in order to communicate these to the rest of the care team and to develop a cogent management plan. Many functions are shared to some degree with respiratory therapists. Whether nurses or respiratory therapists make ventilator changes, the nurse should become familiar with the effects of ventilator setting changes on blood gases. $PaCO_2$ is affected by changes in ventilator rate and tidal volume. Tidal volume depends on the difference between PIP and PEEP. Thus, to decrease $PaCO_2$, either rate or inspiratory pressure should be increased. PaO_2 depends on the fraction of inspired oxygen concentration (FiO_2) and mean airway pressure (MAP). MAP depends on PIP, PEEP, inspiratory to expiratory time ratio, and gas flow. To improve PaO_2, the most effective changes are to increase MAP by increasing PIP or PEEP or to increase FiO_2. The nurse should also be familiar with ventilator functioning so that malfunctions can be detected promptly. The nurse should always be prepared to bag-ventilate an intubated neonate in the event that decompensation occurs while the status of the ventilatory apparatus is checked. Nurses and therapists often share such functions as airway suctioning, monitoring and recording of inspired oxygen concentration, and delivery of chest physical therapy.

The delivery of oxygen therapy should always be carefully monitored. Desired oxygenation parameters should be recorded in the nurse's notes and followed using continuous pulse oximetry and measurement of arterial blood gases as indicated. The acutely ill infant should have FiO_2 measured continuously and recorded frequently. The goal for oxygenation depends on the patient's diagnosis and condition. For example, in infants with PPHN, an apparently acceptable saturation may occur despite marked right-to-left shunting. In preterm infants, oxygen saturation should be kept in the low 90s, thus avoiding the risks associated with hyperoxia or hypoxemia. Large randomized controlled trials (e.g., Carlo et al., 2010; Schmidt et al., 2013; Stenson et al., 2013) and meta-analyses (e.g., Askie et al., 2017, 2018) indicate that targeting lower oxygen saturations (85%–89%) versus higher saturations (91%–95%) in extremely preterm infants less than 28 weeks' gestation increases mortality and necrotizing enterocolitis without decreasing blindness. Targeting different saturations does not result in differences in neurodevelopmental impairment. Thus, targeting 91% to 95% or 90% to 95% oxygen saturations as others have suggested is now recommended by most experts to reduce mortality and necrotizing enterocolitis in extremely preterm infants.

Airway suctioning is a procedure that may be associated with cardiopulmonary derangement, hypoxemia, bradycardia, and hypertension. Various techniques to perform airway suctioning exist—including preoxygenation (increase in FiO_2 before the procedure), normal saline instillation before the suctioning to improve secretion aspiration, and the use of a closed system to avoid disconnection from the ventilator. The nurse should become familiar with the

techniques used in the NICU and be aware of the associated complications. Suctioning of the airway should be done only as often as necessary to remove pulmonary secretions that could occlude the airway. The suction catheter should be passed no further than the end of the tracheal tube because epithelium is easily damaged. There is perhaps little need to vigorously suction the intubated infant with RDS in the first days after birth because secretions are minimal and lung volume is lost with every disconnection of the ventilator circuit.

The sudden decompensation of a ventilated infant should alert the nurse to assess disconnection of the ventilator, pulmonary air leak, ventilator failure, or obstructed tracheal tube (see Figure 6.4). The very small infant who suddenly decompensates may have experienced a severe intracranial hemorrhage.

Care of the infant who is receiving CPAP can be particularly challenging. These infants should be kept calm and swaddled if necessary. Crying releases pressure through the mouth; thus, lung volume is lost. Nasal CPAP is effective, but particular attention must be given to maintaining patency of the nose, the nasal prongs, and the pharynx. The infant's nares and nasal septum should be guarded from pressure necrosis from inappropriately applied prongs. The infant with respiratory disease must be constantly assessed for airway patency. If the infant is unable to grunt against a closed glottis and maintain positive airway pressure, the condition may worsen if airway pressure is not maintained properly. Vibration and percussion should be used judiciously in the infant with pulmonary secretions to loosen them and allow removal via suction.

ASSESSMENT AND MONITORING

The most important aspect in monitoring patients with respiratory disease is the close and continuous observation of signs and symptoms. The color of the patient gives important clues. An infant with pink lips and oral mucosa has good oxygenation and perfusion; a cyanotic patient has poor tissue oxygenation. If the hemoglobin concentration is too low, the patient can be hypoxemic, but because the concentration of deoxyhemoglobin is low, there may be no cyanosis. An infant with tachypnea and retractions usually has decreased lung compliance. A patient with a barrel-shaped thorax, taking deep breaths, and with a normal or low respiratory rate probably has an increased airway resistance and gas trapping. Observation of the intubated patient is especially important. An anguished infant, who is cyanotic and breathing deeply, may have an obstructed endotracheal tube. An infant with RDS and increased chest expansion over time, despite no change in ventilatory pressure, is experiencing improvement in lung compliance. The same infant with later asymmetry in chest and sudden deterioration of oxygenation may have a pneumothorax. Cardiac beats, easily seen through the thoracic wall, may be caused by the presence of a symptomatic patent ductus arteriosus. A recently extubated infant, in whom increased retractions and inspiratory stridor develop, probably has upper airway obstruction. Auscultation helps in the diagnosis of increased airway resistance or the presence of secretions. It also allows the clinician to assess the response to different treatment maneuvers, such as suctioning, chest physiotherapy, and bronchodilation. Asymmetries in auscultation suggest mainstream bronchial intubation, atelectasis, pneumothorax, or pleural effusion.

Great progress has been made in noninvasive monitoring of blood gas tensions, but blood sampling is still necessary for pH determination and arterial samples are preferable. Capillary specimens are undependable, especially for Po_2. If peripheral perfusion is adequate, capillary blood approximates arterial values of pH and Pco_2. However, capillary blood Po_2 values do not reliably reflect arterial oxygenation.

Neonatal care has changed dramatically with the advent and widespread use of transcutaneous monitoring of Pao_2, $Paco_2$, and Sao_2. The neonatal intensive care team should become familiar with the devices used in noninvasive gas monitoring. Knowing the basis for their functioning as well as how to interpret the information they provide and being aware of clinical situations in which the information provided is not reliable or needs to be complemented before any management decisions are made is essential.

Transcutaneous Po_2 ($TcPo_2$) is measured with an electrode that is applied over the skin and heated to 42°C to 44°C. The electrode measures skin Po_2, not arterial Po_2. Skin Po_2 measurement depends on skin perfusion and on oxygen diffusion across the epidermis. Warming the skin to 42°C to 44°C under the electrode increases skin perfusion so that $TcPo_2$ correlates better with arterial Po_2. For initiation of $TcPo_2$ monitoring, 10 to 15 minutes are needed to obtain a stable reading. Thereafter, $TcPo_2$ reflects changes on Fio_2 with a 10- to 20-second delay. After 4 to 6 hours, the method becomes unreliable because of changes in skin secondary to hyperthermia, so the electrode position should be changed. In premature infants with more labile skin, the electrode placement should be changed even more frequently to avoid skin burns. The nurse should be aware of situations that make $TcPo_2$ lose its reliability. Overestimation of oxygenation occurs when an air bubble or leak between the electrode and the skin occurs or when the calibration is improper. Underestimation occurs with skin hypoperfusion, in older infants (increased thickness of the skin), with insufficient heating of the electrodes, or with improper calibration.

$TcPo_2$ monitoring has been largely supplanted by continuous pulse oximetry. Arterial oxygen saturation is computed from absorption of emitted low-intensity red or infrared light. The probe is attached to a finger or toe in large infants or to a hand or foot in small premature infants. Pulse oximetry offers the following advantages over transcutaneous oxygen monitoring: (a) avoidance of heating the skin and the risk of burns; (b) elimination of a delay period for transducer equilibration; (c) accurate measurement regardless of the presence of edema or patient age; (d) in vitro calibration not required; and (e) frequent position changes not required. However, the nurse should be aware that Sao_2 higher than 97% may be associated with Pao_2 higher than 100 mmHg. This is important in premature infants who are at risk for retinopathy of prematurity. Sao_2 between 90% and 95% probably is associated with a safe range of Pao_2. With Sao_2 over 95% to 97% and especially when it is 100%, the clinician cannot predict a patient's Pao_2. When the saturation is 100%, the Pao_2 can be approximately 100 mmHg or much higher (see Figure 6.1). This situation is particularly important in infants with PPHN because the decision whether to wean ventilator settings depends on Pao_2. In these patients, the simultaneous use of $TcPo_2$ and pulse oximetry is a useful alternative.

A common problem of pulse oximetry is the presence of motion artifact, an altered signal caused by movement of the part of the body where the sensor is applied. Because the pulse waveform is not detected, this movement is recognized by the loss of correlation between the oximeter pulse rate and the electrical monitor heart rate. With current technology the motion artifacts have been minimized (Malviya et al., 2000). Peripheral pulse oximetry may not detect pulse signals in patients with hypotension and poor perfusion. $TcPo_2$ may also give false readings in this situation. The clinician should be aware that pressure of the probe over the skin can produce skin pressure necrosis. This consideration is particularly important in the premature infant. Phototherapy may interfere with accuracy of Sao_2 monitoring, but this problem can be avoided by covering the sensor with an opaque material (e.g., a diaper).

Pulse oximetry is now the standard of care in the NICU. Additional $TcPo_2$ monitoring may be useful in several clinical

situations. They may be used in neonates with mild respiratory distress, such as transient tachypnea, to assess the oxygen requirement and to allow weaning without placement of an arterial catheter. In infants receiving mechanical ventilation, $TcPo_2$ or pulse oximetry helps to assess the effects of ventilator setting changes, thus reducing the need for arterial blood sampling. Continuous oxygenation monitoring reduces the risk of hyperoxemia or hypoxemia during interventions such as airway suctioning, position change, lumbar puncture, or venous cannulation. This monitoring is particularly helpful in the care of infants who do not tolerate excessive stimulation, such as those with PPHN. $TcPo_2$ and pulse oximetry monitoring are also useful in caring for patients with PPHN because simultaneous monitoring of preductal (head, right arm, right upper chest) and postductal (left arm, abdomen, legs) $TcPo_2$ or Sao_2 allows assessment of the magnitude of ductal shunting or the response to therapies such as vasodilation or alkalinization.

Transcutaneously measured Pco_2 is accomplished with a glass electrode that is pH-sensitive. Transcutaneous Pco_2 response is slower than that of $TcPo_2$, and the value measured must be corrected for skin production of carbon dioxide. Thus, transcutaneously measured values are approximately 1.3 to 1.4 times higher than arterial Pco_2 values. Most modern monitors display an electronically corrected value to $TcPo_2$. This modality is especially useful for monitoring chronically ventilated patients without indwelling catheters and also to reduce the number of laboratory tests in infants with indwelling catheters. Blood gas values during arterial puncture or vigorous crying during the procedure are often affected by breath holding and shunting and thus may be misleading.

ENVIRONMENTAL CONSIDERATIONS

Maintenance of the therapeutic environment is an important nursing function. Much attention has been given recently to the effects of sensory stimulation on the infant with respiratory distress. The sick newborn often has unstable pulmonary vasculature and may be particularly prone to hypoxic vasoconstriction. This phenomenon may be triggered in some individuals by excess stimulation, such as loud noise, handling, or venipuncture. It has been shown that the agitated neonate has more difficulty with oxygenation and that a quiet, minimally stimulating environment allows for more stable oxygenation (Als, 1998). The nurse should develop a care plan that allows the baby long periods of undisturbed rest by clustering interventions into short periods whenever possible. Positioning the infant in the flexed or fetal position or "nesting" may help in calming some infants. Always watch for stress cues to see how the infant is tolerating the care. Clustering of care only works if the infant tolerates a longer period of care rather than episodic care. Either way the infant needs undisturbed periods where rest and recovery can occur.

FAMILY CARE

Neonates with respiratory distress frequently require multiple instrumentations. They are typically in an incubator and may have endotracheal tubes, umbilical catheters, oximeter probes, chest leads, and other paraphernalia attached or applied to the skin. All of these interventions can give parents a feeling of increased separation from the infant. The nurse should explain the equipment surrounding the bedside as well as the function of invasive catheters, monitoring leads, and tracheal tubes. Terminology appropriate to the parents' level of understanding should be used. Even the most astute parents may be bewildered, and repetition is necessary. Staff should maintain consistent terminology so that the parents do not become confused between "respirators" and "ventilators." Whenever possible, the use of frightening or inaccurate terms should be avoided. Imagine the fear engendered by the phrase, "We paralyzed your baby last night."

Parents should be involved in developing and implementing the plan of care as much as possible. The mother who plans to breastfeed can be assisted in pumping her breasts and freezing the milk, even if enteral feedings are delayed for some time. This pumping may be the only thing that she alone can do for her baby.

Often lost in the bustle of critical care is the need for privacy. The perceptive nurse senses this need and backs away from the bedside when appropriate, allowing the parent some time with the infant. Care of the neonate requires a team—a coordinate team and that includes the parents!

SUMMARY

Most infants admitted to the NICU present with breathing difficulty. Nursing care of these infants requires a broad knowledge of newborn physiology and practical skills in the application of therapies that are directed toward solving the many problems that sick infants can have. The nurse often must anticipate these problems. While managing the nursing care for several patients, the neonatal nurse must also care for the sickest of infants. Parents and families of all infants in the NICU require special attention not only to achieve an understanding of the complex issues surrounding the infant's illness but also to calm fears and guilt that are often experienced. The rewards of being part of the accomplishments in the NICU may be overlooked as they are usually slowly achieved. However, when they are recognized, the victories surpass the greatest of expectations.

CASE STUDY

■ **Identification of the Problem.** A term infant was admitted to the NICU. The infant developed respiratory distress soon after birth. Birth weight was 4,000 g. Since birth, the infant had an increasing oxygen requirement and because of a recent desaturation episode, he is now receiving 100% oxygen on a ventilator. The ventilatory settings are PIP of 25 cm H_2O, PEEP of 5 cm H_2O, ventilator rate 60 per minute, and inspiratory time 0.4 seconds. A recent blood gas showed a pH of 7.35, Pco_2 of 42, Po_2 of 60, and bicarbonate of 22.

■ **Assessment: History and Physical Examination.** The infant was born by emergency C-section because of late decelerations and thick meconium-stained fluid. No signs of infection were observed. His mother had gestational diabetes and was maintained on insulin. The infant was not vigorous at birth and received bag mask ventilation at birth as endotracheal suction is no longer recommended. Blow-by oxygen was then administered and the infant responded well, initially weaned to 40% oxygen. However, after transfer to the NICU, he had increasing oxygen requirements.
The physical examination is now pertinent for excellent chest rise, equal breath sounds, central cyanosis with oxygen saturations in the mid-80s, good color and perfusion, and normal tone and reflexes.

■ **Differential Diagnosis.** Many conditions should be considered in the differential diagnosis in this patient.

1. Persistent pulmonary hypertension of the neonate. This is likely, given the severity and persistence of the very abnormal alveolar to arterial oxygen gradient ($AaDo_2$). Pulmonary hypertension may be associated with MAS. It is important to consider that right-to-left shunting can occur associated with disorders such as myocardial dysfunction, sepsis, metabolic abnormalities, and others.

2. MAS. MAS with intrapulmonary (ventilation–perfusion mismatch) or extrapulmonary shunting (atrial or ductal shunting with pulmonary hypertension) may lead to desaturation despite high oxygen supplementation.
3. Pneumothorax. Infants with MAS are at high risk for pneumothorax. A pneumothorax can cause severe desaturation.
4. Gas trapping. Because this infant has a large tidal volume for the given pressure gradient (PIP − PEEP) and thus high compliance, a long-time constant of the respiratory system leading to gas trapping at a borderline high ventilator rate should be considered.
5. Other causes. There are other less frequent causes in the differential diagnosis.

■ **Diagnostic Tests.** The chest radiograph was obtained, repeat blood gases were followed, and pre- and postductal pulse oximetry and transcutaneous measurements of gases were monitored continuously. In addition, a complete blood count (CBC) and blood culture were obtained. Four extremity blood pressures and an echocardiogram were obtained.

■ **Working Diagnosis.** The chest radiograph showed bilateral gas trapping. The CBC and the blood cultures were negative. The echocardiogram was consistent with persistent pulmonary hypertension.

■ **Development of Management Plan.** The infant was given surfactant, and initial improvement was seen. However, during the next 24 hours, there were episodes of repeated intracardiac and ductal shunting, which led to the initiation of nitric oxide.

■ **Implementation and Evaluation of Effectiveness.** Nitric oxide resulted in a marked reduction in the shunting episodes. The infant was gradually weaned off FiO_2 and subsequently weaned off nitric oxide before extubation. He was entirely weaned off the ventilator and FiO_2 over the subsequent 3 days.

EVIDENCE-BASED PRACTICE BOX

RDS is the most common cause of respiratory distress in preterm neonates (Hamvas, 2011). Most children that are born extremely premature develop RDS in the first hours after birth. The incidence of RDS is progressively more common the lower the infant's gestational age. Up to 98% of infants born at 23 weeks and 86% of infants born at 28 weeks develop RDS (Stoll et al., 2010). Many of these are treated with surfactant (Stoll et al., 2010). RDS can develop in term infants born to mothers with diabetes or in term infants who have experienced asphyxia, but it is substantially less frequent than in premature infants.

Antenatal steroids accelerate lung maturation (Roberts, Brown, Medley, & Dalziel, 2017). Present recommendations are to give steroids to all mothers between 23 and 34 weeks gestational age with threatened delivery. Antenatal steroids significantly reduce the incidence of RDS in premature infants. Antenatal steroids also decrease mortality, intraventricular hemorrhage, necrotizing enterocolitis, and neurodevelopmental impairment (Carlo et al., 2011; Schmidt et al., 2006). Adverse effects have not been reported with the usual single course of antenatal steroids (Carlo et al., 2011; Schmidt et al., 2006). Data at the limits of viability (i.e., <25 weeks) show benefits to giving steroids to infants as early as 22 weeks with a reduction in mortality at all gestational ages between 23 and 27 weeks (Carlo et al., 2011; Travers et al., 2018).

The hallmark of RDS is deficiency of pulmonary surfactant. Surfactant reduces the alveolar surface tension, thus preventing alveolar collapse. Therapy is directed toward improving oxygenation as well as maintaining optimal lung volume. CPAP can be used to prevent volume loss during expiration. Exogenous surfactants are also quite effective at treating RDS but require endotracheal intubation and exposure to mechanical ventilation. Early clinical trials indicated that prophylactic surfactant administration to extremely premature infants in the delivery room is more effective than waiting for the treatment after development of RDS (Soll & Morley, 2001). However, more recent trials show equivalence between prophylactic surfactant administration and early CPAP with rescue surfactant. However, the recent randomized clinical trials (Dunn et al., 2011; Finer et al., 2010) and the Cochrane review (Rojas-Reyes et al., 2012) indicate that early CPAP with selective surfactant for infants who require intubation reduces death/BPD when compared with prophylactic surfactant administration in extremely preterm infants.

PARENT VOICES

Heather McKinnis

Our micro-preemie was a complete surprise. My perfect pregnancy ended abruptly after just 4 hours of labor. I was given one steroid injection as they rapidly prepped me for my emergency C-section. Owen came into the world with low APGAR scores that did slightly improve as the NICU team worked on him. He was stabilized and moved to the NICU. When I first saw him, 12 hours later, he was so tiny and hooked up to so many pieces of equipment, including a vent that we would get to know well over the next week. Miraculously, my little fighter only required intubation for 8 days. He spent another week on CPAP and several weeks on high flow cannula. We had prepared to take him home with oxygen support but a week and a half before discharge, he proved us all wrong and came off oxygen as well. Throughout this entire journey, I was incredibly grateful for the patience and kindness of our nurses. They took the time to explain everything to me, helped me wrap my mind around the fragility of my baby, and how I could best help him thrive.

Laurel Kapferer, MS

Our son Blake was born via a scheduled C-section at 37 weeks. When he was born, everything appeared to be fine. He weighed 7 lbs 1.4 oz, and was breathing on his own. He was placed on my chest as soon as we left the operating room and began breastfeeding almost immediately. When he was 2 hours old, he went for a routine examination at which time everything quickly changed. During his examination, Blake went into respiratory distress and was rushed to the NICU.

The doctors told us that his respiratory distress was due to his lungs not being completely matured, the presence of fluid in his lungs, or both. Blake was hooked up to monitors and oxygen, which made holding him difficult. Anytime it was loud or Blake got excited, his oxygen saturation would drop, and eventually he had to be intubated and given two rounds of surfactant. Seeing Blake with tubes down his throat was absolutely excruciating for us. Even though we had been in the NICU before, nothing could have prepared us for that. Fortunately, the surfactant worked and all tubes and oxygen were removed. Blake was able to maintain his O_2 sats on room air. When he was 6 days old, he was discharged from the NICU. Today Blake is a happy, healthy 5-year-old. The only complication that he has from his NICU stay are fractures in the base of his baby teeth from being intubated.

Blake's journey was made more difficult because we knew the pain of losing a child. His brother had passed away the year prior while in the NICU. We were so very fortunate to have such amazing NICU doctors and nurses caring for Blake. They all knew our story and they all did everything they could to help us through. They went above and beyond and really understood the trauma and posttraumatic stress disorder (PTSD) that we suffered. They took the time to look at the details of our past and made sure to put us in a different room from our previous NICU stay. They made sure not to discharge us on the same count of days that our other child passed on. They also met with us every day and told us what would likely happen so that we were emotionally prepared.

The compassion and understanding that our NICU team showed us made such an incredible impact on our journey and we are eternally grateful for them.

Jennifer M. Driscoll

Our daughter, Lilian Hope, was born 7 weeks premature, weighing only 2 lbs 12 oz and 15 inches long. Lily's lungs were her main problem, as they are for many preemies, because the lungs are the last thing to develop. On the day she was born, she was doing well, but still needed a CPAP machine to help her breathe. As the day progressed, her condition worsened. She was given nitric oxide, put onto a ventilator to breathe for her, and needed an oscillator to vibrate the lungs to help the flow of oxygen. Due to the force of the ventilator and oscillator, an air sac in her lungs burst and she had a chest tube inserted. Additionally, she had an erratic blood pressure, jaundice, and needed multiple blood transfusions. But the miracle continued as she began to gain strength inside herself; she came off the oscillator after 7 days and took out the ventilator herself. By day 8 we were able to hold her for the first time. She ended up by only needing to stay in the NICU at Lehigh Valley Hospital for 24 days and was able to come home at a mere 3 lbs 11 oz.

Our son, Aidan Patrick, was also born only 4 weeks premature, weighing 4 lbs 11 oz and 18 inches long. These few weeks, pounds, and inches may seem small but were huge victories for us. I was labeled high risk as soon as I found out I was pregnant and put on aspirin and bed rest much sooner because we knew what happened when Lily was born. Aidan's NICU stay was much shorter than Lily's, only a few days. Unfortunately, because of that, Aidan didn't qualify for the RSV vaccine as Lily did, and by 4 months old he was hospitalized on oxygen for over a week with RSV.

(*continued*)

(*continued*)

This incident catapulted his asthma and subsequent allergy issues. Aidan has been hospitalized seven times since that RSV diagnosis with severe asthma flare-ups. Allergies and sickness trigger his asthma, so he is on two maintenance inhalers and daily medication and continues to see pediatric pulmonologists and allergists for his lung issues.

Both Aidan and Lily were born early because I had preeclampsia. They both had a very rough beginning, but with their strength, wonderful doctors and nurses, hope, and prayers, they have been able to rise above it all.

Keira Sorrells

One of my daughters spent 14 months on the ventilator and had severe reflux, causing her to have extreme oral aversions and tracheomalacia. We spent the first 60 days of her 291-day NICU stay simply staring at her because we were told she was too fragile to hold. As a parent, this was absolutely devastating. NICU parents confront so many barriers in access to their children, from the locked door we have to be buzzed through to gain entry to the yellow gowns we wear over our clothing and of course the isolette, tubes, and wires encasing our babies. Parents of typical, healthy newborns obtain instantaneous and open access to their babies at birth while we are stripped of every maternal instinct we have. I wish, during those 60 days, something could have been done to allow us to be closer to her. If there was any chance of holding her before she was 2 months old we would have cherished every minute. We spent so many hours simply sitting next to her and watching the hours pass by, hoping and praying she would be strong enough to hold.

CHAPTER 7

Cardiovascular System

Donna A. Goff

INTRODUCTION

This chapter presents the physiology of normal cardiac function, including fetal circulatory patterns and the changes that occur during transition to extrauterine life. The most common congenital heart defects (CHDs) and cardiac complications are described including information about the incidence, hemodynamics, manifestations, diagnosis, and medical and surgical management. The importance of prenatal detection of CHD and critical congenital heart defect (CCHD) pulse oximetry screening is discussed. Risk factors for brain injury in the neonate with CHD and age-related neurodevelopmental (ND) problems are reviewed. The chapter concludes with a discussion about the support of the family of an infant with a CHD. A case study is used to illustrate the complex care required by infants and families of infants with cardiac disorders.

CARDIOVASCULAR ADAPTATION

Fetal Circulation

Knowledge of the normal route of fetal blood flow is essential to understand the circulatory changes that occur in the newborn at delivery. The pattern of fetal circulation is illustrated in Figure 7.1. Fetal circulation involves four unique anatomic features.

In fetal life, the placenta serves as the exchange organ for oxygen and carbon dioxide and for nutrients and wastes. Fetal circulation involves parallel circulation, which is different from series circulation—right ventricle (RV) pumps deoxygenated blood to the lungs, which return oxygenated blood to the left ventricle (LV), which pumps blood to the body—seen postnatally. The oxygenated blood from the placenta enters the umbilical vein (UV), and the ductus venosus (DV) allows approximately one third of this oxygenated blood to bypass the liver to stream right to left across the foramen ovale (FO), an opening in the atrial septum. This oxygenated blood enters the LV, which then pumps the well-oxygenated blood to the developing brain. Deoxygenated blood from the superior vena cava (SVC) and inferior vena cava (IVC) enters the right atrium (RA) to the RV, which pumps the blood into the main pulmonary artery. Since the lungs are collapsed in utero, only 5% to 10% of the blood flow in the

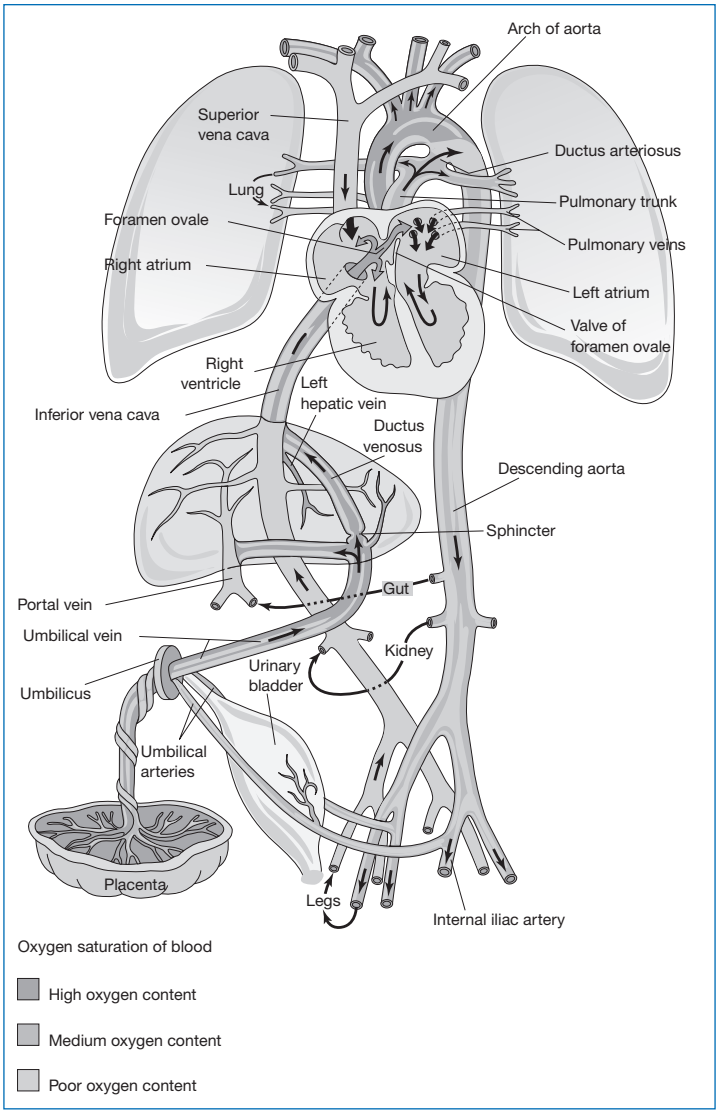

FIGURE 7.1 Anatomical features and pattern of fetal circulation.

pulmonary artery perfuses the lungs, so the majority of the blood flow shunts across the ductus arteriosus (DA) into the descending aorta and returns to the placenta via the umbilical artery (UA; Godfrey & Rychik, 2012; Park, 2014; Rudolph, 2001; Webb, Smallhorn, Therrien, & Redington, 2012).

Extrauterine Circulation

The cardiac and pulmonary systems undergo drastic changes at birth; these changes usually occur immediately upon onset of respiration. The most significant change is that the lungs now assume the role of primary oxygenator. Clamping of the umbilical cord removes the placenta, and subsequently results in immediate circulatory changes in the newborn. With the first breath and occlusion of the umbilical cord, the newborn's systemic vascular resistance is elevated, decreasing the amount of blood flow through the DA. Cord occlusion causes an increase in blood pressure and a corresponding stimulation of the aortic baroreceptors and the sympathetic nervous system. The onset of respiration and consequent lung expansion causes a decrease in pulmonary vascular resistance secondary to the direct effect of oxygen and carbon dioxide on the blood vessels. Pulmonary vascular resistance decreases as arterial oxygen content increases and arterial carbon dioxide decreases (Park, 2014; Webb et al., 2012).

Most of the RV output flows through the lungs and increases the pulmonary venous return to the left atrium (LA). This increased blood flow into the lungs that returns to the heart results in an increase in pressure in the LA, and, combined with the increased systemic vascular resistance, functionally closes the FO.

The DA functionally closes around 12 to 15 hours after birth as a result of constriction of the medial smooth muscle. The DA is anatomically constricted, becoming the ligamentum arteriosum by 3 weeks of age as a result of changes that occur in the endothelium and subintimal layers in response to oxygen, prostaglandin E_2 (PGE_2), acetylcholine, and bradykinin. Clamping of the umbilical cord causes the cessation of blood flow through the UV, DV, and UA (Park, 2014; Rudolph, 2001).

Functional closure refers to the cessation of flow through the structure caused by changes in pressure. *Anatomic closure* refers to obliteration of the structure by constriction as a result of intraluminal growth of tissue.

Because anatomic closure of the fetal pathways lags behind functional closure, the shunts may open and close intermittently before anatomic closure, resulting in transient functional murmurs.

Pulmonary artery pressure remains high for several hours after delivery. As the pulmonary vascular resistance decreases, the direction of blood flow through the DA changes. Initially, the PDA is bidirectional, the flow becomes entirely left to right typically by 24 to 48 hours of life, and the DA may be functionally insignificant by 48 hours of life. Intermittent or functional murmurs do not cause any cardiovascular compromise for the newborn and are not clinically significant. Conditions that cause transient opening of fetal shunts, allowing deoxygenated blood to shunt from the right side of the heart to the left, thereby bypassing the pulmonary circuit, produce transient cyanosis. Any murmur or cyanosis in the newborn should be carefully evaluated and monitored to detect cardiovascular abnormalities (Jones, 2005; Park, 2014; Webb et al., 2012). Hypoxemia and acidosis can cause a functionally constricted DA to reopen, while the pulmonary artery and arterioles respond by constricting (Park, 2014; Webb et al., 2012).

NORMAL CARDIAC FUNCTION

The normal anatomy of the heart is shown in Figure 7.2.

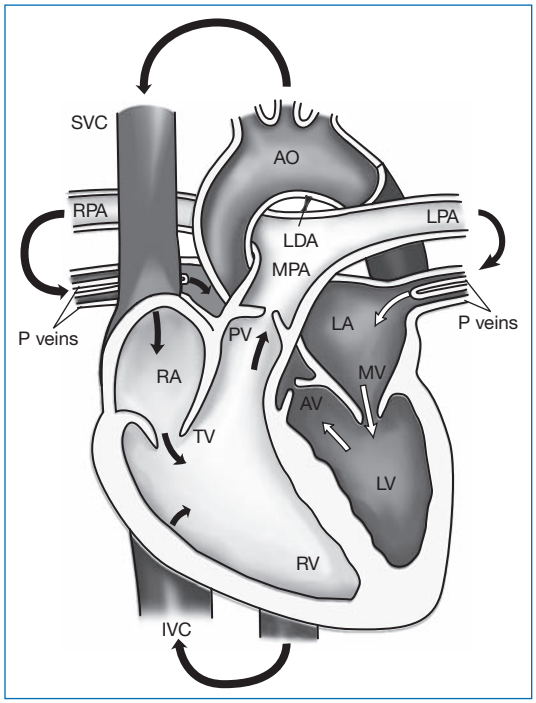

FIGURE 7.2 Normal cardiac anatomy and circulation.

AO, aorta; AV, aortic valve; IVC, inferior vena cava; LA, left atrium; LDA, ligamentum ductus arteriosus; LPA, left pulmonary artery; LV, left ventricle; MPA, main pulmonary artery; MV, mitral valve; PV, pulmonary valve; P veins, pulmonary veins; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava; TV, tricuspid valve.

Source: Adapted and modified from Ross Laboratories, Columbus, OH, Clinical Education Aid, 1985.

Cardiac Valves

Blood flow through the heart is directed through two sets of one-way valves. The atrioventricular valves (AVs) consist of the tricuspid valve and the mitral valve. The tricuspid valve connects the RA and the RV. The mitral valve connects the LA and the LV. The semilunar valves consist of the pulmonary valve and the aortic valve. The pulmonary valve connects the RV and the pulmonary artery. The aortic valve connects the LV and the aorta.

Cardiac Cycle

Normal cardiac function involves two stages: *systole* and *diastole*. During systole, contraction of the ventricle causes the pressure inside the ventricle to increase to approximately 70 mmHg in newborns (compared with 120 mmHg in adults). When sufficient pressure is generated, the aortic and pulmonary valves open and blood is ejected from the ventricles. As the blood flows from the ventricles, the pressure decreases, causing the aortic and pulmonary valves to close.

During diastole, the mitral and tricuspid valves open, and 70% of the blood in the atria enters the ventricles. A small portion of the aortic blood flows back into the coronary arteries to perfuse the heart. At the end of diastole, a small atrial contraction occurs (4–6 mmHg on the right side; 7–8 mmHg on the left side), and then the mitral and tricuspid valves close. Metabolism of the heart is decreased during diastole. The average newborn's cardiac cycle is approximately 0.4 second, with 0.2 second for diastole and 0.2 second for systole (based on a heart rate [HR] of approximately 150 beats per minute [bpm]; Opie & Hasenfuss, 2012).

Cardiac Output

Cardiac output (CO) is the amount of blood pumped by the LV in one minute. CO is equal to the stroke volume (SV) times the HR (CO = SV × HR). The SV is the volume of blood pumped per beat from each ventricle; the higher the SV, the greater the volume of blood in the systemic circulation. CO is influenced by changes in HR and pulmonary and systemic vascular resistance.

CO is influenced by the amount of blood returned to the heart, as explained by the Frank-Starling law, which states that within physiologic limits, the heart pumps all the blood that enters into it without allowing excessive accumulation of blood in the veins. The passive movement of blood through the veins, the thoracic pump, and the venous muscle pump determines venous return; normally, when increased volume enters the heart, contractility is increased as a response to stimulation of stretch receptors in the heart muscle. The newborn's heart has fewer muscle fibers and is unable to stretch sufficiently to accommodate increased volume; therefore, increased HR is the only effective mechanism by which the newborn can respond to increased volume (Mann, 2012; Opie & Hasenfuss, 2012).

Cardiac failure occurs when the volume exceeds the ability of the heart to pump. Local factors that affect venous return to the heart include hypoxia, acidosis, hypercarbia, hyperthermia, increased metabolic demand, and increased metabolites (potassium, adenosine triphosphate, and lactic acid).

Vascular pressure and resistance also influence CO. Pressure and resistance are inversely related: if pressure in the arterial bed is increased, resistance decreases and flow improves. The size (radius) of vessels influences resistance: the greater the radius of a vessel, the lower the resistance. Vessels obstructed by thrombosis or constriction have greater resistance to vascular flow (Mann, 2012; Opie & Hasenfuss, 2012).

Autonomic Cardiac Control

Cardiovascular function is modulated by the autonomic nervous system (ANS). Baroreceptors and chemoreceptors in the aorta and carotid sinus provide feedback to the ANS. Feedback from these receptors stimulates the parasympathetic or sympathetic nervous system. Most parasympathetic and sympathetic nervous system effects are on the atria, but decreased ventricular contractility may also occur.

The parasympathetic nervous system is less powerful than the sympathetic system. Stimulation of the parasympathetic nervous system results in vagal nerve stimulation and decreased HR. Right vagal stimulation affects the sinoatrial (SA) node, and left vagal stimulation affects the AV node. Acetylcholine is the active neurotransmitter for the preganglionic neurons of the parasympathetic and sympathetic nervous systems (Opie & Hasenfuss, 2012).

Stimulation of the sympathetic nervous system through the ganglionic chain releases norepinephrine and epinephrine, which act on the SA node, the AV node, the atria, and the ventricles. Maximal stimulation of the sympathetic nervous system can increase HR to 250 to 300 bpm. Contractility can be improved by approximately 100%. Alpha adrenergic and beta adrenergic receptors are stimulated. Alpha receptors cause increased contractility (inotropic) and increased rate (chronotropic); beta-2 receptors cause vasodilation, bronchodilation, and smooth muscle relaxation (Kaplan, 2011).

Term newborns have a decreased number of receptors but are capable of normal cardiovascular system function. The preterm newborn is not able to smoothly maintain autonomic function, and energy expenditure is increased. Hence, cardiovascular signs such as color changes and bradycardia may occur because of excessive demand for ANS function.

CARDIAC ASSESSMENT

In many regions of the United States, less than 50% of CHD is detected prenatally (Quartermain et al., 2015). Early recognition of signs and symptoms of CHD resulting in earlier CHD diagnosis and treatment can potentially result in improved outcomes (Eckersley, Sadler, Parry, Finucane, & Gentles, 2016). CCHD pulse oximetry screening typically performed around 24 hours of age may contribute to earlier CHD diagnosis before ductal closure with the resultant hemodynamic collapse. Careful newborn assessment is a crucial component of newborn care. Cardiac assessment includes history taking, physical assessment, and interpretation of diagnostic tests. Review of the maternal, fetal, and neonatal history and type of prenatal screening performed is helpful in the cardiac evaluation of the newborn. Box 7.1 lists maternal and fetal conditions that are considered higher risk for fetal cardiac conditions resulting in referrals for fetal echocardiograms (Donofrio et al., 2014). Table 7.1 lists heart defects commonly associated with maternal drug use and conditions.

Typically, these pregnant mothers are considered higher risk and are screened with detailed ultrasounds and fetal echocardiograms resulting in prenatal detection of cardiac conditions (Donofrio et al., 2014). Sometimes, pregnant mothers who are considered higher risk may not have received adequate prenatal ultrasound and fetal echocardiogram screening; therefore, their newborns will require screening after birth since they are at increased risk for cardiac conditions. In addition, the fetal effects of uncontrolled diabetes during pregnancy, especially during the third trimester, may go undetected and will result in a newborn who is large for gestational age, sometimes with associated hypertrophic cardiomyopathy.

Methods of Assessment

Assessment for evidence of a cardiac problem begins with a careful history, followed by a thorough physical examination. Family history of hereditary diseases, CHD, or rheumatic fever increases the risk for certain CHD lesions (Table 7.2).

The overall incidence of CHDs is approximately 1%, or 8 per 1,000 live births, excluding persistent PDA in preterm newborns. Maternal history of CHD, however, increases the risk of recurrence from 3% to 7% (Donofrio et al., 2014).

A neonatal history of cyanosis, tachypnea without pulmonary disease, sweating, poor feeding, and pulmonary edema, or, in older infants, poor feeding and failure to gain weight, is suggestive of CHD. Careful evaluation of the maternal, fetal, and neonatal history, in conjunction with a thorough physical assessment, helps identify infants for whom further diagnostic testing with echocardiogram is indicated.

Physical examination of the newborn with a suspected cardiac condition includes inspection, palpation, and auscultation (Park, 2014).

Inspection

Valuable information about the cardiovascular system of the newborn can be obtained by observation of the newborn's general appearance before examination. The following states of the newborn should be observed: sleeping or awake, alert or lethargic, anxious or relaxed. Respiratory effort, including signs of respiratory distress such as nasal flaring, expiratory grunting, stridor, retractions, or paradoxical respirations, should be noted. Tachypnea and tachycardia are early signs of LV dysfunction (Park, 2014).

Box 7.1

COMMON MATERNAL AND FETAL INDICATIONS FOR REFERRAL FOR FETAL ECHOCARDIOGRAM

Indications With the Highest Risk Profile (estimated >2% absolute risk for fetal cardiac disease)

- Maternal pregestational diabetes mellitus
- Diabetes mellitus diagnosed in the first trimester
- Maternal phenylketonuria (uncontrolled)
- Maternal autoantibodies (SSA/SSB+)
- Maternal medications (ACE inhibitors, retinoic acid, NSAIDs in third trimester)
- Maternal first-trimester rubella infection
- Maternal infection with suspicion of fetal myocarditis
- Assisted reproductive technology
- CHD in first-degree relative of fetus (maternal, paternal, or sibling)
- First- or second-degree relative with disorder with Mendelian inheritance with CHD association
- Fetal cardiac or extracardiac abnormality suspected on obstetric ultrasound
- Fetal karyotype abnormality
- Fetal tachycardia or bradycardia, or frequent or persistent irregular heart rhythm
- Fetal increased NT >95% (>3 mm)
- Monochorionic twinning
- Fetal hydrops or effusions

Indications With a Lower Risk Profile (estimated >1% but <2% absolute risk for fetal cardiac disease)

- Maternal medications (anticonvulsants, lithium, vitamin A, SSRIs (only paroxetine), NSAIDs in first or second trimester)
- CHD in second-degree relative of fetus
- Fetal abnormality of umbilical cord or placenta
- Fetal intraabdominal venous anomaly

ACE, angiotensin converting enzyme; CHD, congenital heart defect; NSAIDs, nonsteroidal anti-inflammatory drugs; NT, nuchal traslucency.

Source: Data from Donofrio, M., Moon-Grady, L., Hornberger, L., Copel, J., Sklansky, M. S., Abuhamad, A., . . . Rychik, J. (2014). Diagnosis and treatment of fetal cardiac disease. A scientific statement from American Heart Association. *Circulation, 129*, 2183–2242. doi:10.1161/01.cir.0000437597.44550.5d

The color of the newborn should be observed. Cyanosis is the bluish color of the skin, mucous membranes, and nail beds that occurs when there is at least 5 g/100 mL of deoxygenated hemoglobin in circulation. If cyanosis is present, note whether it is peripheral or central and whether it improves, stays the same, or becomes worse with crying. Cyanosis can result from pulmonary, hematologic, central nervous system, or metabolic diseases, as well as from cardiac defects. Pulmonary and cardiac defects are the two most common causes of central cyanosis in the newborn.

Pallor may indicate vasoconstriction resulting from congestive heart failure (CHF) or circulatory shock caused by severe anemia.

TABLE 7.1

MATERNAL CONDITIONS AND ASSOCIATED FETAL CARDIAC DISEASE

Condition	Defect
Maternal Disease	
Diabetes mellitus	Cardiomyopathy, TGA, VSD, PDA
Lupus erythematosus	Congenital heart block
Collagen disease	Congenital heart block
Congenital heart defect	Increased risk for congenital heart defect (3%–4%)
Viral Disease	
Rubella	
First trimester	PDA, pulmonary artery branch stenosis
Later	Various cardiac and other defects
Cytomegalovirus	Various cardiac and other defects
Herpes virus	Various cardiac and other defects
Coxsackie virus B	Cardiomyopathy
Drugs	
Amphetamines	VSD, PDA, ASD, TGA
Phenytoin	PS, AS, COA, PDA
Trimethadione	TGA, TOF, HLHS
Progesterone/ estrogen	VSD, TOF, TGA
Alcohol	VSD, PDA, ASD, TOF

AS, aortic stenosis; ASD, atrial septal defect; COA, coarctation of the aorta; HLHS, hypoplastic left heart syndrome; PDA, patent ductus arteriosus; PS, pulmonary stenosis; TGA, transposition of the great arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

Source: Data from Park, M. K. (2014). *Pediatric cardiology for practitioners.* Chicago, IL: Mosby.

Prolonged physiologic jaundice may occur in infants with CHF or congenital hypothyroidism, which is associated with PDA and pulmonary stenosis (PS). A ruddy or plethoric appearance is often seen in polycythemia. These infants may appear cyanotic without significant arterial desaturation.

The presence of significant diaphoresis, particularly with feeding, is very suggestive of a CHD in the newborn. The cause of sweating is sympathetic overactivity as a compensatory mechanism for decreased CO (Park, 2014).

TABLE 7.2

CONGENITAL HEART DEFECTS ASSOCIATED WITH SPECIFIC GENETIC OR CHROMOSOMAL ABNORMALITIES

Disease or Syndrome	Defect
Trisomy 13, 18	PDA, VSD
Trisomy 21	AVC, VSD, PDA
Marfan syndrome	MVP, aortic dilation, and/or aneurysm
Noonan's syndrome	PS, HCM
Turner syndrome	BAV, COA
Williams syndrome	Supravalvar AS and PS
Deletion 22q11 DiGeorge sequence Velocardiofacial syndrome	Conotruncal defects (Truncus, TOF, IAA-B, aortic arch anomalies)

AS, aortic stenosis; AVC, atrioventricular canal defect; BAV, bicuspid aortic valve; COA, coarctation of the aorta; HCM, hypertrophic cardiomyopathy, IAA, interrupted aortic arch; MVP, mitral valve prolapse; PDA, patent ductus arteriosus; PS, pulmonic stenosis; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

Allen, R. E. Shaddy, D. J. Penny, T. F. Feltes, & F. Cetta (Eds), *Moss and Adams heart disease in infants, children and adolescents* (9th ed., Vol. 1, pp. 87–116). Philadelphia, PA: Lippincott Williams & Wilkins.

Palpation

Palpation includes the palpation of the precordium and peripheral pulses. Palpation of the precordium detects a thrill, hyperdynamic activity, and the point of maximal impulse (PMI). Irregularities or inequalities of rate or volume can be detected by counting the peripheral pulse rate. Evaluation of the carotid, brachial, femoral, and pedal pulses detects differences between right and left sides and upper and lower extremities. If pulses are unequal, four extremity blood pressures should be measured. Strong arm pulses with weak leg pulses suggest coarctation of the aorta (COA; Park, 2014).

Heart defects that lead to "aortic runoff," or diastolic reversal of flow in the descending aorta, such as PDA, aortic insufficiency, large arteriovenous malformations, or truncus arteriosus, may cause bounding pulses. Preterm newborns frequently have a bounding pulse secondary to relatively decreased subcutaneous tissue and/or PDA. Cardiac failure or circulatory shock causes weak or thready pulses (Park, 2014).

The hyperdynamic precordium indicates a heart defect with volume overload, such as CHDs with large left-to-right shunts (e.g., PDA, VSD) or valvular regurgitation (e.g., aortic regurgitation or mitral regurgitation). The location of the PMI depends on whether the RV or LV is dominant. With RV dominance, the PMI is at the lower left sternal border (LLSB). LV dominance places the PMI at the apex. A diffuse, slow-rising PMI is called a *heave* and is associated with volume overload. A sharp, fast-rising PMI is called a *tap* and is associated with pressure overload. The normal newborn has RV dominance. The LV apical impulse of the newborn is normally felt in the fourth intercostal space to the left of the midclavicular line. Lateral or downward displacement of the apical impulse may indicate cardiac enlargement (Park, 2014).

The presence and location of a thrill provides important diagnostic information. The palms of the hands, rather than the fingertips, should be used to feel for a thrill, except in the suprasternal notch and carotid arteries. The examiner should palpate for the presence of thrills in the upper left, upper right, and LLSB, in the suprasternal notch, and over the carotid arteries. A thrill in the upper left sternal border is derived from the pulmonary valve or pulmonary artery. Thrills in the LLSB suggest PS, or occasionally PDA. A thrill felt in the upper right sternal border signifies aortic origin, usually AS, or, less frequently, PS, PDA, or COA. A thrill over the carotid arteries along with a thrill in the suprasternal notch suggest COA or AS, or other defects of the aorta or aortic valve (Park, 2014).

Palpation of the abdomen is performed to determine the size, consistency, and location of the liver and spleen. Increased liver size is a frequent finding with CHF (Park, 2014).

Auscultation

Careful auscultation by a skilled evaluator is an essential component of any cardiovascular assessment. Auscultation includes HR and regularity, heart sounds, systolic and diastolic sounds, and heart murmurs. The skillful evaluation of cardiac sounds requires systematic auscultation and much practice.

Identification of Heart Sounds

Individual heart sounds should be identified and evaluated before evaluation of cardiac murmurs is attempted. There are four individual heart sounds: S_1, S_2, S_3, and S_4. However, S_3 and S_4 are rarely heard in the newborn. S_1 is the sound resulting from the closure of the mitral and tricuspid valves following atrial systole and is best heard at the apex or LLSB. S_1 is the beginning of ventricular systole. Splitting of S_1 is infrequently heard in newborns. Wide splitting of S_1 is heard in the right bundle branch block or Ebstein anomaly (Park, 2014).

S_2 is the sound created by closure of the aortic and pulmonary valves, which marks the end of systole and the beginning of ventricular diastole. S_2 is best heard in the upper left sternal border or pulmonic area. Evaluation of the splitting of S_2 is important diagnostically. The volume of blood ejected from the aorta and pulmonary artery and the resistance against which the ventricles must pump determine the timing of the closure of the aortic and pulmonary valves. In the immediate newborn period, there may be no appreciable splitting of S_2. Because the RV and LV pump similar quantities of blood and the pulmonary pressure is close to the aortic pressure, these valves close almost simultaneously. Thus, S_2 is heard as a single sound. As the pulmonary vascular resistance decreases, the pulmonary resistance becomes lower than the aortic pressure, causing a splitting of S_2 as the valve leaflets on the left side of the heart (aortic valve) close before those on the right (pulmonary valve). By 72 hours of life, S_2 should be split. The absence of a split S_2 or the presence of a widely split S_2 usually indicates an abnormality. A fixed, widely split S_2 occurs in conditions that prolong RV ejection time or shorten LV ejection time. It occurs in (1) atrial septal defect (ASD) and

partial anomalous pulmonary venous return (PAPVR; amount of blood ejected by RV is increased, resulting in volume overload); (2) PS (stenosis delays right ventricular ejection time, resulting in pressure overload); (3) right bundle branch block (delayed electrical activation of RV); and (4) mitral regurgitation (decreased forward output, decreased LV ejection time; Park, 2014).

A narrowly split S_2 occurs when there is early closure of the pulmonary valve (pulmonary hypertension) or a delay in aortic closure. A single S_2 is significant because it could represent the presence of only one semilunar valve (e.g., aortic atresia [AA], pulmonary atresia [PA], or truncus arteriosus). A single S_2 may also occur with critical PS, in which the pulmonary closure is not audible. Severe AS may also cause a single S_2 because aortic closure is delayed. Severe pulmonary hypertension may cause early closure of the pulmonary valve, thus causing a single S_2.

The relative intensity of the aortic and pulmonary components of S_2 must be assessed. In the pulmonary area (upper left sternal border), the aortic component is usually louder than the pulmonary component. Increased intensity of the pulmonary component, compared with the aortic component, occurs with pulmonary hypertension. Conditions that cause decreased diastolic pressure of the pulmonary artery (e.g., critical PS, TOF, tricuspid atresia) may cause decreased intensity of the pulmonary component. Evaluation of intensity and splitting of S_2 is difficult, particularly in newborns with faster hearts, and requires frequent practice listening to heart sounds (Park, 2014).

As discussed, S_3 and S_4 are rarely heard in the neonatal period; their presence denotes pathologic origin. Likewise, a gallop rhythm, the result of the presence of S_3 or S_4 gallop, is abnormal and associated with CHF (Park, 2014).

After evaluation of individual heart sounds, the systolic and diastolic sounds are evaluated. The ejection sound, or click, occurs after S_1 and may sound like splitting of S_1. The ejection click is best heard at the upper left or right sternal border. The pulmonary click can best be heard at the second or third left intercostal space and is louder with expiration. The aortic click, best heard at the second right intercostal space, does not change in intensity with change in respiration. Ejection clicks are associated with PS or AS or with the dilated great arteries seen in systemic or pulmonary hypertension (Park, 2014).

CARDIAC MURMURS

Cardiac murmurs should be evaluated for intensity (grades 1–6), timing (systolic or diastolic), location, transmission, and quality (musical, vibratory, or blowing).

The grade scale for murmurs is as follows:

Grade 1: barely audible
Grade 2: soft but easily audible
Grade 3: moderately loud, no thrill
Grade 4: loud, thrill present
Grade 5: loud, audible with stethoscope barely on chest
Grade 6: loud, audible with stethoscope near chest

The murmur grade is recorded as 1/6, 2/6, and so on. Again, practice in auscultation improves the practitioner's evaluation skills. The intensity of the murmur is affected by CO; anything that increases CO (e.g., anemia, fever, exercise) increases the intensity of the murmur (Park, 2014).

The next step in evaluating a murmur is its classification in relation to S_1 and S_2. There are three types of murmurs: systolic, diastolic, and continuous.

Systolic Murmurs

The majority of heart murmurs are systolic, occurring between S_1 and S_2. Systolic murmurs are either ejection or holosystolic murmurs. Systolic ejection murmurs (SEMs) occur after S_1 and end before S_2, and are a result of blood flow through narrowed or deformed semilunar valves or increased flow through normal semilunar valves. SEMs are best heard at the second left or right intercostal space. Regurgitant and holosystolic murmurs begin with S_1, with no interval between S_1 and the beginning of the murmur, and continue throughout systole. These murmurs are caused by flow of blood from a chamber at a higher pressure than the receiving chamber throughout systole. Regurgitant and holosystolic murmurs are typically associated with mitral and tricuspid regurgitation and ventricular septal defects (VSDs; Park, 2014).

Location

The location of the maximal intensity of the murmur is helpful in evaluation of the cardiac murmur. Figure 7.3 shows the locations at which various systolic murmurs can be heard.

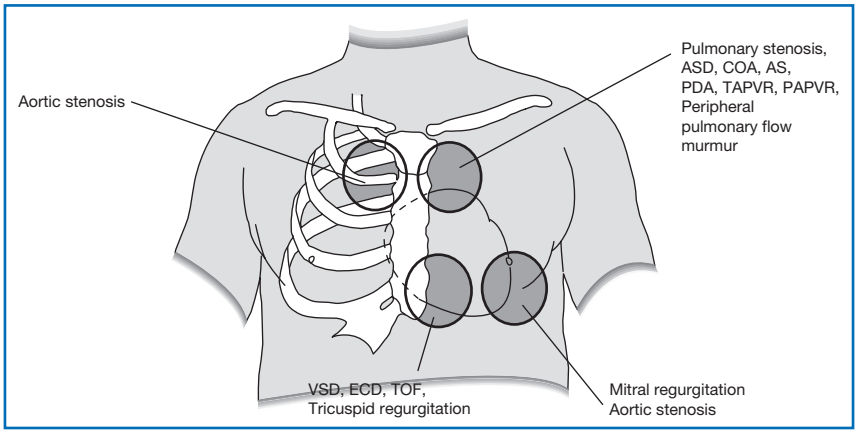

FIGURE 7.3 Location of systolic murmurs.

AS, aortic stenosis; ASD, atrial septal defect; COA, coarctation of the aorta; ECD, endocardial cushion defect; PAPVR, partial anomalous pulmonary venous return; PDA, patent ductus arteriosus; TAPVR, total anomalous pulmonary venous return; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

Related to the location is the radiation of the murmur. Knowledge of radiation of the murmur can help determine the origin. A SEM that radiates well to the neck is usually aortic in origin, whereas one that radiates to the back is usually pulmonic in origin. An apical systolic murmur that radiates to the left axilla and lower back is characteristic of mitral regurgitation, but one that radiates to the upper right sternal border and neck is likely to be aortic in nature (Park, 2014).

Quality

Murmurs are described as musical, vibratory, or blowing (Park, 2014). VSDs or mitral regurgitation murmurs have a high-pitched, blowing quality. AS and PS murmurs have a rough, grating quality. Establishing the quality of the murmur is subjective, and expertise is gained only after extensive practice and experience.

Diastolic Murmurs

Diastolic murmurs occur between S_1 and S_2. Diastolic murmurs are classified according to their timing in relation to heart sounds as early diastolic, middiastolic, or presystolic.

Early diastolic (protodiastolic) murmurs occur early in diastole, right after S_2, and are caused by incompetence of the aortic or pulmonary valve. Aortic regurgitation murmurs are high pitched and are best heard with the diaphragm of the stethoscope at the third left intercostal space. Aortic regurgitation murmurs radiate to the apex. Bounding pulses are present with significant aortic regurgitation. Aortic regurgitation murmurs occur with the bicuspid aortic valve. Pulmonary regurgitation murmurs are medium pitched unless pulmonary hypertension is present, in which case they are high pitched. Diastolic regurgitation murmurs are heard best at the second left intercostal space, radiating along the left sternal border. Pulmonary regurgitation murmurs are common with postoperative TOF and pulmonary valvotomy for PS, or other deformities of the pulmonary valve where there is no competent pulmonary valve and severe or free pulmonary insufficiency (Park, 2014).

Middiastolic murmurs result from abnormal ventricular filling. These murmurs are low pitched and can best be heard with the bell of the stethoscope placed lightly on the chest wall. The murmur results from turbulent flow caused by stenosis of the tricuspid or mitral valve. Mitral middiastolic murmurs are best heard at the apex and are referred to as *apical rumbles*. Mitral middiastolic murmurs are associated with mitral stenosis or large VSDs with a large left-to-right shunt or PDA, producing relative mitral stenosis secondary to increased flow across the normal-sized mitral valve. Tricuspid middiastolic murmurs can best be heard along the LLSB and are associated with moderate to large ASDs, PAPVR or TAPVR, or abnormal stenosis of the tricuspid valve. Presystolic or late diastolic murmurs result from flow through AV valves during ventricular diastole as a result of active atrial contraction ejecting blood into the ventricle. These are low-frequency murmurs found with true mitral or tricuspid valve stenosis (Park, 2014).

Continuous Murmurs

Continuous murmurs begin in systole and continue throughout S_2 into all or part of diastole. Continuous murmurs are caused by (1) aortopulmonary or AV connection (e.g., PDA, AV fistula), (2) disturbances of flow in veins (e.g., venous hum), and (3) less commonly by disturbances of flow in arteries (e.g., severe COA or pulmonary artery stenosis; Park, 2014).

PDA is the most commonly heard continuous murmur in the newborn. The PDA murmur is described as a machinery murmur, louder during systole, peaking at S_2, and decreased in diastole. PDA murmurs are loudest in the left infraclavicular area or the upper left sternal border (Park, 2014).

Other Murmurs

Functional or innocent cardiac murmurs are common in newborns and in school-age children. Innocent murmurs occur in the absence of abnormal cardiac structures. Functional murmurs are asymptomatic. The presence of any unusual or abnormal finding warrants further evaluation with cardiac consultation. Findings such as cyanosis, enlarged heart size on examination or enlarged cardiac silhouette on chest radiograph, abnormal ECG, diastolic murmur, a loud murmur (grade 3/6 systolic murmur or associated with a thrill), weak or bounding pulses, or other abnormal heart sounds have pathologic origins and must be investigated (Park, 2014).

Peripheral pulmonary stenosis murmur or pulmonary flow murmur of infancy is commonly auscultated in newborns. The murmur is thought to be secondary to anatomic discrepancy in size between the main pulmonary artery (MPA) and the branch pulmonary arteries or the angle of takeoff of the branch pulmonary arteries. In utero, the lungs only receive 5% to 10% of the RV CO, so the branch pulmonary arteries are relatively small compared to the MPA since most of the flow shunts from the PA to the ductus to return to the placenta via the umbilical artery. The increased flow after birth creates turbulence in the small vessels, which is transmitted along the smaller branches of the pulmonary arteries. This murmur is best heard at the upper left sternal border with grade of 1/6 to 2/6 intensity radiating to the right and left chest, both axillae, and back. There are no other significant cardiac findings. Typically, it is no longer present after 3 to 6 months of age, and persistence beyond this period should lead to further evaluation for true pathologic peripheral pulmonary artery stenosis (Park, 2014).

CONGENITAL HEART DEFECTS

Etiology

Cardiac development typically is completed by 8 weeks of gestation. Most CHDs are classified as multifactorial (85%), whereas some are associated with chromosomal abnormalities (10%–12%), genetic (1%–2%), or maternal or environmental factors (1%–2%; Wernovsky & Gruber, 2005).

Many chromosomal abnormalities are associated with structural heart defects. Approximately 50% of newborns with trisomy 21 (Down syndrome) have CHD, most commonly ECD, ASD, VSD, and TOF with and without an AVC defect (Goldmuntz & Crenshaw, 2016).

Maternal or environmental factors include maternal illness and drug ingestion. Maternal rubella during the first 7 weeks of pregnancy carries a 50% risk of congenital rubella syndrome (CRS) with major defects of multiple organ systems. Heart defects include PDA and branch pulmonary artery stenosis. Other viral diseases, such as cytomegalovirus, or protozoal diseases, such as toxoplasmosis, are also associated with CHDs. The diagnosis of CHD calls for a careful maternal history to identify viral-like illnesses that may have been unrecognized or unreported at the time of occurrence and careful examination to rule out the presence of other congenital defects (Park, 2014; Seidman, Pyeritz, & Seidman, 2012).

Maternal drug use may also cause cardiac malformations. Fifty percent of newborns with fetal alcohol syndrome (FAS) have CHD. Only a few drugs are proven teratogens (e.g., thalidomide); however, *no* drugs are known to be completely safe.

Metabolic disease of the mother increases the risk for CHDs. Infants of diabetic mothers have a 3% to 5% risk of having CHD (double outlet right ventricle [DORV], truncus, *d*-transposition of the great arteries [TGA], hypoplastic left heart syndrome [HLHS], VSD) and 30% risk of hypertrophic cardiomyopathy (Hornberger, 2006; Rychik, 2012).

Most CHDs are considered to be of multifactorial origin; these defects are probably the result of an interaction effect of the other causes. Research into genetic causes of cardiac defects may identify specific genetic causes for some heart defects that are currently thought to have multifactorial origin. Infants with other congenital defects often have associated CHDs. Multiple congenital defects affect the development of structures that are forming at the time, resulting in interference with normal fetal development.

Incidence

Estimates of incidence of CHD vary from 4 to 10.2 per 1,000 live births. The overall incidence of CHD is slightly less than 1%, or 8 per 1,000 live births, excluding PDA in the preterm newborn (Nouri, 1997; Park, 2014; Webb et al., 2012). CHD accounts for 30% to 50% of mortality of congenital anomalies in infancy, with HLHS accounting for the highest percentage of these deaths (Gilboa, Salemi, Nembhard, Fixler, & Correa, 2010).

Although only 50% of CHD is detected prenatally (Quartermain et al., 2015), with the introduction of pulse oximetry screening for CHD it is expected that the majority of CHDs will be detected earlier or at least before discharge from the newborn nursery. Some of these defects will require surgery in the neonatal period while others may be medically managed. The following discussion of CHDs extends beyond the neonatal period. Table 7.3 is an overview of the diagnosis of CHD.

The discussion of defects is based on the common pathophysiologic features. CHDs can be classified in numerous ways. The simplest classification is based on whether the defect produces cyanosis, a method described by Dr. Helen Taussig in 1947. Cyanosis is the bluish discoloration of the skin that occurs when there is approximately 5 g/100 mL of desaturated hemoglobin in the circulating volume (Taussig, 1947). Thus, the appearance of cyanosis depends on the hemoglobin concentration. An infant with low hemoglobin may be hypoxic but may not appear cyanotic; thus, low

TABLE 7.3

DIAGNOSIS OF CONGENITAL HEART DEFECTS

Defect	Chest Radiograph	Electrocardiogram	Echocardiogram	Catheterization
PDA	Cardiomegaly, increased pulmonary vascularity	In large PDAs: LA enlargement and LV hypertrophy	PDA size, shunt direction, LA/LV dilation, LA/Ao ratio, diastolic reversal of flow in descending aorta	Increased O_2 saturation in pulmonary artery; increased RV and pulmonary artery pressure (with pulmonary hypertension)
VSD	Cardiomegaly, increased pulmonary vascularity	Moderate VSD: LVH and LA enlargement, large VSD: BVH +/− LA enlargement	VSD type/location, size, and number, shunt direction, LA/LV dilation	Increased O_2 saturation in RV, evaluation for elevated pulmonary pressures
ASD	Cardiomegaly, increased pulmonary vascularity	Right axis deviation; RV hypertrophy or RBBB	ASD type and size, shunt direction, RA/RV dilation	Increased O_2 saturation in RA; normal right side pressure; 10% PAPVR
ECD/AVC	Cardiomegaly, increased pulmonary vascularity	Left axis deviation; LA enlargement; RVH; incomplete RBBB	Primum ASD and inlet VSD size, regurgitation of AV valves, RV/LV outflow tract obstruction	Increased O_2 saturation in RA; increased right ventricular and/or pulmonary artery pressure; with angiography, a "goose neck" deformity of ventricular outflow area
PS	Normal heart size; normal pulmonary vascularity; enlarged pulmonary artery	Right axis deviation; RA enlargement; RVH	PS gradient (mild, moderate, or severe), level of obstruction: subvalvar, valvar, supravalvar	Evaluation of level of RVOT obstruction, gradient from RV across the pulmonary artery
TOF	Normal heart size; boot-shaped contour; decreased pulmonary markings; prominent aorta; right aortic arch in 13 cases	Right axis deviation; RVH	VSD size and number, overriding aorta, PS gradient (mild, moderate, or severe), level of obstruction: valvar, subvalvar; size of right and left pulmonary arteries, arch sidedness, coronary artery patterns	Demonstrates anatomy of right ventricular outflow region, VSD directionality, coronary pattern
PA/IVS	Normal heart size or cardiomegaly; decreased pulmonary vascularity	LVH, RA enlargement, occasionally RVH	PA, size of TV, tricuspid regurgitation, RV coronary fistula, branch pulmonary artery size, PDA	RV angiogram to evaluate for presence of coronary sinusoids, radiofrequency perforation of pulmonary valve in two-ventricle approach

(*continued*)

TABLE 7.3

DIAGNOSIS OF CONGENITAL HEART DEFECTS (*continued*)

Defect	Chest Radiograph	Electrocardiogram	Echocardiogram	Catheterization
TAPVR	Cardiomegaly; increased pulmonary vascularity	RVH, RA enlargement	TAPVR connections, RA/RV dilation, pulmonary HTN, PFO right to left	Higher O_2 saturation in right atrium; angiography reveals abnormal pulmonary venous return
AS	Normal heart size; slight prominence of left ventricle and aorta in older kids	Normal in mild cases, LVH with strain in severe obstruction	Aortic valve morphology, level of obstruction in LVOT, LVH, LV function	Performed to evaluate level of LVOT obstruction and gradient, LV end diastolic pressure
COA	Cardiomegaly, pulmonary edema	RVH or RBBB in infants, LVH in older kids	Transverse arch size, discrete or long segment coarctation, LV function, bicuspid aortic valve, mitral valve abnormality, LVOT obstruction	In infants, performed in patients with recurrent obstruction after surgery
HLHS	Cardiomegaly; increased pulmonary vascularity	RVH	HLHS subtype: AS or AA, MA or MS, ascending aorta size, ASD size, RV function, TR	Balloon atrial septostomy and stenting if ASD is inadequate.
TGA	Cardiomegaly; increased pulmonary vascularity	Right axis deviation; RVH	Aortic outflow arises from RV, ASD size, coronary pattern, RV or LV outflow tract obstruction, presence of a VSD	Balloon atrial septostomy if ASD is inadequate. Increased right ventricular pressure; catheter can enter aorta from right ventricle; pulmonary artery can be entered only through PDA or ASD
Truncus	Cardiomegaly; increased pulmonary vascularity	BVH	Truncus type, truncal stenosis or insufficiency, arch sidedness, VSD size	Left-to-right shunt at level of ventricle; pressure equal in ventricles, truncus, and pulmonary arteries

AA, aortic atresia; AS, aortic stenosis; ASD, atrial septal defect; AVC, atrioventricular canal; BVH, biventricular hypertrophy; COA, coarctation of the aorta; ECG, electrocardiogram; ECD, endocardial cushion defect; HLHS, hypoplastic left heart syndrome; LA, left atrium, LA/Ao, left atrium to aortic root; LV, left ventricle; LVH, left ventricular hypertrophy; LVOT, left ventricular outflow tract; MA, mitral atresia; MS, mitral stenosis; PA/IVS, pulmonary atresia with intact ventricular septum; PAPVR, partial anomalous pulmonary venous return; PDA, patent ductus arteriosus; PFO, patent foramen ovale; PS, pulmonary stenosis; RA, right atrium; RRBB, right bundle branch block; RV, right ventricle; RVH, right ventricular hypertrophy; RVOT, right ventricular outflow tract; TA, truncus arteriosus; TAPVR, total anomalous pulmonary venous return; TGA, transposition of the great arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

Source: Data from Park, M. K. (2014). *Pediatric cardiology for practitioners.* Chicago, IL: Mosby.

hemoglobin cannot be the sole criterion for determining pathologic origin. Cyanosis in the extremities, or acrocyanosis, is frequently seen in newborns because of reduced blood flow through the small capillaries. Oxygen is extracted from the hemoglobin in the capillaries, giving the skin a blue appearance. This blue appearance is a normal phenomenon in the newborn. Differentiation of central cyanosis from peripheral or acrocyanosis is essential since acrocyanosis is a benign condition while central cyanosis is associated with respiratory, cardiac, or metabolic conditions.

The presence or absence of cyanosis depends on whether or not deoxygenated blood is oxygenated by going through the lungs. CHD lesions that allow the blood to go through the lungs and then shunt from the left side of the heart and back to the right side of the heart are generally acyanotic and typically result in too much pulmonary blood flow. Defects that shunt deoxygenated blood directly to the left side of the heart, bypassing the lungs, are cyanotic heart defects and are typically a result of inadequate pulmonary blood flow. Some defects have mixed anatomic or functional features and do not fit into this schema, or there is overlap between the classifications. For this discussion, the following categories are used: (1) acyanotic defects with a left-to-right shunt due to communication between the systemic and pulmonary circulations typically resulting in too much pulmonary blood flow; (2) cyanotic defects that typically are a result of inadequate pulmonary blood flow; (3) left-sided obstructive defects with inadequate systemic blood flow; and (4) defects with abnormal aortopulmonary connections.

Defects With Left-to-Right Shunts

Typically, these defects have left-to-right shunts with increased pulmonary blood flow and volume overload on the heart. These defects typically result in too much pulmonary blood flow and include PDA, VSD, ASD, and endocardial cushion (ECD) or AV canal defects (AVC).

Patent Ductus Arteriosus

The DA is a vascular connection between the pulmonary artery and the aorta. The DA originates from the main pulmonary artery and enters the aorta distal to the left subclavian artery; it allows deoxygenated blood from the RV to bypass the lungs and enter the descending aorta. The DA functionally closes around 15 hours of life. During the first 24 hours of life, there may be some shunting

of blood, but typically it is insignificant unless the ductal opening is large and remains patent.

Closure of the DA occurs in response to increased arterial oxygen concentration after the initiation of respiratory function. Other factors that contribute to closure of the DA include a decrease in prostaglandin E (PGE) and an increase in acetylcholine and bradykinin (Park, 2014). Closure of the DA occurs within 48 hours in 80% of newborns and close to 100% close within 96 hours. PDA in the preterm newborn presents a different clinical problem and is discussed separately from PDA in the term newborn (Park, 2014; Webb et al., 2012).

Patent Ductus Arteriosus in the Term Newborn

Incidence. PDA accounts for approximately 5% to 10% of all CHDs, excluding those in preterm newborns. There is a higher ratio of PDA in females (about 3:1). PDAs are more common in infants with Down syndrome or those whose mothers had rubella during pregnancy (Park, 2014).

Hemodynamics. In extrauterine life, the flow of blood through the DA is reversed. The PDA allows blood to flow from left to right, thereby reentering the pulmonary circuit and increasing pulmonary blood flow. The amount of blood flow through the PDA and the effects of the ductal flow depend on the difference between systemic and pulmonary vascular resistance and the diameter and length of the ductus.

Over time, high pulmonary blood flow causes increased pulmonary vascular resistance, pulmonary hypertension, and right ventricular hypertrophy. Figure 7.4 depicts the hemodynamics of PDA.

Manifestations. A small PDA may be asymptomatic. A large PDA with significant shunting may cause signs of CHF including tachypnea and poor feeding. Frequent lower respiratory tract infections, poor feeding, and poor weight gain are common in older infants with PDA.

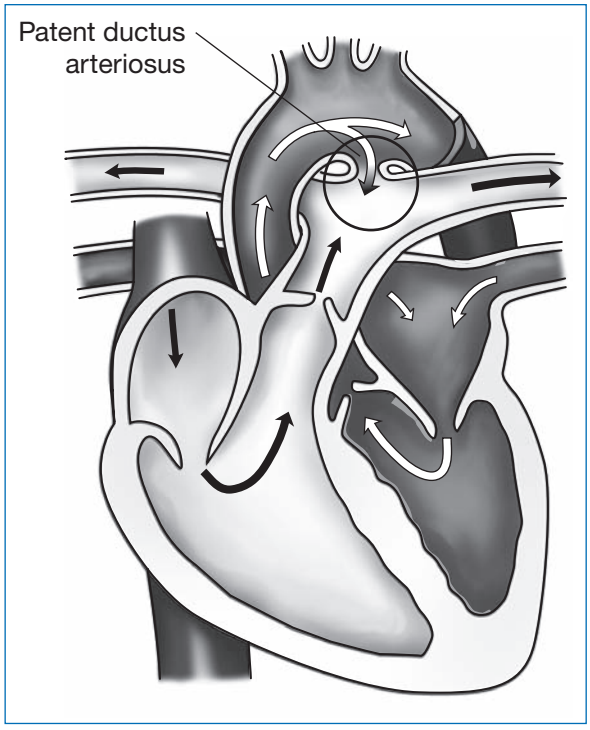

FIGURE 7.4 Patent ductus arteriosus is a communication between the pulmonary artery and the aorta.

Source: Adapted and modified from Ross Laboratories, Columbus, OH, Clinical Education Aid, 1985.

Diagnosis. The diagnosis of PDA is based on history and physical examination findings, chest radiograph, and echocardiogram. Characteristic findings on physical examination include bounding peripheral pulses, widened pulse pressure (>25 mmHg), and a hyperdynamic precordium. A systolic thrill may be felt at the upper left sternal border. A grade 1/6 to 4/6 continuous "machinery" murmur is audible at the upper left sternal border or left infraclavicular area. The murmur is heard throughout the cardiac cycle because of the pressure gradient between the aorta and the pulmonary artery in both systole and diastole. In cases of a large PDA with a significant shunt, the S_2 may be accentuated because of pulmonary hypertension (Park, 2014; Webb et al., 2012).

A small PDA may not be distinguishable on chest radiograph. With more significant shunting, there may be cardiomegaly and increased pulmonary vascularity. An ECG may demonstrate left atrial enlargement and left ventricular hypertrophy and an abnormal QRS axis, more leftward, for age. The definitive diagnosis is made by echocardiogram. Echocardiogram demonstrates size and directionality of PDA, LA to aortic ratio (LA/Ao ratio), presence of LA and LV dilation, arch sidedness, diastolic flow reversal in the descending aorta, ventricular function, and pulmonary hypertension.

Management. The treatment of the clinically significant PDA is medical or surgical closure. However, there is no absolute agreement on the criteria for determining clinical significance in the term newborn. If the term newborn's signs and symptoms are not affecting feeding and weight gain, a conservative approach to management may be used because the ductus may close over time on its own. Conservative treatment includes fluid management, diuretics, and close observation to assure that the baby is feeding well and gaining weight. The incidence of spontaneous closure decreases as the infant becomes older. **Quality and Safety: If the newborn exhibits signs of increased pulmonary blood flow, such as respiratory distress or inability to feed, closure of the PDA is indicated.** Closure by medications is not effective in term infants; so, a clinically symptomatic PDA requires transcatheter closure with a coil or device in the cardiac catheterization laboratory. Surgical ligation through a posterolateral thoracotomy is the preferred method of closure in cases of large PDAs or if there are structural challenges due to anatomic variations. The mortality rate for surgical ligation is less than 1% (excluding preterm newborns). The prognosis is excellent, and complications are rare (Park, 2014; Webb et al., 2012).

Patent Ductus Arteriosus in the Preterm Newborn

PDA is a common complicating factor in the care of preterm newborns. As the newborn recovers from respiratory distress, pulmonary vascular resistance decreases as oxygenation improves. The ductus arteriosus in the preterm newborn is not as responsive (compared to term newborns) to increased oxygen content and will remain patent. Decreased pulmonary vascular resistance causes blood to shunt from left to right, resulting in increased pulmonary blood flow and pulmonary venous congestion, which decreases lung compliance. Consequences of large PDA shunts include CHF symptoms, inability to wean ventilatory support, and/or increased oxygen requirement.

Clinical findings indicative of PDA include bounding peripheral pulses, hyperdynamic precordium, widened pulse pressures (>25 mmHg), and a continuous murmur, best heard at the upper left and middle sternal borders. Chest radiograph findings include increased pulmonary vascularity and pulmonary edema along with cardiomegaly. An echocardiogram provides diagnostic imaging for

a PDA including size, directionality, LA/Ao ratio, presence of LA and LV dilation, arch sidedness, diastolic flow reversal in the descending aorta, ventricular function, and pulmonary hypertension (Park, 2014; Webb et al., 2012).

Management of PDA depends on the severity of the symptoms. In asymptomatic or mildly symptomatic newborns, conservative management may be elected to allow for spontaneous closure, since one third of extremely low birthweight (ELBW) neonates undergo spontaneous PDA closure. Conservative management consists of fluid restriction, diuretic therapy, and careful monitoring (Koch et al., 2006; Park, 2014).

In symptomatic and/or ventilator-dependent preterm newborns, closure of the DA may improve oxygenation and has been associated with decreased complications of prematurity (Koch et al., 2006). Two medications can be used to promote ductal closure. Indomethacin is a prostaglandin synthetase inhibitor. PGE_2 is produced in the walls of the DA to prevent closure during fetal life. Indomethacin inhibits the production of PGE_2 and promotes ductal closure. Smaller babies may require a higher dose to obtain effective plasma levels. Indomethacin is highly nephrotoxic; so, the blood urea nitrogen (BUN) and creatinine (Cr) levels must be followed to monitor renal function. Contraindications to using indomethacin include renal failure, low platelet count, bleeding disorders, necrotizing enterocolitis (NEC), and hyperbilirubinemia (Park, 2014; Webb et al., 2012). Ibuprofen is an alternative to indomethacin for closure of the DA in preterm infants. Both medications are equally effective in closure of PDA and have similar adverse effects on renal function (Kushnir & Pinheiro, 2011; Sekar & Corff, 2008). Surgical ligation is reserved for cases where indomethacin or ibuprofen fails or is contraindicated. Mortality from surgical ligation is highest in the more preterm, sicker infants, especially if pulmonary hypertension has developed (Park, 2014; Webb et al., 2012). Associated complications of short- and long-term outcomes of ligation, such as ND outcomes, must be considered in the selection of PDA management.

Ventricular Septal Defect

A VSD is a defect or opening in the ventricular septum caused by inadequate septal formation during early fetal development. There are several types of VSDs that involve the membranous or muscular part of the ventricular septum. The location, size of the defect, and the degree of shunting are important in determining the hemodynamic impact and need for intervention. With a small defect, there is a large resistance to the left-to-right shunt at the defect, and the shunt does not depend on the pulmonary vascular resistance. With a large VSD, there is little resistance at the defect and the amount of left-to-right shunt depends on the level of pulmonary vascular resistance (Park, 2014; Turner, Hunter, & Wyllie, 1999; Webb et al., 2012).

Incidence. VSD is the most common CHD in children. It accounts for approximately 20% to 25% of all CHDs.

Hemodynamics. The hemodynamic consequences of a VSD depend on its size: small, moderate, or large.

Small VSD. Small VSDs produce minimal shunting and may not be symptomatic. Chest radiograph and ECG are generally normal. A loud high-frequency holosystolic heart murmur may be best heard in the third and fourth left intercostal spaces at the sternal border (Park, 2014; Turner et al., 1999; Webb et al., 2012). Figure 7.5 shows a VSD.

Moderate VSD. With moderate-sized VSDs, the blood is shunted from the LV to RV because of higher pressure in the LV and higher systemic vascular resistance. The shunt of blood occurs during systole, when the RV contracts, such that the blood enters the pulmonary artery rather than remaining in the RV.

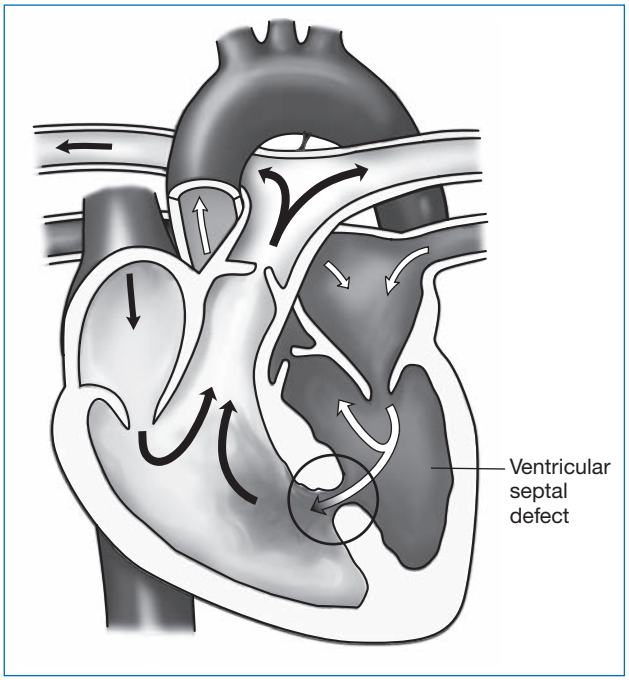

FIGURE 7.5 Ventricular septal defect is a communication between the right and left ventricles.

Source: Adapted and modified from Ross Laboratories, Columbus, OH, Clinical Education Aid, 1985.

Large VSD. With large VSDs, blood is shunted from the LV to RV. The volume of blood shunted is related to the size of the VSD and the pulmonary vascular resistance. The larger the VSD, the greater the volume of blood shunted, and the higher the pressure in the RV and pulmonary artery. If pulmonary artery pressure is significantly increased, thickening of the walls of the pulmonary arterioles may develop, and the increased resistance may decrease the left-to-right shunt. If left untreated, over long periods of time, pulmonary vascular disease can develop and lead to Eisenmenger syndrome with fixed right-to-left shunting resulting in significant cyanosis.

Manifestations. Manifestations of VSD depend on the degree of shunting. Small VSDs may produce no hemodynamic compromise and no clinical symptoms, but will typically be detected by a cardiac murmur on examination. Larger defects are associated with inadequate feeding, poor growth, symptoms of CHF, and can also be associated with recurrent pulmonary infections.

Diagnosis. VSDs typically will have a 2/6 to 4/6 holosystolic murmur best heard at the left sternal border (LSB). There may also be an apical diastolic rumble and the pulmonary heart sound may be loud.

Chest radiograph can help detect moderate to large VSDs (Danford, Gumbiner, Martin, & Fletcher, 2000), demonstrating cardiomegaly as a result of LA and LV dilation and increased pulmonary vascularity and edema. ECG may reveal LV hypertrophy. RV hypertrophy may also be present in severe cases. An echocardiogram will provide information about the location and size of the VSD, directionality of the flow, and presence of LA and LV dilation along with presence of additional VSDs.

Management. Treatment of the VSD depends upon the size of the defect and the resultant cardiovascular symptoms. Spontaneous closure of the VSD can occur; so, infants with hemodynamically insignificant defects may be followed clinically to allow time

for spontaneous closure to occur. Small VSDs generally close spontaneously over the first few years of life. Muscular VSDs have a higher spontaneous closure rate than perimembranous VSDs (29% vs. 69%; Turner et al., 1999).

Quality and Safety: Initial management of the hemodynamically significant VSD includes monitoring for signs of CHF and prompt initiation of therapy. CHF in the older infant is treated with diuretics, angiotensin converting enzyme (ACE) inhibitors, and/or digitalis.

Surgical management involves primary suture or patch closure of the VSD. Cardiopulmonary bypass is required for surgical correction. The timing of the surgery depends on the location and size of the VSD. Large VSDs typically result in a significant left-to-right shunt with left atrial and ventricular dilation and CHF symptoms of poor feeding and inadequate weight gain. **Emergency Alert: If CHF symptoms cannot be medically managed, then this is an indication for surgical repair** (Park, 2014).

The aggregate surgical mortality rate for VSD correction is less than 0.6%. The mortality rate is higher among small infants less than 2 months of age and those with other defects or multiple VSDs (Jacobs et al., 2018; Park, 2014).

Atrial Septal Defect

An ASD is a defect or opening in the atrial septum that develops as a result of inadequate septal formation early in fetal cardiac development.

There are three types of ASDs (Park, 2014; Webb et al., 2012):

1. Ostium secundum ASD
2. Ostium primum ASD, associated with AVC
3. Sinus venosus ASD, typically associated with partial anomalous pulmonary venous connection

Incidence. ASDs account for 5% to 10% of all CHDs.

Hemodynamics. An ASD usually does not produce symptoms until pulmonary vascular resistance begins to decrease and RV end-diastolic and RA pressures decline. All types of ASDs produce some blood flow alterations. With an ASD, blood shunts from left to right across the defect because the RV offers less resistance to filling, due to it being more compliant than the LV. Any factors that decrease RV distensibility or obstruct flow into the RV (e.g., PS or tricuspid stenosis) can reduce or reverse the shunt direction (Massin, Derkenne, & von Bernuth, 1998). The left-to-right shunt increases RV volume, but pulmonary vascular resistance decreases, so pulmonary artery pressure is almost normal. Over long periods of times, typically years, the increased pulmonary blood flow due to a large ASD gradually leads to increased pulmonary artery pressures and CHF in adults (Park, 2014). Figure 7.6 illustrates an ASD.

Manifestations. Newborns with ASDs are usually asymptomatic. In infants and children, a grade 2/6 to 3/6 SEM can best be heard at the upper left sternal border with a fixed, widely split S_2. With a large secundum ASD, there may be a middiastolic rumble caused by the relative tricuspid stenosis audible at the LLSB (Park, 2014; Webb et al., 2012). On chest radiograph, the heart is enlarged with a prominent main pulmonary artery segment and increased pulmonary vascularity. ECG enhances detection of ASD, showing RA deviation, RV hypertrophy, and there may be incomplete right bundle branch block (Danford et al., 2000; Park, 2014).

Diagnosis can be made by echocardiogram, which demonstrates the ASD type, size, and associated RA and RV dilation as a result of a hemodynamically significant left-to-right shunt in moderate to large secundum ASDs.

Management. Untreated ASDs can lead to CHF, pulmonary hypertension, and atrial dysrhythmias in adults. Spontaneous closure of ASDs occurs in the first 5 years of age in up to 40% of children (Park, 2014). ASDs typically are asymptomatic. Large ASDs may result in right-sided dilation, and rarely CHF. Secundum ASDs that are hemodynamically significant with right-sided dilation may be closed using transcatheter device closure in the cardiac catheterization laboratory. This approach is less invasive since it involves access via femoral vein/arteries, does not require cardiopulmonary bypass, and the patient typically can be discharged the next day.

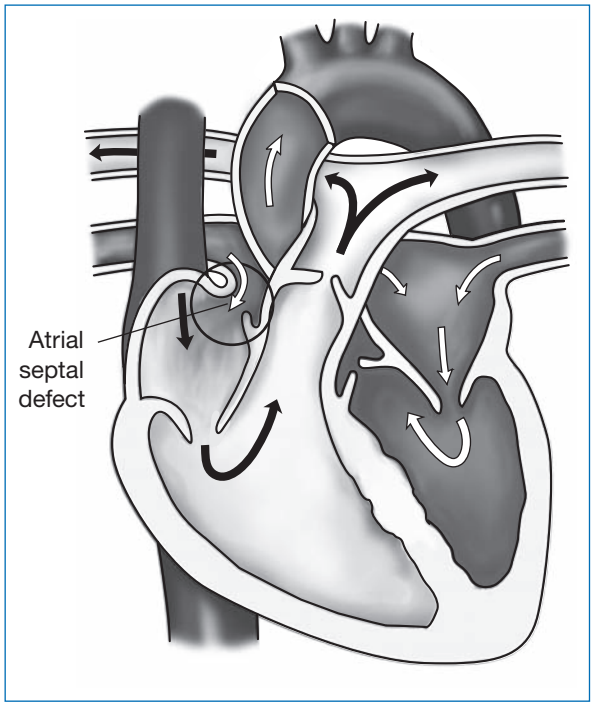

FIGURE 7.6 Atrial septal defect is a communication between the right and left atria.

Source: Adapted and modified from Ross Laboratories, Columbus, OH, Clinical Education Aid, 1985.

Surgical correction is reserved for infants for whom the transcatheter approach is unsuccessful due to the size of the ASD or inadequate septum attachments for the device, for primum ASDs, and sinus venosus ASDs. Surgical correction is accomplished by a simple patch or with direct closure during open-heart surgery using cardiopulmonary bypass. Timing of surgery varies depending on the ASD type, size, and presence of a significant left-to-right shunt with RA and RV dilation. The surgical mortality rate is less than 0.5% with a higher risk for mortality in small infants with CHF or increased pulmonary vascular resistance (Park, 2014; Webb et al., 2012).

Atrioventricular Canal Defects/Endocardial Cushion Defects

ECDs result from inadequate fusion of the endocardial cushions during fetal development, resulting in a common AV valve with an ASD (ostium primum) and inlet VSD. There are three types of AVC: a complete AV canal with a primum ASD and inlet VSD, a transitional AVC with a primum ASD and a restrictive inlet VSD, and an incomplete AV canal with only a primum ASD. The type of AVC is important in the presentation of clinical symptoms and timing of surgery (Park, 2014).

Incidence. AVCs account for 2% of all CHDs. AVCs are common in infants with Down syndrome (Park, 2014).

Hemodynamics. The hemodynamic consequences of AVCs depend on the type of defect. There may be interatrial and interventricular

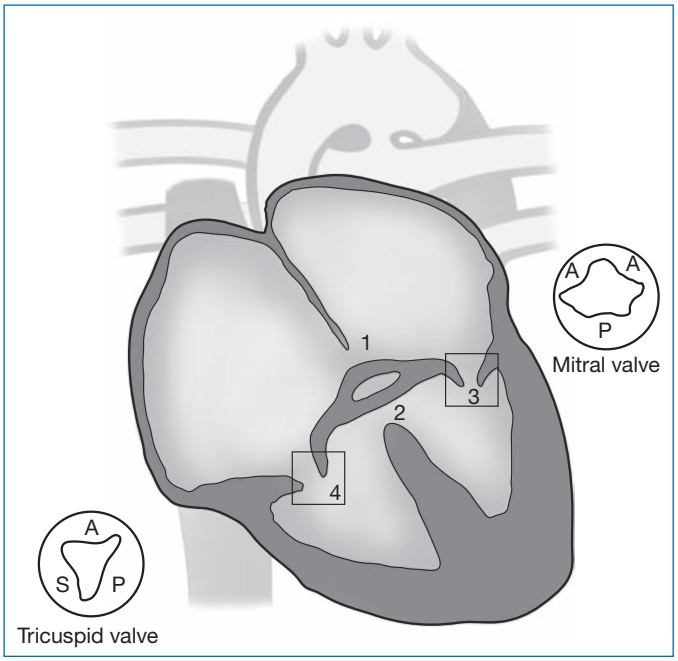

FIGURE 7.7 Endocardial cushion defect. (1) Ostium primum atrial septal defect; (2) a ventricular septal defect in the inlet portion of ventricular septum; (3) cleft in anterior mitral valve leaflet; (4) cleft in septal leaflet of the tricuspid valve, resulting in common anterior and posterior cusps of the atrioventricular valve.

A, anterior; P, posterior; S, septal.

shunts, LV to RA shunts, or AV valve regurgitation. Figure 7.7 shows an ECD.

Manifestations. The manifestations of AVCs result from the increased pulmonary blood flow from left-to-right flow from the VSD and regurgitation of the common AV valves if present. **Emergency Alert: The newborn may have respiratory distress, signs of CHF, tachycardia, and a cardiac murmur. The mitral regurgitation may be heard as a grade 3/6 holosystolic regurgitant murmur audible at the LLSB and may be audible at the apex.** There is also a middiastolic rumble at the LLSB or at the apex caused by the relative stenosis of tricuspid and mitral valves (Freedom, Yoo, & Coles, 2007; Park, 2014).

Chest radiograph reveals generalized cardiomegaly with increased pulmonary vascularity and a prominent main pulmonary artery segment. ECG shows left axis deviation with a prolonged P-R interval, right and left atrial enlargement, right ventricular hypertrophy, and incomplete right bundle branch block. An infant with an AVC may demonstrate signs of CHF with failure to thrive due to poor feeding, inadequate weight gain, and recurrent respiratory infections. Physical examination of an untreated infant with AVC reveals a poorly nourished infant with signs of respiratory distress and tachycardia (Freedom et al., 2007; McElhinney, Paridon, & Spray, 2000; Park, 2014).

Management. Initial medical management is aimed at preventing or treating CHF with diuretics, ACE inhibitor, and/or digitalis. Definitive management consists of surgical closure of the ASD and VSD, with reconstruction of AV valves under cardiopulmonary bypass, or in rare cases, pulmonary artery banding may be performed as a temporizing palliative procedure as part of a two-staged surgical correction.

Surgery is indicated when there is CHF with failure to thrive that is unresponsive to medical therapy and/or a large shunt with development of pulmonary hypertension and increasing pulmonary vascular resistance. Timing of surgical repair depends on the type of defect. Complete AVCs undergo repair around 2 to 4 months of age, sometimes earlier if the CHF symptoms cannot be medically managed. Transitional AVCs typically undergo repair within the first year of life and incomplete AVCs between 1 to 2 years of age, sometimes even older if they are asymptomatic. The aggregate mortality rate is 2.7%. Factors that increase the risks of mortality for AVC repair include (1) very young age, (2) severe AV valve incompetence, (3) hypoplastic left ventricle, and (4) severe symptoms before surgery (Jacobs et al., 2018; Park, 2014).

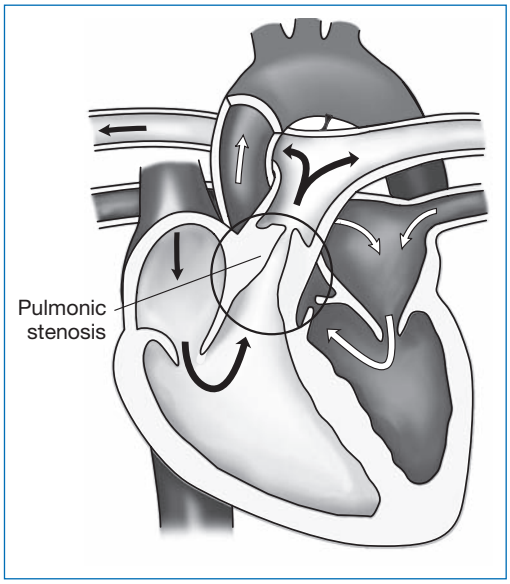

FIGURE 7.8 Pulmonary stenosis.

Cyanotic Defects

These CHDs are defects with obstruction to RV outflow that result in reduced pulmonary blood flow or abnormality in venous return. The defects described in this section include PS, TOF, pulmonary atresia with intact ventricular septum (PA/IVS), and total anomalous pulmonary venous return (TAPVR).

Pulmonary Stenosis

PS is caused by abnormal formation of the pulmonary valve leaflets during fetal cardiac development. PS can be valvular, subvalvular (infundibular), or supravalvular. Valvular PS is the most common, accounting for 90% of cases. PS is frequently seen in Noonan syndrome. It is one of the four defects found in TOF. Isolated infundibular PS is uncommon.

Incidence. PS makes up 5% to 8% of all CHDs. It is often associated with other defects.

Hemodynamics. PS results in obstruction to blood flow from the RV to the pulmonary artery, and there is a spectrum of disease from mild PS to critical PS (duct dependent). In cases of more severe obstruction, the RV hypertrophies in response to the increased pressure caused by the obstruction to outflow. Pulmonary blood flow volume is normal in the absence of intracardiac shunting. PS is shown in Figure 7.8.

Manifestations. PS may be asymptomatic if it is mild or moderate with normal oxygen saturations. Neonates with severe or critical PS may have saturations less than 95%.

Diagnosis. The findings of PS depend on the severity of the defect. A pulmonary systolic ejection click may be heard at the upper

left sternal border and S_2 may be widely split with the pulmonary component soft and delayed. A SEM (grade 2/6–4/6) is audible at the upper left sternal border and radiates to the back. The severity of the PS is directly related to the loudness and duration of the murmur. A systolic thrill can sometimes be felt at the upper left sternal border, which would result in a grade 4/6 SEM.

The ECG is normal in mild PS. There may be right axis deviation and RV hypertrophy with moderate stenosis and right atrial enlargement and RV hypertrophy with strain with severe PS.

Chest radiograph demonstrates normal heart size with a prominent main pulmonary artery segment. In mild to moderate PS, pulmonary markings are normal. The critical type of PS causes decreased pulmonary markings. Echocardiogram evaluation involves determining level of obstruction (subvalvular, valvular and supravalvular), valve morphology, PDA patency, and associated defects. Decreased motion of the pulmonary valve leaflets and poststenotic dilation of the main pulmonary artery segment may be present (Danford, Salaymeb, Martin, Fletcher, & Gumbiner, 1999; Park, 2014).

Management. Management of PS is determined by the severity of the obstruction to flow. The mild type generally requires no therapy unless there is worsening of the PS. Moderate to severe PS is treated through balloon valvuloplasty during cardiac catheterization. Surgical correction is performed in children with critical PS when balloon valvuloplasty is not successful in relieving the gradient, or when the pulmonary valve fails to grow after balloon valvuloplasty. Infants with critical PS require PGE_1 infusion to maintain ductal patency until surgery is performed (Park, 2014).

The overall prognosis for PS is excellent. The mortality rate is less than 1% in older infants. The mortality rate is higher in newborns with critical PS and CHF (Park, 2014).

Tetralogy of Fallot

Edward Fallot, a French physician, first described TOF in 1888. During fetal development, TOF is a result of anterior deviation of the conal septum (wall between the aortic and pulmonary valves), which causes subpulmonary/pulmonary outflow obstruction and a large anterior malalignment VSD. TOF is comprised of four defects: VSD, pulmonary valve stenoisis, overriding aorta, and RV hypertrophy. There is a spectrum of TOF from mild PS with no cyanosis (pink TOF) to PA that is duct dependent.

Incidence. TOF accounts for 10% of all CHDs. TOF is the most common cyanotic heart defect beyond infancy.

Hemodynamics. In TOF, the large VSD causes equalization of pressure in the ventricles. Unsaturated blood flows through the VSD into the aorta because of the obstruction to blood flow from the RV into the pulmonary artery. TOF is illustrated in Figure 7.9.

Manifestations. Newborns may be asymptomatic or may present with a loud murmur and/or cyanosis. Severe decompensation or "tet" spells may occur in infants or children, but these can also occur in neonates. Children instinctively assume a squatting position, which traps venous blood in the legs, decreases systemic venous return to the heart, and increases systemic vascular resistance to increase left-to-right flow (Park, 2014).

Diagnosis. Neonates with TOF exhibit varying degrees of cyanosis, depending on the severity of the obstruction of blood flow through the RVOT. A long, loud, grade 3/6 to 4/6 SEM is heard at the upper left sternal border. A PDA murmur may also be heard in TOF with critical PS or PA (Park, 2014).

Chest radiograph demonstrates decreased or normal heart size with decreased pulmonary vascularity. The contour of the heart may be boot-shaped due to the concave main pulmonary artery segment with upturned apex. There may also be RA enlargement and some patients may have a right aortic arch.

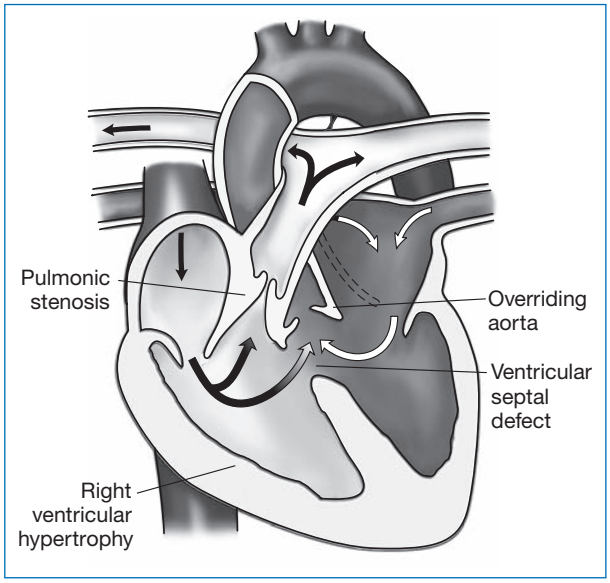

FIGURE 7.9 Tetralogy of Fallot consists of pulmonary stenosis, ventricular septal defect, overriding aorta, and hypertrophy of the right ventricle.
Source: Adapted and modified from Ross Laboratories, Columbus, OH, Clinical Education Aid, 1985.

Echocardiogram demonstrates a large anterior malalignment VSD with overriding aorta, degree of PS and level of RVOT obstruction, coronary artery pattern, and presence of additional VSDs or right aortic arch.

Management. The definitive therapy for TOF is surgical repair under cardiopulmonary bypass. The surgical correction can sometimes be delayed with careful medical management. **Quality and Safety: Careful follow-up is essential to detect signs of clinical deterioration and worsening cyanosis.** Parents need adequate education and support for home management (Dipchand, Giuffre, & Freedom, 1999; Park, 2014).

Parents must be taught how to recognize the early signs and symptoms of decompensation. They must also be taught to recognize and treat hypercyanotic or tet spells (Table 7.4). Tet spells are precipitated by events that lower the systemic vascular resistance, producing a large right-to-left ventricular shunt. Increased activity, crying, nursing, or defecation may trigger a hypoxemic episode. The right-to-left shunt causes a decreased Pao_2, increased $Paco_2$, and decreased pH, which stimulate the respiratory center, causing increased rate and depth of respirations (hyperpnea). The hyperpnea causes increased systemic venous return by increasing the efficiency of the thoracic pump. The RVOT obstruction prevents the increased blood flow from entering the pulmonary artery, so the increased flow is shunted through the VSD to the aorta, which further decreases the arterial Po_2. Severe, uninterrupted hypercyanotic spells lead to loss of consciousness, hypoxemia, seizures, and death.

Surgical treatment is indicated in the presence of hypercyanotic spells (tet spells) that result in increased hypoxemia, metabolic acidosis, inadequate systemic perfusion, and increased cyanosis. Systemic perfusion can be evaluated by observing peripheral pulse intensity, urine output, capillary filling time, blood pressure, or peripheral vasoconstriction.

Surgical management can be either palliative or corrective. Palliative procedures are undertaken to improve pulmonary blood flow by creating a pathway between the systemic and pulmonary circulations. In addition, these procedures allow time for the right

TABLE 7.4

RECOGNITION AND TREATMENT OF TET SPELLS

Manifestations	Treatment	Rationale
Irritability, crying, hyperpnea	Knee to chest or squatting position	Traps blood in lower extremities to decrease systemic venous return; increases pulmonary blood flow
Cyanosis	Oxygen administration	Improves arterial oxygen saturation
Diaphoresis, loss of consciousness	Morphine sulfate (0.1–0.2 mg/kg/dose)	Suppresses respiratory center to decrease hyperpnea
Seizures	Bicarbonate	Corrects acidosis and eliminates stimulation of respiratory center
Decreased murmur	Propranolol (Inderal; 0.15–0.25 mg/kg/dose)	May decrease spasm of right ventricular outflow tract or may act peripherally to stabilize

and left pulmonary arteries to grow. Palliative procedures are indicated for newborns with TOF with PA or critical PS (duct dependent) or children with a hypoplastic pulmonary artery, in whom early corrective surgery may be difficult (Park, 2014).

Surgical correction is performed under cardiopulmonary bypass, and the timing of surgery depends on the cardiac center. Some centers perform complete TOF repair in the neonatal period; some perform palliative surgery for TOF/PA or critical PS with a BT shunt and then complete repair after 6 months of age. The defect is repaired by patch closure of the VSD with widening of the RVOT with a transannular patch if the pulmonary valve is moderate to severely hypoplastic. Postoperative care of the newborn requires careful assessment and monitoring so that complications can be prevented or quickly identified and treated (Russo & Russo, 2005). Complications of cardiac surgery are listed in Tables 7.5 and 7.6. The mortality rate for TOF varies with the severity of the circulatory compromise caused by the defect. The aggregate mortality rate is now 1.1% for uncomplicated TOF. More severe cases have a higher mortality rate, exhibit residual pulmonary outflow tract obstruction, and may require further surgery (Jacobs et al., 2018; Park, 2014).

Pulmonary Atresia With Intact Ventricular Septum

PA/IVS results in the absence of communication between the RV and the pulmonary artery and is a duct-dependent lesion. Determining whether the RV is adequate based on the tricuspid valve annulus size and Z score is important to determine if the neonate will require a single ventricle palliation or two ventricle repair. In addition, evaluation for RV-dependent coronary circulation is important to determine the pathway of single ventricle palliation versus two ventricular repair. If the RV is inadequate and/or there are RV-dependent coronaries, then the patient will require single

TABLE 7.5

COMPLICATIONS OF CARDIAC SURGERY

Low Cardiac Output	*Low Cardiac Output*
Hypovolemia	Pulmonary hypertension
Hemorrhage	Inadequate ventilatory support
Diuresis	Ineffective pleural drainage
Inadequate fluid volume	Hypoventilation secondary to pain
Tamponade	***Renal Dysfunction or Failure***
Mediastinal bleeding	Poor systemic and renal perfusion
Inadequate mediastinal drainage	Intravascular hemolysis
Decreased cardiac contractility	Thromboembolus
Hypervolemia	Nephrotoxic drugs
Electrolyte imbalance	***Electrolyte Imbalance***

TABLE 7.6

COMPLICATIONS OF CARDIAC SURGERY: POSTOPERATIVE SYNDROMES

	Causes	Manifestations	Treatment
Postcoarctectomy syndrome	Results from changes in pressure and flow	Severe intermittent abdominal pain, fever, and leukocytosis; abdominal distention, melena, and ascites with gangrenous bowel; rebound systemic hypertension	Monitor blood pressure; prevent hypertension; delay postoperative feeding
Postpericardiotomy syndrome	Immunologic syndrome in response to blood in the pericardial sac	Fever, chest pain, pericardial and pleural effusions, hepatomegaly, leukocytosis, left shift, increased ESR, persistent ST and T wave changes on ECG; rare in children younger than 2 years of age	Rest, aspirin for pain, corticosteroids in severe cases, pericardiocentesis if tamponade develops, diuretics
Postperfusion syndrome	Cytomegalovirus	Onset 3–6 weeks after surgery; fever, splenomegaly, atypical lymphocytosis	Supportive care; self-limiting disease process
Hemolytic anemia syndrome	Trauma of RBCs or autoimmune action	Onset 1–2 weeks postoperatively; fever, jaundice, hepatomegaly, reticulocytosis	Iron supplementation or blood transfusions, correction of turbulent flow

ESR, erythrocyte sedimentation rate; RBC, red blood cell.

ventricle palliation pathway with a modified BT shunt in the neonatal period, bidirectional Glenn (BDG), and subsequent Fontan. If the RV is adequate and there are no RV-dependent coronaries, then a two ventricle approach with radiofrequency (RF) perforation of the pulmonary valve along with balloon dilation of the pulmonary valve in the cardiac catheterization laboratory can be undertaken. The presence of a PDA, ASD, or patent foramen ovale (PFO) to allow mixing of blood is crucial for survival (Hanley et al., 1993). PA/IVS is illustrated in Figure 7.10.

Incidence. PA accounts for less than 1% of all CHDs (Park, 2014).

Hemodynamics. PA/IVS manifests as a spectrum of TV and RV hypoplasia. The absence of a RVOT results in high RV end-diastolic pressure, causing tricuspid regurgitation (TR), increasing RA pressure, and causing systemic venous blood to shunt from the RA to the LA through the PFO or ASD. Mixed venous blood flows into the LV and aorta. This is a duct-dependent lesion and the PDA is the only source of pulmonary blood flow. Closure of the PDA causes severe cyanosis, hypoxemia, and acidosis.

Manifestations. PA/IVS results in cyanosis at birth secondary to right-to-left shunt at the atrial level. Tachypnea is present, but there is no obvious respiratory distress. S_2 is single, and TR may produce a harsh regurgitant holosystolic murmur along the lower right and left sternal borders (Park, 2014).

Chest radiograph demonstrates a normal or enlarged heart with a concave main pulmonary artery segment, similar to the appearance of tricuspid atresia. Pulmonary vascular markings are decreased and continue to decrease as the PDA closes.

ECG may reveal a normal QRS axis, left ventricular hypertrophy (type I), or, less frequently, RV hypertrophy (type II), and RA enlargement is seen in approximately 70% of cases (Park, 2014). Echocardiogram demonstrates presence of an atretic pulmonary valve, degree of hypoplasia of the right ventricular cavity and tricuspid valve, amount of tricuspid regurgitation, size of ASD, and possible RV coronary fistula.

Management. Immediate management of PA is administration of prostaglandin to maintain ductal patency. PGE_1 (Prostin) is given as a continuous intravenous infusion. The initial dose varies from 0.025 to 0.1 mcg/kg/minute. When the desired effect is achieved, the dose is incrementally decreased to a maintenance dose of 0.01 mcg/kg/minute. Careful attention to the site of the infusion is important.

Surgical correction versus cardiac catheterization is determined by the size of the tricuspid valve. If the RV is inadequate in size based on a TV annulus *Z* score and/or presence of RV-dependent coronaries, then the neonate will require palliative procedures beginning with a systemic pulmonary artery shunt using Gore-Tex graft tube between the brachiocephalic artery and the pulmonary artery (modified Blalock-Taussig [BT] shunt) in the neonatal period. The surgical mortality rate varies, depending on whether single ventricle palliation or two ventricle repair is required.

Total Anomalous Pulmonary Venous Return

TAPVR is a result of the pulmonary veins draining into the RA (rather than the LA). There are four types of TAPVR (Park, 2014), based on the path of pulmonary venous return: Supracardiac type is the most common and involves drainage of the pulmonary veins via a confluence to the left vertical vein, innominate vein, and right SVC into the RA. Infracardiac type involves pulmonary veins entering a confluence, descending vertical vein that enters the portal vein in the liver to return to the RA via IVC. Cardiac involves drainage to the coronary sinus. Infracardiac is the most common type to be obstructed and typically requires emergent surgery to relieve the obstruction and repair the anomalous pulmonary veins. Mixed type involves a combination of pulmonary venous drainage.

Incidence. TAPVR accounts for 1% of all CHDs. There is a 1:1 male to female ratio of occurrence.

Hemodynamics. TAPVR has an obligate right-to-left shunt at the atrial level to allow some of the oxygenated blood from the anomalous pulmonary venous return that mixes with deoxygenated blood to shunt into the LA to the LV, pumping blood into the aorta and to the systemic circulation.

Two clinical hemodynamic states exist with TAPVR. If pulmonary blood flow is not obstructed, pulmonary flow is greatly increased. The result is highly saturated blood in the RA and mild cyanosis. If there is obstruction to pulmonary blood flow, the volume of flow is decreased, cyanosis is severe, and there is associated pulmonary hypertension. Obstruction to pulmonary blood flow is a common occurrence when the TAPVR is infracardiac (Park, 2014).

Manifestations. The manifestations of TAPVR depend on the presence of pulmonary venous obstruction (PVO). TAPVR without PVO includes a history of mild cyanosis and tachypnea. TAPVR with PVO causes severe cyanosis, respiratory distress, and poor CO (Park, 2014).

Diagnosis. TAPVR without PVO produces a precordial bulge with hyperactive RV impulse. The PMI is at the xiphoid process or LLSB. S_2 is widely split and fixed; the pulmonic sound may be pronounced. A grade 2/6 to 3/6 SEM can be heard at the upper left sternal border, and there is always a middiastolic rumble at the LLSB. The rhythm is a quadruple or quintuple gallop (Park, 2014).

TAPVR with PVO may produce minimal cardiac findings. S_2 is loud and single, and there is a gallop rhythm. There may be a faint SEM at the upper left sternal border. Pulmonary rales may be audible.

Chest radiographic findings of TAPVR without PVO include mild to moderate cardiomegaly and increased pulmonary markings. The characteristic "snowman" sign occurs because of the anatomic appearance of the left SVC, the left innominate vein, and the right SVC. This sign is seldom visible before the patient is 4 months of age. With TAPVR with PVO, the heart size is normal on chest radiograph, and there are signs of pulmonary edema (Park, 2014).

On ECG, TAPVR without PVO has right axis deviation of the QRS axis and sometimes RA enlargement. TAPVR with PVO has right axis deviation for age and RV hypertrophy in the form of tall R waves in the right precordial leads.

Echocardiography of TAPVR demonstrates right-to-left flow across the atrial septum, RA and RV dilation, pulmonary veins draining to a confluence returning to the heart via a vertical vein to the SVC or innominate vein in the supracardiac type, or descending vein to the portal system in infracardiac type. Infracardiac type is the most common to present with obstruction secondary to obstruction of flow that occurs when the descending vein enters the portal system to return to the RA via the DV and IVC. Supracardiac type can also present with obstruction, particularly when blood flow increases to the lungs as the pulmonary vascular resistance decreases. The vertical vein typically passes between the left bronchus and left pulmonary artery and can become compressed by these two structures (Brown & Geva, 2016).

Management. Management of TAPVR is surgical, and surgery is emergent when PVO is infracardiac. Medical management is aimed at preventing or treating CHF and preventing hypoxemia until surgical correction. Diuretics may be required to manage pulmonary edema. Balloon atrial septostomy at cardiac catheterization is performed to enlarge the interatrial communication and promote better mixing of blood. Surgery may be delayed when response to medical management is good, but it is usually performed when the patients are neonates (Park, 2014). The surgical procedure depends on the site of the anomalous drainage. Cardiopulmonary bypass is required. Surgery involves the anastomosis of the pulmonary veins to the LA, closure of the ASD, and division of the anomalous connection. The surgical mortality rate is between 5% and 10% for infants with the unobstructed type. This rate can be as high as 20% for infants with the infracardiac type (Park, 2014).

DEFECTS WITH LV OUTFLOW OBSTRUCTION

These are CHDs resulting from a defect with obstruction to LV outflow, causing reduced or inadequate systemic blood flow. The defects described in this section include aortic stenosis (AS), COA, and HLHS.

Aortic Stenosis

AS is one of a group of defects that produces obstruction to ventricular outflow. AS may be valvular, subvalvular, or supravalvular. Valvular stenosis is the most common, and supravalvular is the least common (Park, 2014).

In valvular stenosis, there is usually a bicuspid valve. Subvalvular stenosis can involve either a subaortic membrane or a long tunnel-like ventricular outflow tract. Idiopathic hypertrophic

subaortic stenosis is a form of subvalvular stenosis that presents as a cardiomyopathy. Supravalvular stenosis is associated with Williams syndrome, or elfin facies, characterized by mental retardation, short palpebral fissures, and thick lips (Park, 2014).

Incidence. AS accounts for 5% of all CHDs. It is four times more common in males.

Hemodynamics. AS causes increased pressure load on the LV, leading to LV hypertrophy. The resistance to blood flow through the stenosis gradually causes a pressure gradient between the ventricle and the aorta, and coronary blood flow decreases. AS is illustrated in Figure 7.11.

Manifestations. Symptoms depend on the severity of the defect. Mild AS is typically asymptomatic; with more severe defects, there is activity intolerance, chest pain, presyncope, or syncope. With severe defects, CHF develops.

Diagnosis. Physical examination reveals normal development without cyanosis. There may be a narrow pulse pressure and a higher systolic pressure in the right arm with severe supravalvular AS. There is a systolic murmur of approximately grade 2/6 to 4/6, best heard at the second right or left intercostal space with transmission to the neck. With valvular AS, there may be an ejection click. With severe AS, there may be paradoxical splitting of S_2. Aortic insufficiency may cause a high-pitched, early diastolic, decrescendo murmur if there is bicuspid aortic valve or subvalvular stenosis (Park, 2014).

Chest radiographs may be normal or may show a dilated ascending aorta, or, in the case of valvular stenosis, a prominent aortic "knob" caused by poststenotic dilation (Park, 2014). Cardiomegaly is present if there is CHF or severe aortic regurgitation. ECG may be normal or may show mild left ventricular hypertrophy and inverted T waves. Echocardiogram may demonstrate a bicuspid aortic valve, dysplastic thickened aortic valve, or in rare cases a unicuspid aortic valve, degree of AS, presence of aortic insufficiency (AI), LVH, and subvalvular and supravalvular AS. Cardiac catheterization may be performed to identify the exact anatomy and to analyze pressure gradients.

Management. Management is aimed at preventing or treating the CHF with fluid restriction, diuretics, and/or digitalis. In children with moderate to severe AS, activity is restricted to prevent increased demand on the heart. Balloon valvuloplasty is sometimes performed at the time of cardiac catheterization to improve circulation. In newborns with critical AS, maintenance of the patency of the DA with PGE_1 at a dose of 0.01 to 0.1 mcg/kg/minute is required to prevent inadequate CO with poor perfusion and metabolic acidosis.

The type of surgical correction depends on the exact location and severity of the defect. The procedure may consist of aortic valve commissurotomy or valve replacement with a prosthetic valve or a graft. The placement of prosthetic valves is usually deferred until adult-sized prosthetic valves can be inserted. The timing of the surgery depends on the severity of the defect. Infants with severe AS without AI will require balloon valvuloplasty and potentially surgery if the gradient does not improve or there is severe AI. Surgery is typically performed on children when there is a peak systolic pressure gradient greater than 50 to 60 mmHg (Park, 2014).

The surgical mortality risk varies depending on the timing and surgical approach required. Surgical mortality for neonates with critical AS is 10% (Park, 2014).

Coarctation of the Aorta

COA is a narrowing or constriction in the aortic arch. The most common location is in the isthmus region located distal to the left subclavian artery. It may be a discrete coarctation or long-segment coarctation associated with aortic arch hypoplasia. COA may occur as a single lesion due to improper development of the aorta, or in rare instances may occur after constriction of the DA. The severity of the circulatory compromise depends on the location and degree of constriction. A large number of infants with COA, more than 75%, have a bicuspid aortic valve (Park, 2014). Coarctation is illustrated in Figure 7.12.

Incidence. COA accounts for 8% of all CHDs. Coarctation occurs twice as often in males. COA is found in 30% of infants with Turner syndrome (Park, 2014).

Hemodynamics. COA causes obstruction to flow that leads to varying pressure across the aortic arch, with the portion of aorta proximal to the constriction with an elevated pressure,

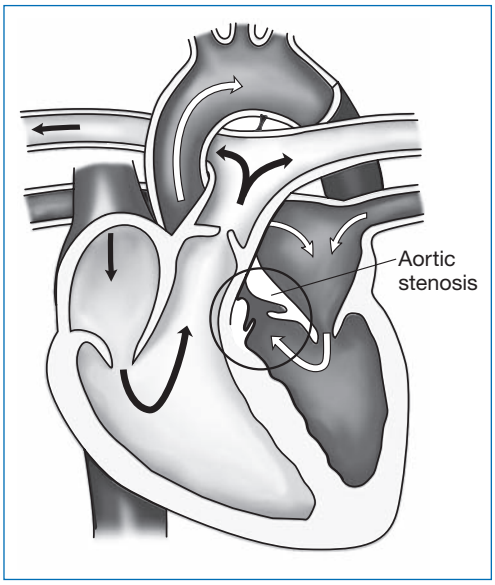

FIGURE 7.11 Aortic stenosis is a narrowing or thickening of the aortic valvular region.

Source: Adapted and modified from Ross Laboratories, Columbus, OH, Clinical Education Aid, 1985.

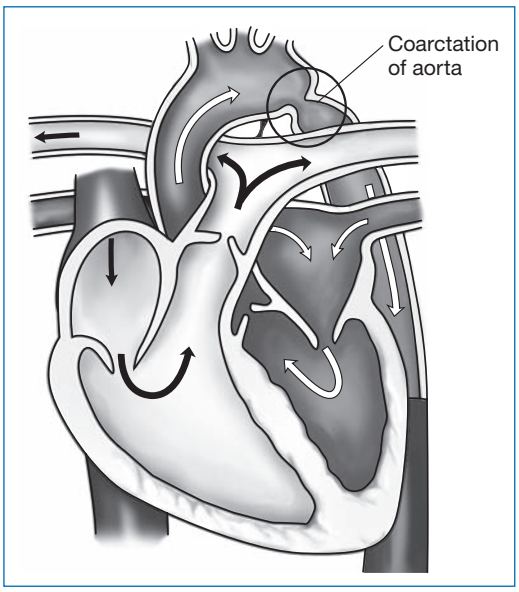

FIGURE 7.12 Coarctation of the aorta is a narrowing or constriction of the aorta near the ductus arteriosus.

Source: Adapted and modified from Ross Laboratories, Columbus, OH, Clinical Education Aid, 1985.

resulting in increased LV pressure. In newborns, right ventricular hypertrophy is a predominant finding since the RV is the main pumping chamber in utero. In cases of delayed diagnosis, the increased LV pressure results in LV hypertrophy and dilation; over time, collateral circulation develops from the proximal to distal arteries, bypassing the constricted segment of the aorta. This is a compensatory mechanism to increase flow to the lower extremities and abdomen resulting in decreased pulses in the lower extremities. COA is shown in Figure 7.11. Children with delayed diagnosis of coarctation will present with elevated systolic blood pressures in the right arm and decreased femoral pulses (Park, 2014).

Manifestations. The severity and time of appearance of symptoms of COA depend on the degree of constriction and associated aortic arch hypoplasia, as well as the presence of associated cardiac defects. COA and/or arch hypoplasia may be missed prenatally (Anuwutnavin et al., 2016). Those neonates with a murmur or who fail pulse oximetry screening for CHD will be diagnosed before becoming symptomatic. Some neonates may go undetected by CCHD pulse oximetry screening, only being diagnosed with coarctation after developing symptoms as the DA closes. In these cases, symptoms of coarctation include CHF with tachypnea, diaphoresis, poor feeding, and weak or delayed pulses in the lower extremities with bounding pulses in the upper extremities. In the presence of CHF, however, all pulses may be weak. With severe COA, S_2 is loud and single, a systolic thrill may be felt in the suprasternal notch, and a SEM of grade 2/6 to 3/6 can be heard at the upper right, middle, or lower left sternal border, and at the left interscapular area on the infant's back; however, no murmur is heard in more than half of infants with COA (Park, 2014).

Diagnosis. Diagnosis of COA is based on history, physical findings, chest radiograph, ECG, and definitive diagnosis by echocardiogram. In asymptomatic infants and children, chest radiographs may show a normal or slightly enlarged heart. In symptomatic infants and children, chest radiographs show cardiomegaly and increased pulmonary venous congestion.

The ECG in asymptomatic children may show left axis deviation of the QRS and LV hypertrophy. In symptomatic children, the ECG reveals normal or right axis deviation of the QRS. RV hypertrophy is present in infants since the RV is the main pumping chamber in utero, whereas LV hypertrophy is present in older children (Park, 2014). Echocardiogram demonstrates the location and degree of the coarctation, presence of aortic arch hypoplasia, and associated defects such as VSD, bicuspid aortic valve, and LV dysfunction.

Management. In neonates prenatally diagnosed with coarctation, a postnatal echocardiogram is performed to assess the severity of coarctation and presence and severity of arch hypoplasia. In some cases, findings from the postnatal echocardiogram will determine postnatal management, with close monitoring for detection of definitive coarctation after the ductus closes versus initiation of PGE_1 to maintain ductal patency until surgical repair. Oxygen saturations in the right hand and right or left foot should be monitored for a significant difference, with saturations in the right or left foot being lower than that in the right hand. The surgical approach depends on the extent of arch obstruction. If there is a discrete coarctation, then surgical repair can be performed via a left thoracotomy. If there is significant arch hypoplasia with coarctation, then a surgical approach via a median sternotomy will be required to augment the arch (Marino, Ostrow, & Cohen, 2006).

The mortality rate for surgical corrections is less than 5% (Park, 2014).

Hypoplastic Left Heart Syndrome

HLHS consists of a group of cardiac defects, including a hypoplastic aortic valve and mitral valve with stenosis or atresia, and a small LA and LV. The great vessels are normally related. There are four different subtypes (mitral atresia with AA, mitral stenosis with AS, mitral atresia with AS, and mitral stenosis with AA). HLHS is illustrated in Figure 7.13.

Incidence. HLHS accounts for 1% to 2% of all CHDs, but it accounts for 7% to 8% of heart defects, producing symptoms in the first year of life; it is the leading cause of death from CHDs in the first month of life (Gilboa et al., 2010).

Hemodynamics. HLHS is a duct-dependent lesion requiring prostaglandin to maintain ductal patency in order to provide systemic blood flow. Since the LV is inadequate or absent, LV output is greatly reduced or absent. Retrograde flow through the aortic arch supplies the head, upper extremities, and coronary arteries. Left atrial and pulmonary venous pressures are elevated, and may result in pulmonary edema.

Although circulation is abnormal in utero, the high pulmonary vascular resistance and the low systemic vascular resistance make survival possible. The RV maintains normal perfusion pressure in the descending aorta by a right-to-left ductal shunt. At birth, the onset of pulmonary ventilation causes decreased pulmonary vascular resistance. The systemic vascular resistance increases because the placenta is eliminated. In cases where HLHS is not prenatally detected, closure of the DA results in decrease in systemic perfusion leading to metabolic acidosis and circulatory shock (Park, 2014).

Manifestations. Neonates with HLHS may be asymptomatic and have near-normal saturations if there is an adequate atrial communication and mixing of blue and pink blood. Importantly, these neonates may not be detected by CCHD pulse oximetry screening typically performed at 24 hours of age since the ducts may be patent. As the ductus closes, circulatory shock develops resulting in metabolic acidosis with signs and symptoms of progressive cyanosis, tachypnea, tachycardia, and poor peripheral pulses. Typically, the S_2 is single and a cardiac murmur may be

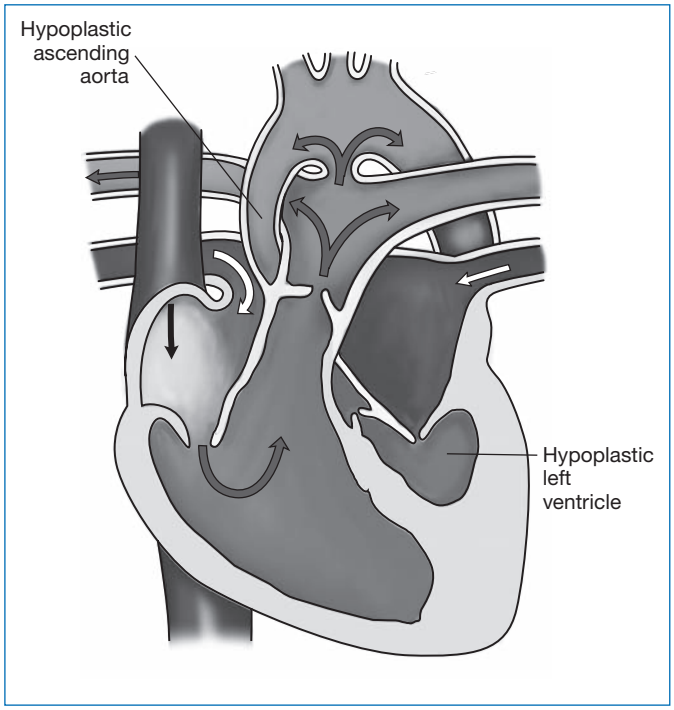

FIGURE 7.13 Hypoplastic left heart syndrome.

absent in neonates with mitral and aortic atresia. In neonates with mitral stenosis and AS, there may be a grade 2/6 to 3/6 systolic murmur (Park, 2014).

Diagnosis. Chest radiograph of HLHS demonstrates mild to moderate heart enlargement and pulmonary venous congestion or pulmonary edema. RV hypertrophy is the characteristic finding on ECG. Echocardiography is diagnostic demonstrating hypoplastic or even absent left-sided heart structures. There may be mitral or aortic stenosis or mitral or aortic atresia associated with a hypoplastic LA, LV, and ascending aorta/aortic arch, RV dilation, and hypertrophy. Size of the ASD and presence of tricuspid regurgitation should also be documented.

Management. Medical management of HLHS is aimed at maintaining ductal patency through continuous infusion of PGE_1 to prevent significant hypoxemia and metabolic acidosis. In rare cases of a restrictive atrial septum, balloon atrial septostomy and/or stenting of the atrial septum may be required if there is an inadequate atrial communication.

Surgical palliation of HLHS is complex and has a high mortality rate; however, over 30 years ago, HLHS was once considered 100% fatal. The goal of surgical palliation is to separate the deoxygenated and oxygenated blood in three stages. The first-stage procedure, the modified Norwood procedure, is typically performed in the first week of life. The Stage I/Norwood procedure involves building a neoaorta utilizing the main pulmonary artery and a BT shunt (Gore-Tex graft tube) or a Sano (RV-PA conduit tube) to provide stable pulmonary blood flow with an atrial septectomy to create adequate atrial communication. Infants with a Stage I/Norwood typically have oxygen saturations of 75% to 80%. The second-stage procedure, the BDG, is typically performed at 4 to 6 months of age. The BDG involves dividing the SVC and anastomosing it to the RPA along with ligating the BT shunt. Infants with BDG have saturations of 80% to 85%. The third-stage procedure, a modified Fontan procedure, is typically performed at 2 years of age. The modified Fontan procedure involves dividing and anastomosing the IVC to the RPA. Children with a Fontan have normal oxygen saturations unless they have a fenestrated Fontan. In some patients who are higher risk for a Fontan or in some centers, the Fontan is fenestrated and these patients will have lower saturations until the fenestration spontaneously closes or is closed later via transcatheter device closure (Goff et al., 2000; Marino et al., 2006).

See Table 7.7 for a description of these procedures (Park, 2014).

The aggregate surgical mortality rate for the Stage I/Norwood palliation procedure, which includes HLHS, is 15.8%. If patients survive up to the BDG/hemi-Fontan and Fontan procedure, the aggregate surgical mortality rate decreases to 2.1% and 1.1%, respectively (Jacobs et al., 2018).

Nursing care focuses on assessment of CO, systemic perfusion, and adequate pulmonary blood flow during the immediate postoperative period. Postoperative care requires close monitoring of vital signs, chest tube output, urine output, laboratory values (hemoglobin, platelets, BUN/Cr, AST/ALT), and pulmonary and circulatory status. Attention to nutritional status is important for long-term recovery.

Dopamine at 5 mcg/kg/minute may be needed to augment CO along with milrinone 0.5 to 1 mcg/kg/minute. Diuretics and/or peritoneal dialysis may be necessary to maintain fluid balance. Fentanyl and Versed drips may be used for sedation and analgesia. In many institutions, Stage I/Norwood patients return to the cardiac intensive care unit (CICU) on extracorporeal membrane oxygenation (ECMO) to maintain oxygenation and CO during the immediate postoperative period, whereas many other institutions maintain an open chest for several days to allow optimization of CO and ventilation (Marino et al., 2006).

Nutritional support is provided through total parenteral nutrition (TPN). Monitoring of daily weights, of urine for ketones, glucose, and protein, and of serum levels of electrolytes and trace minerals is necessary to adjust the parenteral fluids. Enteral feedings may be started in the first few weeks postoperatively once the neonate has been deintensified, is hemodynamically stable, and where NEC risk is somewhat decreased.

Although an alternative treatment approach for HLHS is cardiac transplantation, the wait time for heart transplant in infants is on average 4 to 6 months in many regions; so, listing for heart transplant is primarily utilized for those neonates with poor RV function who are not good candidates for the Stage I/Norwood procedure. Further information about cardiac transplantation is found in Chapter 27, Newborn or Infant Transplant Patient. It is essential that parents be counseled and informed of all available treatment options, including risks and short- and long-term prognoses. Improvement in overall survival has led to an increased focus on long-term morbidity, particularly neurobehavioral and neurocognitive issues. ND problems are common in this cohort and are further discussed in the section on age-related ND problems (Marino et al., 2012).

DEFECTS WITH ABNORMAL AORTOPULMONARY CONNECTIONS

These CHDs result from a developmental defect of either the vascular or the valvular system, frequently with cyanosis. The defects described in this section include TGA and truncus arteriosus.

Transposition of the Great Arteries or Vessels

TGA is the result of abnormal rotation of the outflow tracts during fetal cardiac development. TGA may be dextrotransposition of the great arteries (*d*-TGA) or levotransposition of the great arteries (*L*-GA). In *d*-TGA, the aorta arises from the RV and the pulmonary artery arises from the LV. The aorta receives deoxygenated systemic venous blood and returns it to the systemic arterial circuit. The pulmonary artery receives oxygenated pulmonary venous blood and returns it to the pulmonary circulation. *d*-TGA is illustrated in Figure 7.14.

In *L*-TGA, both the ventricles and the great vessels are transposed, with the aorta arising from the left-sided RV and the pulmonary artery arising from the right-sided LV. The aorta is to the left and anterior to the pulmonary artery. This type of transposition is called *corrected*, because physiologically the cardiac hemodynamics are normal except that the RV is the systemic pumping chamber. The oxygenated blood comes into the LA, enters the left-sided RV, and is pumped via the aorta to the systemic circulation. Frequently, there are other associated cardiac defects; but in the absence of these defects, *L*-TGA may go undetected until a patient reaches adulthood and develops RV heart failure adult congenital heart disease (ACHD); Park, 2014).

Incidence. *d*-TGA accounts for 5% of all CHDs. It is more common in males (3:1). *d*-TGA is the most common cyanotic heart defect in newborns.

Hemodynamics. Hemodynamically, *d*-TGA results in parallel circulation. Oxygenated blood from the lungs is returned to the LA and enters the LV, which pumps blood back to the lungs via the pulmonary artery. Deoxygenated blood from the systemic veins returns to the RA and enters the RV, which pumps blood into the systemic circulation via the aorta. The end result is that the heart, brain, and other vital tissues are perfused with deoxygenated blood. **Emergency Alert: This**

TABLE 7.7

COMMON CARDIAC SURGICAL PROCEDURES

Procedure	Type	Defect	Description
Modified BT shunt	Palliative	Single ventricle with PA, TOF/PA, PA/IVS	Synthetic tube from the brachiocephalic artery to the pulmonary artery to provide a stable source of pulmonary blood flow
Stage I Procedure Norwood/ Damus-Kaye-Stansel	Palliative	HLHS/HLH variants	1. Main pulmonary artery is divided, and anastomosed to the hypoplastic ascending aorta to provide unobstructed systemic and coronary blood flow 2. Modified BT shunt to provide a stable source of pulmonary blood flow 3. Atrial septectomy to allow interatrial mixing
Superior caval connection (Bidirectional Glenn)	Palliative	Single ventricles	1. SVC anastomosis to the RPA 2. Ligation and division of the BT shunt
Modified Fontan	Palliative	Single ventricles	Lateral tunnel (inferior baffle from IVC to SVC) or extracardiac conduit (Gore-Tex tube connection between the vena cava)
Rashkind	Corrective	TGA, HLHS restrictive atrial septum	Balloon atrial septostomy to enlarge the atrial communication
Jatene/ Arterial switch procedure	Corrective	TGA	Switching of TGA to their anatomically correct position along with reimplantation of coronary arteries into the neoaorta
Rastelli	Corrective	TGA, TOF, PA, truncus arteriosus	Commonly applied to all valved conduits from the right ventricle to pulmonary artery
Pulmonary artery banding	Palliative	Multiple VSDs, single ventricles with unobstructed outflow	Placement of a band around the pulmonary artery to decrease the blood flow to the lungs

ASD, atrial septal defect; BT, Blalock-Taussig; HLHS, hypoplastic left heart syndrome; IVC, inferior vena cava; IVS, intact ventricular septum; PA, pulmonary artery; PVA, pulmonic valve atresia; PS, pulmonary stenosis; PV, pulmonary valve; RPA, right pulmonary artery; SVC, superior vena cava; TA, truncus arteriosus; TGA, transposition of the great arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

Sources: Data from Marino, B. S., Ostrow, A. M., & Cohen, M. S. (2006). Surgery for congenital heart disease. In V. Vetter (Ed.), *Pediatric cardiology: The requisites in pediatrics* (pp. 277–320). Philadelphia, PA. Mosby Elsevier; Park, M. K. (2014). *Pediatric cardiology for practitioners.* Chicago, IL: Mosby.

defect is incompatible with life unless there is an adequate atrial communication to allow mixing of the oxygenated and deoxygenated blood. Some cases of *d*-TGA have associated VSDs, which may contribute a little to mixing of oxygenated and deoxygenated blood, but the ASD is required for adequate mixing of blood (Park, 2014).

Manifestations. In cases detected prenatally, PGE_1 is initiated after birth and arterial blood gases (ABGs) are monitored for significant hypoxia in cases not detected prenatally. Cyanosis is typical and may be severe if the atrial communication is restrictive. The right upper saturation typically is lower than the right or left lower leg oxygen saturation, particularly if the atrial communication is restricted (Rudolph, 2001).

Diagnosis. Chest radiograph of *d*-TGA demonstrates a classical finding of an egg-shaped heart, where the heart is enlarged with a narrow base because the aorta is anterior to the pulmonary artery (Park, 2014). On ECG, there is right axis deviation of the QRS and RV hypertrophy. Echocardiography is important to evaluate the adequacy of the atrial communication, presence and size of VSDs, aortic or pulmonary valve abnormalities, and coarctation. In addition, the coronary pattern is important because a small percentage of coronary patterns will require an alternative surgical approach in rare cases.

Management. *d*-TGA may be a cardiac emergency in those neonates who are not prenatally detected and have a restrictive atrial septum. Immediate medical management includes initiation of PGE_1; correction of acidosis, hypoglycemia, hypocalcemia; administration of oxygen; and access to emergent balloon atrial septostomy to promote mixing of oxygenated and deoxygenated blood at the atrial level (Park, 2014).

Surgical correction involves the Jatene or arterial switch operation (ASO), which involves switching the arteries and coronaries (Jatene procedure) along with bringing the branch pulmonary arteries across the anterior aspect of the aorta (LeCompte). See Table 7.7 for a description of these procedures.

Outcomes after the ASO are quite good with aggregate mortality rates of 2.7% for *d*-TGA without a VSD and 5.3% for *d*-TGA with VSD (Jacobs et al., 2018). In the long term, these patients may develop problems with branch pulmonary arteries and coronary problems. Children with *d*-TGA status post ASO have been one of the most widely studied groups for ND problems (Marino et al., 2012).

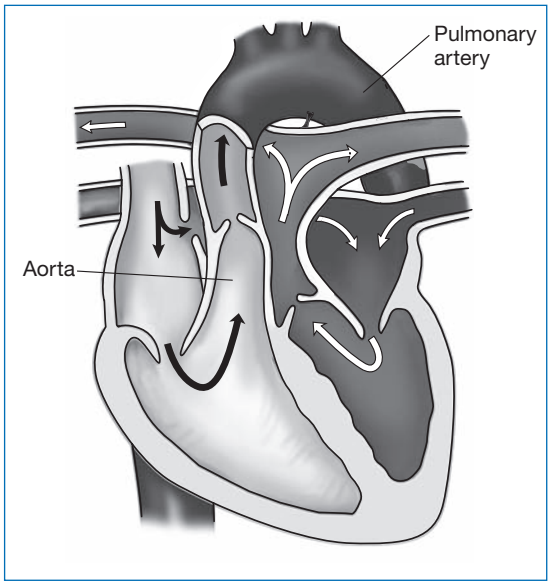

FIGURE 7.14 Transposition of the great arteries or vessels is a condition in which the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle. The result is two distinct circulatory (parallel) pathways.

TABLE 7.8

FOUR MAJOR TYPES OF TRUNCUS ARTERIOSUS

Type	Incidence (%)	Description
I	60	Main pulmonary artery arises from truncus and divides into left and right pulmonary artery; results in increased pulmonary blood flow
II	20	Pulmonary artery arises from posterior portion of truncus arteriosus; pulmonary blood flow is normal or increased
III	10	Pulmonary artery arises from sides of truncus arteriosus; pulmonary blood flow is normal or increased
IV	10	Bronchial arteries arise from descending aorta to supply lungs; pulmonary blood flow may be decreased

Truncus Arteriosus

Early fetal development involves a single, large great vessel or trunk arising from the ventricles, which ultimately gives rise to the systemic and pulmonary circulations. During development, if there is inadequate septation of the trunk then both the pulmonary and aortic outflows will arise from one large vessel, and inadequate septation of the ventricular septum will result in a large VSD. Four types of truncus arteriosus have been described; see Table 7.8 for the classifications (Park, 2014). Truncus arteriosus is illustrated in Figure 7.15.

Incidence. Truncus arteriosus accounts for less than 1% of all CHDs.

Hemodynamics. Deoxygenated blood from the RV and oxygenated blood from the LV mix via the large VSD and enter the truncal artery. The pressures of both ventricles are equal as a result of the large VSD. The amount of flow to the pulmonary and systemic circulations depends on the resistance of the two circulations. Pulmonary vascular resistance is high at birth, so pulmonary and systemic flows are relatively equal initially. Pulmonary resistance gradually decreases, causing increased pulmonary blood flow. CHF may develop as a result of increased pulmonary blood flow and there may be associated inadequate systemic perfusion. If not corrected early, over time, pulmonary vascular disease develops in response to increased pulmonary blood flow; subsequently, pulmonary blood flow decreases as a result of development of increased pulmonary vascular resistance. These changes, although compensatory initially, complicate the hemodynamics with increased risk for pulmonary hypertension in the postoperative period. The volume overload can also be compounded by incompetent truncal valves that allow regurgitation of blood into the ventricles.

Manifestations. If truncus arteriosus is not prenatally diagnosed, it typically will be detected in the newborn period as a result of a murmur, cyanosis, symptoms of poor feeding, and signs of CHF; or it may be detected on CCHD pulse oximetry screening. The presence of cyanosis depends on the amount of pulmonary blood flow, and signs of CHF due to increased pulmonary blood flow may be the first indication of truncus arteriosus. On auscultation,

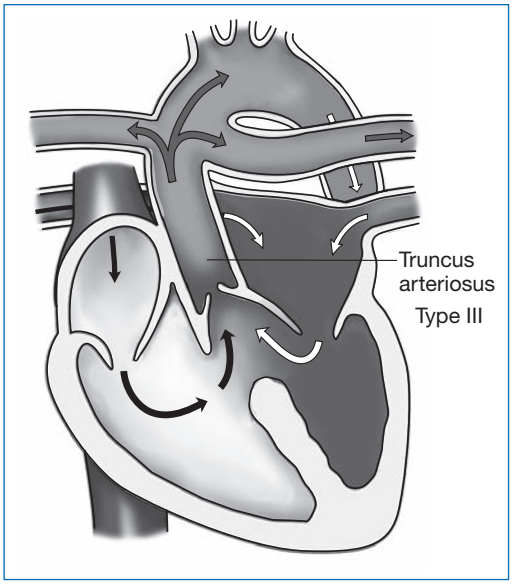

FIGURE 7.15 The truncus arteriosus is a single arterial vessel that gives rise to the coronary arteries, pulmonary arteries, and aorta.

Source: Adapted and modified from Ross Laboratories, Columbus, OH, Clinical Education Aid, 1985.

S_2 is single and there may be a systolic click at the apex and upper left sternal border. A murmur may be auscultated if there is truncal stenosis or insufficiency. Truncal valve insufficiency produces a high-pitched, early diastolic decrescendo murmur. There may be bounding arterial pulses and a widened pulse pressure. The right upper oxygen saturation and lower right and left oxygen saturations will be similar and less than 95%.

Diagnosis. On chest radiograph, the heart size is increased and pulmonary blood flow may be increased. Thirty-five percent of cases have a right aortic arch, and this finding increases the risk of deletion of 22q11. ECG reveals a normal QRS axis and ventricular hypertrophy. Echocardiography demonstrates the presence of a

single common arterial truncal valve overriding a large VSD and further details of the type of truncus with location of the pulmonary arteries, presence of truncal stenosis/insufficiency, additional VSDs, and arch sidedness (Park, 2014; Schultz & Kreutzer, 2006).

Management. Medical management consists primarily of treatment of CHF. Current surgical correction consists of complete primary repair, with closure of the VSD, committing the common arterial trunk to the LV, and reconstruction of the RVOT with a conduit from the RV to the branch pulmonary arteries (Park, 2014). The definitive surgical correction is the Rastelli procedure (see Table 7.7 for a description of common surgical procedures). Surgery is typically performed in the first week of life. The aggregate surgical mortality rate for truncus is 10.1%. Repeat surgery typically is required to enlarge the conduit as growth occurs (Jacobs et al., 2018; Park, 2014).

Congenital Arrhythmias

Cardiac arrhythmias in infants generally arise from primary cardiac lesions as a result of abnormal conduction pathways. Alternatively, cardiac arrhythmias can develop following cardiac surgical palliation or repair. It is not clear whether the arrhythmia is secondary to the cardiac lesion or the surgical procedure. Some arrhythmias are a result of electrolyte imbalances, neurologic conditions, or infections. Generally, in infants, rhythm disturbances are not the primary manifestation of a cardiac problem; instead, CHF or cyanosis is present before dysrhythmias occur (Sacchetti, Moyer, Baricella, Cameron, & Moakes, 1999). Some conditions present with rhythm disturbances in the newborn period. The most commonly occurring include congenital complete heart block (CCHB) and supraventricular tachycardia (SVT). These two arrhythmias are discussed in more detail.

Congenital Complete Heart Block

The AV node and the bundle of His arise as separate structures that join. CCHB is a result of a discontinuity between the atrial conduction pathway and the AV node, or the bundle of His and the AV node. One risk factor for CCHB is exposure to SSA and SSB antibodies in utero due to maternal systemic lupus erythematosus (SLE). In most cases, the heart structure is normal and the etiology of CCHB is unknown. Congenital heart block can also be a manifestation of CHDs, including congenitally corrected TGA or *L*-TGA.

Prenatally, CCHB can be detected by fetal bradycardia (HR < 100 bpm) on auscultation, electronic monitoring, or screening ultrasound. Fetal echocardiography is diagnostic with identification of AV dissociation with atrial rate faster and not associated with the slower ventricular rate by M-mode, and spectral Doppler techniques of the inflow and outflow of the heart (O'Connor & Shah, 2012).

Treatment. Asymptomatic neonates do not require treatment. If the neonate has inadequate systemic perfusion due to the bradycardia, then insertion of a pacemaker may be required. Children with implanted pacemakers need close follow-up due to complications or adverse effects of the pacemakers (Massimo et al., 2006; Webb et al., 2012).

Supraventricular Tachycardia

SVT can arise in utero or in the neonatal period. The most common arrhythmias that produce signs are paroxysmal SVT with or without ventricular preexcitation, atrial flutter, and junctional tachycardia. If the SVT occurs in utero, it can lead to heart failure and hydrops fetalis. SVT treatment depends on gestational age of the fetus, the type of SVT, whether it is intermittent or persistent, and the presence of CHF and/or hydrops. SVT treatment in the fetus depends on the presence or absence of hydrops. If the fetus is near term, then delivery with postnatal treatment may be the management strategy. If the patient is not near term, then the medication regimen depends on the type of SVT and presence or absence of hydrops. In paroxysmal SVT without hydrops, digoxin, flecainide, or sotalol may be used as first-line therapy. If first-line therapy is not successful, then combination therapy will be used (O'Connor & Shah, 2012).

In most cases of SVT, no cause is found. Ebstein anomaly of the tricuspid valve can be the cause in some cases. Ten to 50% of infants with SVT have Wolf-Parkinson-White (WPW) syndrome, in which the atrial impulse activates the whole or some part of the ventricle, or the ventricular impulse activates the whole or some part of the atrium earlier than would be expected if the impulse traveled via the normal pathway. WPW is characterized by a normal QRS with regular rhythm and ventricular rates of 150 to 200 bpm (Olgin & Zipes, 2011).

Symptoms produced by SVT after birth are subtle and often undetected until signs of CHF develop. Medical management typically begins with vagal maneuvers; elicitation of a diving reflex by covering the face with a cold washcloth for 4 to 5 seconds is generally successful in establishing normal sinus rhythm. If this approach is unsuccessful, then IV adenosine is attempted, typically resulting in cardioversion to sinus rhythm. A baseline 12-lead EKG is required to document presence of delta waves consistent with WPW, since it will determine the medical management and medication therapy used. Propranolol is a common medical therapy used, particularly if WPW is diagnosed. In some centers, digoxin therapy may be utilized for SVT when WPW has been ruled out. Infants are followed closely for breakthrough SVT episodes; if no further SVT is documented, then at 1 year of age medical therapy is discontinued with close follow-up to monitor for SVT recurrence. Since recurrence is more likely in WPW, these infants typically will be maintained on beta blocker therapy.

Recurrence decreases between ages 2 and 10 years of age. Prognosis for SVT is good (Webb et al., 2012).

Congestive Heart Failure

Congestive heart failure (CHF) is a condition in which the blood supply to the body is insufficient to meet the metabolic requirements of the organs. CHF is a manifestation of an underlying disease or defect, rather than a disease itself. Before development of CHF, compensatory mechanisms are activated to maintain adequate CO (Park, 2014; Wernovsky & Gruber, 2005). Normal mechanisms for regulation of CO are listed in Box 7.2. CHF is classified according to the cause. Box 7.3 shows common causes of CHF in newborns.

Increased volume may be caused by fluid overload or fluid retention. In the normally functioning myocardium, fluid retention does not cause CHF; however, fluid retention complicates CHF from other causes. In neonates, the most common cause of increased volume is CHD or altered hemodynamics, as in PDA.

CHF caused by obstruction to outflow occurs when the normal myocardium pumps against increased resistance. This increased resistance may be caused by structural defects, such as valvular stenosis or COA, or by pulmonary disease and/or pulmonary hypertension. CHF caused by pulmonary disease is called *cor pulmonale*. Severe systemic hypertension can also cause increased systemic vascular resistance.

CHF in the neonate usually results from abnormal stresses placed on the heart rather than from an ineffective myocardium. However, electrolyte imbalances, acidosis, and myocardial ischemia affect the ability of the heart to function effectively. Conditions such as rheumatic fever, infectious myocarditis, Kawasaki

Box 7.2

MECHANISMS OF CARDIAC OUTPUT REGULATION

Sympathetic Nervous System Activated By:

- Vasomotor center through peripheral sympathetic fibers
- Secretion of norepinephrine from adrenal medullary "fight or flight" response
- Symptoms
  - Characterized by tachycardia, increased contractility, peripheral vasoconstriction, pupil dilation

Parasympathetic Nervous System Activated By:

- Vagal fibers
  - Atrial stimulation causes decreased heart rate.
  - Ventricular stimulation causes decreased contractility.
- Baroreceptor reflexes
  - Located in walls of carotid sinuses and in aortic arch
  - Pressure receptors stimulated by blood pressure
- Results
  - Stimulation causes inhibition of the sympathetic portion of the vasomotor center and stimulation of the parasympathetic (vagal) center; decreased arterial blood pressure

Box 7.3

CAUSES OF CONGESTIVE HEART FAILURE IN THE NEWBORN

Noncardiac causes of congestive heart failure:

- Sepsis
- Anemia
- Polycythemia
- Metabolic diseases (Pompe disease)
- Multiple hemangiomas
- Arteriovenous malformations (cranial, hepatic, abdominal)
- Hyperthyroidism
- Hypoglycemia
- Hypocalcemia
- Renal failure
- Severe systemic hypertension

Congenital heart defects:

- Hypoplastic left heart syndrome
- Interrupted aortic arch
- Coarctation of the aorta
- Total anomalous pulmonary venous return with obstruction
- Transposition of the great arteries
- Patent ductus arteriosus (in preterm infants)

Other cardiac causes:

- Myocarditis
- Arrhythmias
- Anomalous left coronary artery from the pulmonary artery

disease with myocarditis, and anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA) may reduce the effectiveness of the heart function.

Arrhythmias that may produce CHF include complete AV block or sustained atrial or ventricular tachycardia. AV block results in a severe bradycardia that prohibits adequate circulation of blood. Tachycardia causes insufficient time for ventricular filling, decreasing CO and leading to cardiac dysfunction over time.

Severe anemia can cause CHF because of excessive demand for CO. Because the oxygen-carrying capacity of the blood is diminished, the heart must pump more blood per minute to meet the tissue oxygenation requirements. If the heart cannot meet the excessive demand, CHF develops (Park, 2014).

Compensatory mechanisms function to meet the body's increased demand for CO. These mechanisms are regulated by the sympathetic nervous system and mechanical factors. The compensatory mechanisms can sustain adequate CO for only a short period of time. If the underlying condition is not corrected, CHF develops.

Sympathetic Nervous System Compensatory Mechanisms. Decreased blood pressure stimulates vascular stretch receptors and baroreceptors in the aorta and carotid arteries that trigger the sympathetic nervous system. Decreased systemic blood pressure stimulates baroreceptors, causing (1) increased sympathetic stimulation, (2) increased HR, (3) increased cardiac contractility, and (4) increased arterial blood pressure. Catecholamine release and beta-receptor stimulation increase the rate and force of myocardial contraction. Catecholamines also increase venous tone, so that blood is returned to the heart more effectively. Circulation to the skin, kidneys, extremities, and splanchnic bed is decreased, allowing better circulation to the brain, heart, and lungs. Decreased renal blood flow stimulates the release of renin, angiotensin, and aldosterone. This release causes retention of sodium and fluid, resulting in increased circulating volume. The increased volume puts additional work on the heart.

Mechanical Compensatory Mechanisms. The heart muscle thickens to increase myocardial pressure. The hypertrophy is effective in the early stages, but as soon as the muscle mass increases, compliance decreases. This change in compliance requires greater filling pressure to maintain adequate CO. The hypertrophied heart eventually becomes ischemic because it does not receive adequate oxygenation to meet its metabolic needs. Ventricular dilation occurs as myocardial fibers stretch to accommodate heart volume. Initially, this increases the force of the contraction, but it too fails after a certain threshold point.

Effects of Congestive Heart Failure. When the RV is unable to pump blood into the pulmonary artery, the lungs oxygenate less blood, there is increased pressure in the RA and systemic venous circulation, and edema occurs in the extremities and viscera. When the LV is unable to pump blood into the systemic circulation, there is increased pressure in the LA and pulmonary veins. The lungs become congested with blood, causing elevated pulmonary pressures and pulmonary edema.

The end effects of CHF include decreased CO, decreased renal perfusion, systemic venous engorgement, and pulmonary venous engorgement and their consequent effects. Decreased CO stimulates the sympathetic nervous system, causing tachycardia, increased contractility, increased vasomotor tone, peripheral

vasoconstriction, and diaphoresis. Decreased renal perfusion stimulates the renin-angiotensin-aldosterone mechanism, causing sodium and water retention. Systemic venous engorgement leads to hepatomegaly, jugular venous distention, periorbital and facial edema, and, occasionally, ascites and dependent edema. Pulmonary venous engorgement results in tachypnea, decreased tidal volume, decreased lung compliance, increased airway resistance, early closure of the small airways with air trapping, increased work of breathing, and increased respiratory effort, grunting, and rales. Stimulation of the j-receptors in the lung causes infants to become apprehensive and irritable.

Diagnosis. The diagnosis of CHF is based on clinical signs and symptoms, laboratory data, and chest radiography with definitive diagnosis by echocardiography. In contrast to infants with cyanotic heart disease, infants with CHF usually have significant respiratory distress with tachypnea, grunting, and retractions. They exhibit peripheral pallor, appearing to be ashen or gray in color. The precordium is hyperdynamic, and there are usually loud murmurs heard throughout systole and diastole. Pulses are usually full, but there may be a difference between the upper and the lower extremities. Hepatomegaly is common. Infants demonstrate signs of irritability because of the increased effort of breathing and air hunger.

In addition to demonstrating hypoxemia, ABG may reveal a metabolic acidosis resulting from the decreased systemic blood flow. If acidosis is severe, there may be concurrent respiratory acidosis because of the pulmonary edema caused by left-sided heart failure. Pulmonary ventilation–perfusion mismatch may cause hypoxemia. Hypocalcemia is often present in infants with CHF because they have an inappropriate response to stress. In addition, infants with deletion of 22q11 may have hypocalcemia because of absent parathyroids. Conotruncal anomalies such as TOF and truncus arteriosus along with interrupted aortic arch are CHDs that are commonly associated with deletion of 22q11 (Park, 2014).

Hypoglycemia may be present in infants with severe CHF. The myocardium depends on glucose; decreased glucose levels diminish the ability of the heart to compensate for CHF. On chest radiograph, the heart is enlarged and there is increased pulmonary congestion. ECG is not generally diagnostic, unless the CHF is caused by an arrhythmia. There may be nonspecific changes in the T waves, changes in the ST segment, and an increase in the height of the P wave.

Electrolyte imbalances usually include relative hyponatremia due to increased free water. Hypochloremia and increased bicarbonate may result from respiratory acidemia and the use of loop diuretics. Hyperkalemia results from the release of intracellular cations related to poor tissue perfusion. Elevated lactic acid levels are also indicative of tissue hypoxia. Atrial natriuretic factor (ANF), a peptide hormone, may be important in the regulation of volume and blood pressure. ANF is released from the atria when they are distended. ANF release causes natriuresis, diuresis, and vasodilation. ANF acts with other volume regulators, such as renin, aldosterone, and vasopressin. An increased ANF level may be found when there is increased pulmonary blood flow, increased left atrial pressure, or pulmonary hypertension.

Treatment. The goal of management of CHF is to improve cardiac function while identifying and correcting the underlying cause. General measures that decrease the demand on the heart are helpful; however, pharmacologic intervention is the most efficacious therapy.

General Measures. General measures to manage CHF in infants with structurally normal hearts include the administration of oxygen to improve ventilation and perfusion at the alveolar level. Ventilation with positive end-expiratory pressure at 6 to 10 cm/H_2O may relieve the effects of CHF by reducing pulmonary edema.

Fluid restriction may decrease the circulating volume. Careful monitoring of serum electrolytes, BUN/Cr, intake and output, and weight is essential. It is imperative that *all* fluids be counted in the total daily fluid volume. Infants with CHF do not usually feed well and may require caloric supplementation with hyperalimentation or gavage feedings (Park, 2014).

Infants with CHF are irritable and agitated, further complicating their hemodynamic status. Sedation with continuous infusions of morphine sulfate or fentanyl may improve the infant's comfort level and oxygenation by decreasing metabolic demand. Other measures that reduce metabolic oxygen demand include maintenance of a normal hematocrit, maintenance of a thermoneutral environment, and minimal stimulation (Verklan & Walden, 2004).

Pharmacologic Interventions. Table 7.9 lists the medications most commonly used in the management of cardiac conditions. Medical management of CHF *beyond* the neonatal period includes use of ACE inhibitors, diuretics, nonspecific beta blockers (carvedilol), and/or digitalis (digoxin). Digoxin slows conduction through the AV node, prolongs the refractory period, and slows the HR through vagal effects on the SA node.

The use of digoxin in preterm or term neonates is controversial. The preterm newborn is at risk for digitalis toxicity because of the narrow range between therapeutic and toxic drug levels. The preterm infant requires a lower maintenance dose because of limited renal excretion of the drug (Table 7.10). If digoxin is used, the neonate must be carefully monitored for signs and symptoms of digitalis toxicity. Lead II ECGs should be obtained before each dose for the first 3 days; the dose should be withheld if the PR interval is greater than 0.16 second or if there is an arrhythmia present. Digoxin levels should be monitored and should be less than 2.0 ng/mL (Park, 2014). Blood samples for digoxin levels should be drawn after the drug has achieved equilibrium in the body, approximately 6 to 8 hours after administration.

Other inotropic agents can be used to improve CO. Dopamine, a norepinephrine precursor, has direct and indirect dose-dependent beta adrenergic effects. At low doses (2–5 mcg/kg/minute), there is increased renal blood flow with minimal effect on HR, blood pressure, or contractility. Medium doses (5–10 mcg/kg/minute) increase renal blood flow, HR, blood pressure, and contractility. Pulmonary artery pressure may be increased; peripheral resistance is not affected. High doses (10–20 mcg/kg/minute) cause peripheral vasoconstriction, increased cardiac rate, and increased contractility (Park, 2014).

Dobutamine is a synthetic catecholamine that acts on beta and alpha adrenergic receptors. Dobutamine (2–10 mcg/minute) has decreased effect on the HR and rhythm and causes less peripheral vasoconstriction.

Emergency Alert: Isoproterenol (Isuprel), a synthetic epinephrine-like substance, has beta-1 and beta-2 adrenergic effects. The usefulness of Isuprel in the neonate is limited because it produces increased HR, arrhythmias, and decreased systemic vascular resistance, which may worsen the hypotension (Park, 2014).

Diuretics. Diuretics are useful in the treatment of CHF to decrease sodium and water retention. The primary goal is to increase renal perfusion (with inotropic agents or vasodilators) and to increase sodium delivery to distal diluting sites of the renal tubules. Diuretic agents increase the renal excretion of sodium and other anions by inhibition of tubular reabsorption of sodium (Park, 2014).

Furosemide (Lasix), a loop diuretic, blocks sodium and chloride reabsorption in the ascending limb of the loop of Henle. Loop

TABLE 7.9

DRUGS USED IN THE MANAGEMENT OF CONGENITAL HEART DEFECTS

Drug	Dosage	Action	Onset	Comments
Diuretics				
Furosemide (Lasix)	0.5–1 mg/kg/dose IV	Loop diuretic; inhibits sodium and chloride reabsorption in proximal tubule	15–30 minutes	Associated with increased calcium loss
Furosemide (Lasix)	1–3 mg/kg/dose PO		30–60 minutes	
Spironolactone (Aldactone)	1.5–3.0 mg/kg/dose PO	Competitive antagonist of aldosterone	3–5 days	Potassium sparing
Chlorothiazide	20–40 mg/kg/day PO	Inhibits sodium and chloride reabsorption along the distal tubules	1–2 hours	
Inotropic Agents				
Dopamine	Low: 2–5 mcg/kg/minute	Increased renal blood flow; beta adrenergic effects		Monitor ECG; BP
	Mod: 5–10 mcg/kg/minute	Increased renal blood flow; heart rate, BP, and contractility		
	High: 10–20 mcg/kg/minute	Peripheral vasoconstriction, increased heart rate, and contractility		
Dobutamine	2–10 mcg/kg/minute	Increased renal blood flow; increased contractility	Rapid	Decreased systemic vascular resistance; increased pulmonary wedge pressure
Isoproterenol	0.05–0.5 mg/kg/minute	Increased venous return to heart and decreased pulmonary vascular resistance		Tachycardia, dysrhythmias, decreased renal perfusion
Prostaglandins				
PGE_1	0.01–0.1 mg/kg/minute	Produces vasodilation and smooth muscle relaxation of ductus arteriosus and pulmonary and systemic circulations; increased arterial saturation by 25%–100%	Rapid	Monitor BP; vasopressors may be required; apnea, flush, fever, seizure-like activity; decreased heart rate
Prostaglandin Synthetase Inhibitors				
Indomethacin	0.2 mg/kg IV (1st) q 24 h	Promotes ductal closure by inhibition of PGE_2 in the walls of the ductus	12–24 hours	Monitor renal function, bilirubin, electrolytes, glucose, platelets, bleeding
	0.1 mg/kg IV (2nd and 3rd)			
	>48 hours and <14 days: 0.3 mg/kg IV and 3 doses q 24 h			
	>14 days and <6 weeks: 0.2–0.3 mg/kg q 12 h			

BP, blood pressure; IV, intravenously; PDA, patent ductus arteriosus; PO, by mouth; q, every.

TABLE 7.10

DIGOXIN PRESCRIPTION INFORMATION

	TDD (mg/kg)	Maintenance Dose (mg/kg/day)
Preterm	0.025–0.05	0.008–0.012
Term	0.04–0.08	0.01–0.02 (1/8 TDD)

To digitalize:
1. Give 1/2 TDD
2. 6–8 hours later, give 1/4 TDD
3. 6–8 hours later, get a rhythm strip; if normal, give 1/4 TDD.
4. Give maintenance dose (1/8 TDD) 12 hours after last digitalizing dose and then every 12 hours.

Slow digitalization, with decreased risk of toxicity, can be achieved by starting with the maintenance dose.

TDD, total digitalizing dose.

diuretics interfere with the formation of free water and free water reabsorption by preventing the transport of sodium, potassium, and chloride into the medullary interstitium. Loop diuretics cause increased excretion of potassium by delivering increased quantities of sodium to sites in the distal nephron where potassium can be excreted. Furosemide also increases excretion of calcium but does not affect the ability of the kidney to regulate acid–base balance.

An aldosterone antagonist such as spironolactone (Aldactone) may be used because it is a potassium-sparing diuretic. Spironolactone works by binding to the cytoplasmic receptor sites and blocking aldosterone action, thus impairing the reabsorption of sodium and the secretion of potassium and hydrogen ion. Spironolactone has no effect on free water production and absorption. Thiazide diuretics (chlorothiazide and hydrochlorothiazide) inhibit sodium and chloride reabsorption along the distal tubules. They are not as effective as the loop diuretics and are infrequently used (Park, 2014).

Complications of Diuretic Therapy. Diuretic therapy can cause severe electrolyte imbalances if they are not monitored carefully. The complications of diuretic therapy include (1) volume contraction, (2) hyponatremia, (3) metabolic alkalemia or acidemia, and (4) hypokalemia or hyperkalemia. When using diuretics, fluid and electrolyte balance must be maintained by the administration of water and electrolytes. The adequacy of the volume can be determined by monitoring serum electrolytes, BUN, Cr, urinary output, weight, specific gravity, and skin turgor.

The increased renal losses of sodium can lead to hyponatremia, unless adequate amounts of sodium are provided. There may also be increased antidiuretic hormone (ADH) release secondary to changes in the osmoreceptors or inhibition of ADH action. Decreasing the amount of total water and improving the CO, thus increasing renal perfusion, can best manage this.

Metabolic alkalosis can result from administration of loop diuretics that interfere with sodium- and potassium-dependent chloride reabsorption. Hypochloremia results in a greater aldosterone production and an increase in bicarbonate concentration. Hypokalemia is a frequent complication of loop diuretic therapy. An increased ratio of intracellular to extracellular potassium results in the clinical signs and symptoms of hypokalemia. **Emergency Alert:** **Hypokalemia increases the risk for digoxin toxicity.** In contrast, hyperkalemia may result when CO is low and tissue perfusion is severely compromised. Other complications of diuretic therapy include increased calcium excretion, hyperuricemia, and glucose intolerance.

Subacute Bacterial Infective Endocarditis

Subacute bacterial infective endocarditis (SBIE or SBE) can be a complication in certain high-risk CHD patients. Two factors are important in the development of SBIE: (1) certain structural abnormalities that create turbulent flow or pressure gradients resulting in endothelial damage and (2) bacteremia. Certain CHDs and acquired heart disease with turbulent flow or a significant pressure gradient result in trauma to the endothelial lining, predisposing the endothelium to deposition of platelets and fibrin resulting in nonbacterial thrombotic endocarditis. If certain microbial species with pathogenic potential enter the bloodstream, there is potential to cause infective endocarditis at that site. Previously, more than 90% of infective endocarditis was due to *Streptococcus viridians, Streptococcus faecalis* (enterococcus), and *Staphylococcus aureus* but these organisms now only account for 50% to 60% of the cases, while fungi and HACEK (*Haemophilus influenzae, Aggregatibacter, Cardiobacterium, Eikenella,* and *Kingella spp)* organisms have increased. HACEK organisms account for 17% to 30% of the cases in neonates and immunocompromised children (Park, 2014).

Prevention. Based on the 2007 AHA guidelines, prevention of bacterial SBIE requires scrupulous daily oral care along with minimizing dental disease to decrease frequency of bacteremia in routine daily activities. SBIE prophylaxis is recommended for CHD patients considered at high risk for an adverse outcome (Box 7.4) with the following procedures: (1) all dental procedures; (2) respiratory tract procedures not including bronchoscopy; (3) procedures involving infected skin, skin structures, or musculoskeletal tissue. **Quality and Safety:** **Based on the 2007 AHA guidelines, antibiotic prophylaxis to prevent infective endocarditis is no longer recommended for gastrointestinal or genitourinary procedures.**

For further details and complete prescribing and dosing information, refer to the AHA Guidelines from the AHA Rheumatic Fever Endocarditis and Kawasaki Disease Committee of the Council on Cardiovascular Diseases in the Young (Wilson et al., 2007).

Neurodevelopmental Disabilities in CHD

Over 50% of CHD patients are at risk for ND problems, including mild learning disabilities, attention deficit disorder, and speech and motor problems. Children with HLHS and *d*-TGA have been the most widely studied cohort, and at least 50% of these patients are affected by ND issues that significantly impact their academic achievement and quality of life. Several studies have demonstrated that 17% to 40% of neonates with complex congenital heart disease have evidence of periventricular leukomalacia (PVL) on preoperative MRI, whereas 50% had evidence of PVL on postoperative MRI. White matter injury or PVL has been associated with ND problems and impaired functional outcomes in very low birthweight and preterm neonates. By the time CHD patients reach school age, there are notable deficiencies in fine and gross motor functions, tests of intelligence and achievement, speech, language, and behavior (Bellinger et al., 2003; Galli et al., 2004; Goff et al., 2014; Hovels-Gurich et al., 2007; Mahle et al., 2002; Marelli, Miller, Marino, Jefferson, & Newburger, 2016; Marino et al., 2012).

Box 7.4

CARDIAC CONDITIONS FOR WHICH SBIE PROPHYLAXIS IS RECOMMENDED

1. Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
2. Previous history of infective endocarditis
3. CHD
   - Unrepaired cyanotic CHD including palliative shunts and conduits
   - Unrepaired CHD with prosthetic material or device whether placed by surgery or cardiac catheterization during the first 6 months after the procedure
   - Repaired CHD with a residual defect at the site or adjacent to a prosthetic patch or device (that inhibits endothelialization)
4. Cardiac transplant recipient who developed cardiac valvulopathy

CHD, congenital heart disease.

Family Support

Families of infants who are critically ill or have congenital defects generally experience confusion, guilt, anger, and fear. The family must cope with short- and long-term consequences of the CHD. Severity of the defect, availability of treatment, and prognosis influence the amount and type of support required. Parents may be overwhelmed by the knowledge of their infant's heart defect, regardless of the severity. With treatment now available, over 95% of CHDs can be palliated or fully corrected through a combination of medical and surgical management (Cooley, 1997). However, residual defects or cardiovascular sequelae after surgical correction are common (Meberg, Otterstad, Frøland, Lindberg, & Sørland, 2000). Parents need to be able to discuss quality-of-life issues with healthcare professionals in order to make informed decisions about possible treatment options (Møyen et al., 1997). All options must be explained and described objectively. The impact of the cardiac defect on other systems must also be included when giving parents information, as the parents may not be aware of the associated complications, such as respiratory problems, that often accompany cardiac defects (Lubica, 1996). Although often overlooked, neurologic prognosis is a key factor in determining the overall quality of life of a child with a CHD. Pediatric neurologists can be integrated into the healthcare team to assist parents in assessing the neurologic prognosis of their child as well as beginning early intervention programs to facilitate the best outcomes (Shevell, 1999). Parents need frequent contact with members of the healthcare team. Caretakers should speak with parents routinely, not just when there are major changes in the infant's condition.

Although most CHDs do not have an identifiable genetic pattern, genetic counseling should be offered to all parents with a newborn with a CHD. Parents will want answers to questions about the cause of the defect, the likelihood of a recurrence in future pregnancies, and if there may be associated defects (Welch & Brown, 2000; Wolf & Basson, 2010). In addition, improving ultrasound screening for CHD may improve prenatal detection of CHD (Bakiler, Ozer, Kanik, Kanit, & Aktas, 2007; Landis et al., 2013), thus increasing the opportunity for fetal surgery for correction of some defects, improved immediate management at birth, or, in some cases, termination of the pregnancy. Most CHDs can be identified with 18-to-20–week anatomy scans, with almost 90% of CHD prenatally detected if the four-chamber and outflow tract views are visualized (Sklansky, Berman, Pruetz, & Chang, 2009) Despite updated guidelines, in some regions of the United States, the lower prenatal detection rate may be a result of inadequate prenatal screening (Goff, personal communication). Healthcare professionals must be keenly aware of all options to assure that parents receive the most up-to-date information on which to base decisions.

One of the defect diagrams and models illustrating the defect should be used. Parents need frequent reassurance and repetition of information. Parents of infants who do not require immediate surgery but who will eventually require surgical correction must be educated about all aspects of the infant's care, including signs and symptoms of deterioration, medication administration, activity limitations, and normal development. Because growth failure with a cardiac defect is common, efforts to maximize nutrition are important; extra support is needed if the mother plans to breastfeed her baby (Barbas & Kelleher, 2004; Varan, Tokel, & Yilmaz, 1999). Careful follow-up is important to prevent complications.

Identification of support persons for the family is extremely valuable. Parents may be encouraged to talk to other parents of newborns with the same or similar defects. Many neonatal intensive care units (NICUs) have active support groups consisting of parents of patients. Care should be taken in selection of supporters. Parents with a term newborn with a CHD may not be able to relate to parents of a preterm neonate. Other family members or friends should not be overlooked; they can become valuable support persons if they are provided appropriate guidance and education. The needs of siblings should also be assessed. Siblings need support, education, and guidance appropriate for their age and comprehension of the situation. Parents may not recognize their needs because of the overwhelming situation. Healthcare providers can facilitate the parent–child relationship during the initial period and throughout the course of the management.

Financial resources should be addressed because preoperative, operative, and postoperative care is expensive. Many parents need assistance in obtaining aid to which they are entitled. Even the most knowledgeable of parents may not be aware of resources available to them. If experimental surgery is contemplated, parents may need assistance speaking to private insurance companies regarding coverage. Referrals to appropriate local, state, federal, or private organizations that pertain to the CHD should be made for the parents. These include the Department of Family and Children Services, the March of Dimes, and Children's Medical Services. The family may qualify for the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC).

Discharge planning must be comprehensive for the neonate who will receive medical management for a CHD before corrective surgery. A thorough assessment of the home may be needed before discharge. Contact with the primary care provider who will

perform the routine management of the infant is imperative. Initial contact by telephone should be followed up with a copy of the complete medical record and discharge summary. If the infant requires any special equipment for home care, the equipment should be obtained before discharge so that the parents can be taught how to use it. Also, practical details such as whether there are enough electrical outlets in the infant's room must be determined. Notification of local emergency medical services, power companies, and other relevant companies should be completed before discharge.

SUMMARY

The most common CHD lesions are reviewed along with the most common arrhythmias seen in the newborn. The diagnosis and management of the most frequent complications of CHDs, CHF, and recommendations of SBIE are included. Parental support of families with newborns and children with CHDs has been discussed.

CASE STUDY

The NICU in a large women and children's hospital received a call for assistance from the adjacent Mother and Baby Unit to evaluate an infant for cyanosis. Nurse Johnson responded to the call and discovered that Baby Johanna was pale, cyanotic, and tachypneic. She positioned the baby for optimal oxygenation and supplied oxygen via blow-by. Baby Johanna responded to the blow-by oxygen with improved color and tone. Nurse Johnson told the mother that she would take the baby to the NICU for further evaluation and update her as soon as possible. In the NICU, the baby's pediatrician was called and the birth history was obtained from the medical record supplied by the Mother and Baby Unit personnel. Baby Johanna was put in an oxyhood, and vital signs were obtained. The baby was now pink, HR was 164, respiratory rate was 76, and the mean blood pressure was 58.

Johanna was born to a gravida 1, para 0 (now 1), 24-year-old mother with uncomplicated pregnancy and delivery. Birthweight was 3.3 kg, and Apgar scores were 8/9 (−1 color, −1 tone, −1 color). Johanna showed no distress, and the pediatrician's examination at 3 hours post birth was within normal limits, with some slight acrocyanosis of the hands and feet present. Johanna had been in the Mother and Baby Unit and the mother was nursing. At this feeding, the mother had offered the baby a bottle following nursing. She called the floor nurse because the baby seemed to turn blue during the feeding.

Upon auscultation, a soft ejection-type murmur was noted at the upper left sternal border. Right radial arterial blood gas showed a partially compensated metabolic acidosis on 70% Fio_2 per hood. The pulse oximeter registered an oxygen saturation of 58% on arms and legs. A hyperoxia test using 100% Fio_2 showed no improvement in arterial oxygenation. The cardiac murmur had increased and was determined to be systolic in origin, and probably tricuspid regurgitation. Chest x-ray showed normal heart size and decreased pulmonary markings. A stat echocardiogram was ordered to determine whether a cardiac defect was present.

1. What other intervention should be initiated while the definitive diagnosis is being obtained?
2. What are the most likely cardiac defects with this presentation?
3. How does the timing of the episode influence the differential diagnosis?
   Echocardiography revealed presence of PA/IVS with a PDA providing left-to-right flow into the pulmonary system. The PDA was maintained by the continuous infusion of PGE_1 started after the chest x-ray was obtained.
4. What is the general management for PA/IVS?
5. What information should be shared with the parents regarding short- and long-term treatment and prognosis?

EVIDENCE-BASED PRACTICE BOX

Screening for Critical Congenital Heart Defects With Pulse Oximetry

The overall incidence of CHD is slightly less than 1%, or 8 per 1,000 live births, excluding PDA in the preterm newborn, which is the single largest factor for infant mortality due to all birth defects. CHDs that usually cause hypoxia in the newborn period and are associated with the highest mortality are classified as *critical congenital heart defects* (CCHDs). Newborns with CCHDs require immediate intervention to prevent death or disability.

Seven cardiac defects make up the CCHDs: HLHS, PA/IVS, TOF, TAPVR, TGA, tricuspid atresia, and truncus arteriosus. Approximately 4,800 babies are born each year in the United States with one of these seven CCHDs.

Delayed diagnosis of any of these defects significantly increases the risk for morbidity or mortality. Currently, diagnosis depends on prenatal ultrasound identification or physical examination of the newborn. This approach does not identify all defects, and so it leads to late diagnosis and increased morbidity and sometimes mortality. Methods that allow earlier identification of these cardiac defects would lead to quicker diagnosis, implementation of treatment, and improved outcome.

Routine screening of newborns with pulse oximetry was proposed as one method to improve early diagnosis of CCHDs. Pulse oximetry is a noninvasive, painless, relatively inexpensive, and readily available method that measures blood oxygen saturation. Most CCHDs are associated with hypoxia, and thus pulse oximetry screening could identify newborns with one of these defects. Numerous studies were conducted in the United States and in other countries, including Sweden and Germany, to determine whether routine pulse oximetry measurements on newborns improved the detection of CCHDs.

The U.S. Health and Human Services Secretary convened a group of experts to examine evidence of the effectiveness of pulse oximetry screening. The group consisted of members recommended by the Secretary's Advisory Committee on Heritable Diseases in Newborns and Children, the American Academy of Pediatrics (AAP), the American College of Cardiology

EVIDENCE-BASED PRACTICE BOX (*continued*)

Foundation, and the American Heart Association. The work group found sufficient evidence to recommend routine screening with pulse oximetry monitoring to identify low blood oxygen saturation in newborns in well-infant and intermediate nurseries. They recommended further study for screening of special populations, such as those who live in high altitudes.

Based on this review of the evidence, Secretary of Health and Human Services Kathleen Sebelius recommended the addition of pulse oximetry screening for CCHD in newborns in 2011. This recommendation was officially endorsed by the AAP. Most hospitals have adopted this screening method; however, there are differences in the screening process, in the number and type of conditions that are screened for in each state, and in the data collection to review efficacy of the program. As of 2015, most states have introduced or passed legislation to add pulse oximetry screening to the current newborn screening, but not all states have mandated pulse oximetry screening and data reporting. See the status of legislation in your state at this website: www.cdc.gov/ncbddd/heartdefects/documents/2015-critical-chd-newborn-screening-by-state.pdf

Many hospitals have implemented the screening process and have organized reporting voluntarily. This is an example of evidence-based practice change.

PARENT VOICES

Farrin Moreno

My micropreemie was born at 25 weeks' gestational age. The doctors assured me she had 0% chance of survival. In fact, while hospitalized for 6 weeks on strict bed rest leading up to her birth, my doctor tirelessly tried convincing me to terminate my pregnancy. My daughter weighed 1 lb 7 ounces and was 12 inches long. She was placed on a ventilator immediately following her birth, but on her second day of life she began breathing over it. She graduated to a nasal cannula. At 1 week of age, her breathing became harder to regulate and her weight began to drop. After several tests, we were told she had a congenital heart defect called patent ductus arteriosus (PDA). The medical team said the PDA required a surgical closure to prevent blood from getting into her lungs. Their attempt to comfort me failed miserably as they said, "It's just a PDA, these are so common in preemies," driving me to think I was irrational for being terrified. I felt alone. The PDA ligation was performed when she was 2 weeks old. Still on a ventilator following the surgery, her progress remained slow. She developed three staph infections and remained on the ventilator nearly 2 weeks post surgery. Almost a month later, I held my baby girl for 2 short minutes before the alarms attached to her tiny body began to sound. Nurses should know that every step a parent takes toward the NICU doors, they can already hear the gut-wrenching alarms echoing throughout the unit, often mentally preparing them for the worst possible news. I wish my daughter's nurses knew that though I was an unwed, 19-year-old, first-time mom, I fought every day for my child to have a chance at life, even if it meant risking mine. If only the nurses knew how much it hurt when I mustered up the courage to ask if I could change a diaper, take a temperature, or do anything that mommies do, but was told, "No, thank you" as if I were a guest. If only the nurses let me try kangaroo care. I desperately wanted to bond with her but felt completely helpless, as pumping breastmilk seemed like my only contribution. I wish they had known that every NICU interaction would be permanently engrained in my mind. Once a nurse handed me my daughter's laundry bag asking if I thought I could "handle" washing her clothing with hypoallergenic detergent. I remember feeling 2 feet tall. Another time, I rushed to the hospital to get my freshly pumped breastmilk to my daughter before her next feeding, but arrived just as her nurse began feeding her formula while looking at me saying I would need to "do better" if I expected my daughter to have an exclusive breastmilk diet. I wish her nurses knew how much their verbal and nonverbal communication impacted my life well beyond the NICU, and how the trauma earned in the NICU does not go away. How you communicate matters.

CHAPTER 8

Gastrointestinal System

Khiet D. Ngo and Manoj Shah

INTRODUCTION

The intake and digestion of food and the elimination of waste products are critical to long-term survival. Although many complex metabolic processes are involved, the ability to maintain adequate nutrition ultimately requires that the gastrointestinal (GI) tract be patent and structurally intact. With only a few exceptions, the vast majority of conditions causing GI dysfunction are the result of congenital anatomic malformations. The discovery and management of GI dysfunction requires knowledge of both embryogenesis and normal anatomy and physiology. External defects are immediately apparent, but most causes of dysfunction have few initial symptoms unless allowed to progress to serious pathophysiologic changes resulting in a major threat to life. The input and support of a variety of nursing, medical, and other specialists are required for optimizing outcomes of the infant's physiologic well-being and the parents' psychosocial stability. Visible defects, especially those involving the face, appear to be particularly difficult for parents to accept. GI malformations, often associated with other congenital anomalies and prematurity, and the need for transport to a distant center where corrective surgery can be accomplished place additional demands on parental coping.

Parents' emotional needs and their ability to work through the grief process over the loss of the expected "perfect" child cannot be underestimated.

The GI tract is the site of the many complex transport and enzymatic mechanisms required for the absorption and digestion of nutrients. The successful intake and assimilation of these nutrients, however, rest on the ability of the gut to act as a conduit for ingestion, digestion, and elimination. Congenital malformations, particularly those involving anatomic or functional obstruction, clearly hinder this process. Even when structurally intact, the supporting gastric and intestinal musculature of the newborn is relatively deficient, increasing the tendency toward abdominal distention as a result of infrequent and irregular peristaltic movements. Transport of materials through the tract is further diminished in premature infants, who may have poor sucking and swallowing abilities, small gastric capacity, and an incompetent gastroesophageal sphincter. Debilitated, hypotonic infants may similarly exhibit poor sucking and swallowing and decreased GI motility. In addition, the bowel seems particularly susceptible to ischemic conditions in which blood flow is preferentially directed away from the GI tract, the kidneys, and the peripheral vascular bed toward the brain and heart.

Untoward effects of drugs commonly used in the nursery may further compromise intestinal function or integrity. Morphine, for example, in addition to its desired analgesic effect, also slows gastric emptying and reduces propulsive peristalsis. Conversely, erythromycin has been shown to accelerate gastric emptying. Ulceration of the GI tract with possible bleeding and perforation are reported side effects of tolazoline, dexamethasone, and indomethacin (Zenk, Sills, & Koeppel, 2003). Mydriatics administered for ophthalmologic examination in the preterm infant decrease duodenal activity and gastric emptying (James, 2002). Xanthines may cause or exacerbate gastroesophageal reflux (GER; Jadcherla, 2002). The major purposes of this chapter are to discuss the embryologic development and normal anatomic structure and physiology of the GI tract and to describe common causes of neonatal dysfunction and their implications for care.

EMBRYOLOGY

Formation of the GI tract largely depends on the folding of the embryo during the first month of development. At the beginning of the third week of gestation, as a result of the neural plate development, the flat, trilaminar embryonic disk begins to fold in both a cephalic-caudal and a ventral direction, invaginating the dorsal portion of the yolk sac. By the fourth week, this folding is complete, resulting in a horseshoe-shaped cylinder. This hollow tube is divided into three sections corresponding to the foregut, the midgut, and the hindgut.

Foregut

The foregut forms part of the mouth, esophagus, stomach, proximal duodenum, pancreas, liver, and extrahepatic biliary system as well as the lower respiratory system. The most cranial area of the foregut is often known as the pharyngeal gut. Early in the fourth week of fetal life, a depression appears on the ventral surface of the head called the stomodeum or primitive mouth. Oval thickenings, the nasal placodes, develop above and on either side of the primitive mouth, eventually becoming the nostrils. These nasal elevations and the area above the stomodeum merge to form the philtrum. By the eighth week, a continuous ridge forming the upper lip has developed from maxillary processes on either side

of the stomodeum fusing with the nasal pits and philtrum. The lower lip and jaw are formed when two mandibular processes below the stomodeum grow and fuse. Beginning in the fifth week, the primary palate begins to form from a wedge-shaped extension of the maxillary processes, thus separating the future nostrils from the upper lip. Lateral palatine processes also form on each side of the tongue and fuse with the nasal septum, anteriorly progressing posteriorly to form the secondary palate during the 9th to 12th week of development.

At the same time that the mouth is formed, the rest of the foregut is also developing. During the fourth and fifth weeks of gestation, an esophagotracheal septum is formed dividing the proximal foregut into the anterior trachea and posterior esophagus. Initially short, the esophagus elongates over a 2- to 3-week period to allow the development of the lungs, heart, and neck.

The stomach, first appearing as a dilation of the foregut, begins to grow with the dorsal aspect outpacing the ventral aspect, thus forming the greater curvature. As the esophagus grows, the stomach initially in the region of the neck descends and rotates 90° on its longitudinal axis until it reaches its final position. The duodenum develops from the caudal portion of the foregut as well as the cranial portion of the midgut. Around the fifth or sixth week, villi grow and temporarily occlude the lumen until the 9th or 10th week of gestation. Several other buds on the foregut also form the liver, gallbladder, bile ducts, and pancreas.

Midgut

The midgut consists of the distal duodenum, jejunum, ileum, cecum, appendix, ascending colon, and the right two-thirds of the transverse colon. Blood is supplied by the superior mesenteric artery. Although initially in tandem, the lengthening of the tubular intestine outpaces the overall elongation of the embryo.

By the sixth week of gestation, the rate of growth causes the tube to bend ventrally. Simultaneously, rapid growth of the liver quickly limits space within the abdominal cavity. Consequently, around 7 weeks' gestation, loops of intestine begin to protrude into the umbilical cord. As the midgut herniates, it rotates in a counterclockwise fashion approximately 90° around an axis formed by the superior mesenteric artery. At around 10 weeks, when the abdominal cavity has expanded sufficiently and the growth of the liver has slowed, reduction of the midgut herniation occurs. As the loops of intestine are retracted into the abdomen, they rotate another 180°, resulting in a full rotation of 270°. This counterclockwise rotation allows the transverse colon to pass in front of the duodenum and places the cecum and appendix in the right lower quadrant of the abdomen. Once the intestine has rotated into proper placement, the mesentery attaches to the posterior abdominal wall.

Hindgut

The GI components of the hindgut include the left one-third of the transverse colon, the descending colon, ascending colon, sigmoid colon, rectum, and superior portion of the anal canal. Blood is supplied from the inferior mesenteric artery. The major developmental changes occur in the terminal hindgut known as the cloaca and involve formation of the anus. The hindgut initially ends at the cloacal membrane, which separates it from the anal pit or proctodeum. Around the fourth week of gestation, the urorectal septum forms and by the sixth week divides the cloaca into a ventral urogenital sinus and a dorsal anorectal canal.

By the eighth week of gestation, the anal membrane has moved inferior and is found at the bottom of the proctodeum. In the ninth week, this membrane ruptures, completing the patency of the GI tract.

PHYSIOLOGY OF THE GI TRACT

The GI system depends on the coordinated efforts of several organs for normal function. These organs include the oropharynx, esophagus, stomach, small intestine, liver, gallbladder, pancreas, large intestine, rectum, and anus.

The two main functions of the GI tract are digestion and absorption of nutrients and fluids, as well as elimination. Digestion is the process by which macronutrients (carbohydrates, fats, proteins) and micronutrients are broken down to an extent such that they can be absorbed into the bloodstream. Absorption is the process by which products of digestion travel across the cells and paracellular spaces lining the GI tract, and ultimately into the vascular or lymphatic circulation. Solids, liquids, and any materials that are not absorbed are passed out of the body through the process of elimination.

Digestive, absorptive, and elimination functions are supplanted by motility and secretory functions of the GI tract. The layers of the GI tract starting from the inner luminal side to the outermost layer include mucosa, submucosa, muscularis, and serosa. The mucosa includes epithelial enterocytes that directly participate in digestion and absorption. The muscularis layer is comprised of circular and longitudinal smooth muscles that carry out motility functions of the GI tract. Myenteric and submucosal plexuses are found within the muscularis layer and submucosal layer, respectively. These plexuses are the control center of the GI nervous system and help regulate sensory, motility, and secretory functions. In addition to the network of neurons that make up the enteric nervous system, the central nervous system can also process signals coming from the intestines as well as provide signals that affect the activity of the GI tract.

There remains much to be learned about the motility functions of the GI tract. GI motility has two main functions. The first is propulsion or peristalsis, which moves liquid and solid material along different parts of the tract. Motility also contributes to mechanical breakdown and mixing of solid materials that makes food particles more accessible for digestion by digestive juices and enzymes. It is believed that the interstitial cells of Cajal, which is part of the intrinsic GI nervous system, play an essential role in regulating motility by acting as the pacemaker cells of the GI tract. The pacemaker function of the interstitial cells of Cajal are analogous to the pacemaker functions of the sinoatrial node of the heart.

The function of the GI tract is closely regulated by a complex interplay of various hormones. Some of these hormones can be classified by their endocrine, neurocrine, or paracrine functions (Barrett, 2014). Endocrine hormones include gastrin, cholecystokinin, motilin, secretin, ghrelin, and glucose-dependent insulinotropic peptide. Neurocrine hormones include acetylcholine, vasoactive intestinal polypeptide, substance P, nitric oxide, cholecystokinin, 5-hydroxytryptamine, somatostatin, and calcitonin gene–related peptide. Examples of paracrine hormones include histamine, prostaglandins, somatostatin, and 5-hydroxytryptamine (Table 8.1).

Oral Pharynx

In children and adults, digestion begins in the mouth with the act of chewing. Digestion of a small percentage of carbohydrates begins in the mouth by the actions of salivary amylase from the parotid glands (Hall & Guyton, 2016). Since infants are edentulous and rely largely on breast milk or formula feedings, chewing does not play an important role in digestion for infants. However, the act of sucking and swallowing effectively and safely requires a complex orchestration between the central and peripheral nervous systems and oropharyngeal musculature. Dysfunction of any of these

TABLE 8.1

SUMMARY OF SELECT HORMONES AND CHEMICALS THAT AFFECT GASTRIC FUNCTION

Product	Source	Functions
Hydrochloric acid	Parietal cell	Digestion by hydrolysis, immunologic by sterilization of meal
Intrinsic factor	Parietal cell	Vitamin B_{12} transport and absorption
Pepsinogen	Chief cell	Initial protein digestion
Mucus, bicarbonate	Surface mucus cell; production stimulated by prostaglandin	Protection of gastric mucosa from acid injury
Histamine	Enterochromaffin cells	Regulate gastric secretion
Gastrin	G cells in gastric antrum, duodenum, and pancreas	Regulate gastric secretion
Gastrin-releasing peptide	Nerves	Regulate gastric secretion
Acetylcholine	Neurotransmitter at neural junctions	Regulates gastric secretion
Somatostatin	Delta cells found in pyloric antrum, duodenum, pancreatic islet cells	Multiple systemic functions including suppression of gastrointestinal hormones (gastrin, cholecystokinin, secretin, motilin, gastric inhibitory polypeptide, vasoactive intestinal peptide)

Source: Adapted from Barrett, K. E. (2014). *Gastrointestinal physiology*. New York, NY: McGraw-Hill.

structures may result in reduced or unsafe oral intake. Saliva produced by various glands serves an important role in the lubrication of the oral and esophageal mucosa, thereby facilitating comfortable passage of materials through the oral cavity and esophagus.

Swallowing is the first step in digesting and absorbing ingested fluids and solids. Swallowing begins when liquid or solid substances are detected by sensory nerves in the pharynx. These sensory impulses are transmitted via the trigeminal and glossopharyngeal nerves to the swallowing center in the brain, where the signals are processed. The swallowing center in turn coordinates muscle function by sending motor impulses to the pharynx and upper esophagus via cranial nerves 5, 9, 10, and 12 (Hall & Guyton, 2016). Breathing is inhibited during the process of swallowing to prevent aspiration of materials into the respiratory tract. Congenital or acquired dysfunction of the neural or muscular architecture involved in the swallowing process can lead to transient or chronic feeding problems.

Esophagus

The esophagus serves as a conduit for liquids and solids from the mouth to the stomach. It has autonomic motor activity that generates esophageal peristalsis sufficient to propel solids and liquids throughout its length (Hall & Guyton, 2016). Upper and lower esophageal sphincters regulate entry into the esophagus and stomach. Inappropriately high or low pressures generated at the lower esophageal sphincter can result in pathologic conditions such as achalasia or GER disease, respectively.

Stomach

The stomach is where a significant part of digestion begins. Gastric acid produced by parietal cells contributes to the digestive process along with gastric enzymes such as pepsinogen, which begins the breakdown of proteins. Parietal cells also produce intrinsic factor that plays a central role in the absorption of vitamin B_{12} in the terminal ileum. Even in patients who are treated for acid-related conditions, the physiologic importance of acid in digestion and defense against infectious agents needs to be recognized.

In addition to chemical and enzymatic digestion, the intrinsic motor activity of the stomach generates mechanical forces that churn, grind, and mix fluids and solids. These actions contribute to the process of physically breaking down foods to smaller particles. This mechanical breakdown increases the surface area of food boluses, making it more accessible for subsequent chemical and enzymatic digestion. In addition to regulating the rate at which fluids move from the stomach into the small intestine, the pyloric sphincter muscle helps ensure that food particles exiting the stomach are small enough to be acted on by the digestive enzymes and juices of the small intestine. Abnormalities in the neuromuscular function of the stomach can alter gastric motility, which may result in delayed gastric emptying. Delayed gastric emptying plays a role in other GI conditions such as GER and feeding problems.

The lining of the stomach is normally protected from the acidic environment by a mucus layer formed by mucinous film overlying the gastric mucosa. Sandwiched in between this mucus layer and gastric mucosa is a microenvironment containing bicarbonate ions. The mucinous film serves as the first line of defense against acid injury. Any acid that is able to penetrate this layer is neutralized in the bicarbonate microenvironment. Prostaglandins, leukotrienes, and thromboxane are chemical compounds produced by the arachidonic acid pathway. Collectively, these compounds participate in the regulation of numerous physiologic functions including thrombosis, inflammation, temperature regulation, and production of the mucinous layer that protects the stomach. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen are effective in treating fever, pain, and inflammation by blocking enzymes in the arachidonic acid pathway. While the antipyretic and analgesic affects are desired, the collateral reduction on prostaglandin synthesis also reduces the production of the mucosa layer, predisposing the gastric mucosa to acid injury.

Small Intestine

The small intestine is the site of absorption for the majority of liquids, macronutrients, and micronutrients. Digestion continues in the small intestine as the food bolus exiting the stomach is exposed to additional digestive enzymes and secretions from the hepatobiliary system and pancreas.

The liver performs many important metabolic functions that affect all other organ systems. Examples of these functions range from the metabolism of carbohydrate, fats, and proteins to the metabolism of medications. Another key function of the liver is the production of bile. After it is produced in hepatocytes, bile must make its way through the hepatobiliary duct system, which terminates in the first portion of the duodenum. Once it enters the duodenal lumen, bile serves an essential role in the transport of fats and fat-soluble vitamins to the surface of enterocytes, where they are subsequently absorbed. Smaller fat molecules can diffuse across the enterocyte membrane, while larger fat molecules require dedicated transmembrane transporters. Abnormalities in the production, processing, or flow of bile can result in a variety of congenital hepatobiliary abnormalities. Hepatobiliary diseases most often present with jaundice and failure to thrive due to malabsorption. Depending on the stage of the condition, the size of the liver and spleen may be variable. Reabsorption of bile acids in the terminal ileum followed by hepatic recycling accounts for over 90% of the bile pool.

Pancreatic exocrine function produces various enzymes including lipases, amylases, and peptidases that are responsible for breaking down fats, carbohydrates, and proteins, respectively. The pancreas also produces bicarbonate, which neutralizes acid coming from the stomach, protecting the intestinal mucosa from acid-associated injury. At the enterocyte surface, disaccharidases further break down carbohydrates into monosaccharides that can then enter the cell via dedicated transmembrane transport proteins. Amino acids, dipeptides, and tripeptides also use dedicated membrane transporters for absorption into enterocytes. Congenital or acquired causes that affect the architecture or function of these enterocyte surface enzymes can result in malabsorption.

The absorption of water is mainly driven by osmotic gradients that are initially established by the absorption of sodium and glucose. Water is absorbed by following the osmotic gradient through transmembrane and paracellular transport proteins. This mechanism helps explain the basis for including glucose and salts in commercial rehydration solutions.

Colon

The function of the colon is threefold: (1) maintenance of fluid and electrolyte balance, (2) formation of fecal matter, and (3) defecation.

The colon provides the body its last opportunity to reabsorb water and electrolytes. This process helps maintain fluid and electrolyte homeostasis, and serves to concentrate and solidify colonic luminal contents, culminating in stool formation. The major electrolytes included in this process are sodium, potassium, chloride, hydrogen, and bicarbonate. Transmembrane proteins on the apical and basolateral colonic cell surfaces facilitate the movement of electrolytes. Electrolyte movement, in turn, establishes electrochemical gradients that become the driving force for water resorption or secretion. Conditions in which the function of electrolyte transport mechanisms or colonic anatomy is compromised can clinically result in profuse diarrhea, as well as water and electrolyte imbalance.

The process of defecation requires coordination between the local enteric nervous system, central nervous system, abdominal musculature, internal anal sphincter, and external anal sphincter. In healthy individuals, the urge to defecate begins after a fecal bolus in the rectum accumulates and enlarges to a threshold size that leads to activation of mechanical stretch receptors. Activation of these mechanical receptors triggers a reflex relaxation of the internal anal sphincter. At the appropriate moment, under the individual's own volition, the external anal sphincter is relaxed. Coordination of external anal sphincter relaxation with an increase in intra-abdominal pressure from contraction of abdominal muscles facilitates the expulsion of stool.

Congenital or acquired conditions that result in the dysfunction of any of the neurologic or muscular processes can lead to disorders of defecation. Hirschsprung's disease (HD) is an example where dysfunction in local neuromuscular control mechanisms results in the inability to evacuate stool normally. The complexity of the coordination needed for normal defecation helps to explain the seemingly monumental effort infants exhibit in straining when they defecate.

Genetic Syndromes. A syndrome is a group of signs or symptoms that consistently occur together, or a condition characterized by a set of associated symptoms. Many syndromes occur because of a genetic or chromosomal abnormality. Humans have 23 pairs of chromosomes, or 46 in all. Babies with chromosomal conditions have a problem in one or more of their chromosomes. Chromosomes comprise mainly of DNA, the instructions for making proteins, and genes, the building blocks of heredity. Proteins serve essential structural and functional roles throughout the body, but sometimes a mutation—a change in a gene or genes—alters the gene's instructions for making a protein such that the protein does not function properly or is missing entirely. These mutations are the basis of genetic disorders. Because one chromosome in each pair comes from the mother and the other from the father, inherited gene mutations can be from one or both parents. Abnormal genes or chromosomes may result in structural or functional abnormalities in the GI tract as well as other systems. Table 8.2 is a summary of selected syndromes associated with GI abnormalities.

Diagnostic Modalities. The care of neonates has vastly improved with advances in technology. However, many neonates can be evaluated using simple and noninvasive diagnostic modalities. The following spectrum of diagnostic modalities is usually available in centers with neonatal intensive care units for the management of GI problems.

Nasogastric Tube

Nasogastric (NG) tube placement can be used for diagnostic purposes in two situations. The first is to check for patency of the nares and esophagus if anatomic anomalies are suspected. If an esophageal anatomic anomaly is present, the NG tube cannot be advanced into the stomach as evident by plain radiography. A second diagnostic application of NG tube is collection of a gastric aspirate sample. A gastric aspirate sample may be necessary to check for the presence of blood and to determine the blood's origin (infant or mother, via the Apt test). A gastric aspirate sample may also be used to check the gastric pH to guide acid suppression therapy; the normal gastric pH is less than 2, and effective acid suppression is achieved if the pH is greater than 4.

If an NG tube is required for diagnostic purposes, usually a 4 French tube is inserted through the nares (or the oral cavity in some cases) and advanced to a premeasured length.

Stool Studies

Stool is an excretory product of the GI tract composed of GI secretions, bile and pancreatic fluid, undigested/unabsorbed food, and microbes. Stool examination is helpful in identifying the presence and possible causes of GI pathology.

Basic clinical observations and examination of stool can yield important initial diagnostic clues. Timing of the passage of the first meconium stool should be noted, as delayed passage of meconium (beyond 24 hours) is suggestive of a lower colonic obstruction like

TABLE 8.2

COMPARISON OF GASTROINTESTINAL MANIFESTATIONS OF SELECTED GENETIC SYNDROMES

Syndrome	GI Problem	Cleft Lip/ Palate	Omphalocele	Malrotation	Imperforate Anus	Tracheoesophageal Fistula	Hirschsprung's Disease	Pyloric Stenosis	Duodenal Atresia	Liver Disease	Pancreatic Disease

HD or anorectal malformation. Stool color results from bile that is altered by colonic bacteria; normal stool color is yellow to brown. Green stool is usually seen in patients with diarrhea (rapid transit). Bright red stool implies possible bleeding from the colon or anus, while dark red, maroon, or black stool suggests that the source of blood is in the small bowel or stomach. Lighter colored (acholic) or pale stool implies decreased bile in the bowel as seen in patients with biliary obstruction (biliary atresia) or cholestasis.

Several stool tests can help as screening tests for GI tract pathology. Occult blood and white blood cells (eosinophils) are present in patients with cow or soy milk-induced allergic colitis. A stool pH of less than 5.5 is seen in carbohydrate or fat malabsorption. The presence of more than one reducing substance is suggestive of carbohydrate (except sucrose) malabsorption. Stool calprotectin and lactoferrin are used as markers of inflammation in the GI tract. Their usefulness as screening markers in infants with enterocolitis (necrotizing enterocolitis, NEC, or allergic) is under investigation (Nakayuenyongsuk et al., 2018; Pergialiotis et al., 2016).

Stool cultures test for bacterial pathogens in cases of diarrhea. In neonates, stool should not be routinely tested for the *Clostridium difficile* toxin, as healthy neonates can become colonized by *C. difficile* in the first few days of life (Lees, Miyajima, Pirmohamed, & Carrol, 2016).

Fecal elastase 1 (FE1) is a useful marker of exocrine pancreatic function (Lüth et al., 2001). FE1 is usually low in meconium and reaches normal levels by day 3 in term newborns and by 2 weeks in infants born before 28 weeks of gestation. The FE1 level is a useful adjunct diagnostic test for pancreatic insufficiency in patients suspected of having cystic fibrosis (CF).

Radiologic Studies

Radiologic studies of the GI tract are performed to look for anatomic abnormalities, obstruction, or perforation in babies presenting with vomiting, abdominal distension, constipation, or a catastrophic illness like shock. The GI tract is filled with fluid at birth, but as the infant swallows air after delivery, air travels through the gut rapidly, filling the stomach within 30 minutes and reaching the distal small bowel by 4 hours and rectum by 6 to 8 hours. In cases of obstruction, the portion of the intestine distal to the obstruction remains airless and the portion of the intestine proximal to the obstruction becomes dilated. As the infant continues to swallow air, the proximal intestine may become very dilated, causing a large bubble-like appearance on plain radiographs.

Plain radiographs of the chest and abdomen in a supine or upright position are a very useful initial diagnostic modality in patients with suspected GI tract obstruction. The absence of air in the stomach is suggestive of esophageal atresia. A dilated stomach in conjunction with the absence of air in the small intestine is suggestive of duodenal obstruction. The absence of rectal air is suggestive of intestinal obstruction; cross-table lateral plain radiographs may be more helpful to look for air in the rectum. A left lateral decubitus plain radiograph is recommended to look for free intraperitoneal air if perforation is suspected.

An upper GI series is performed using contrast (barium or Gastrografin) that is either swallowed or delivered by a NG tube before a series of radiographs are taken. An upper GI series can be considered in babies who present with vomiting, abdominal distension, or poor growth. Results of an upper GI series may be diagnostic for pyloric stenosis, intestinal malrotation, or duodenal obstruction. An upper GI series often shows reflux of gastric contents back into the esophagus; however, the study cannot distinguish between physiologic versus pathologic reflux. In addition to diagnostic purposes, the upper GI contrast study can also be used to define anatomy prior to surgical intervention such as gastrostomy tube placement or fundoplication. The study usually requires the baby to be fasting for at least one feeding (4–6 hours), and the examination may last 30 minutes. A small bowel series examination may take up to 4 to 6 hours. In cases of suspected perforation, water-soluble contrast (Gastrografin) should be used.

Contrast enema examination is performed using barium or Gastrografin to evaluate the large intestine in suspected cases of malrotation, small left colon, HD, or obstruction by meconium plug. Contrast enema examination should be done prior to upper GI series, as contrast from the upper GI examination may take several days to clear. If a patient already has had an upper GI series, then a gentle saline enema may help clear contrast faster; otherwise, no special preparation is needed prior to contrast enema. A saline enema may be used after a contrast enema if the contrast is not cleared.

Ultrasonography is a noninvasive test that is the modality of choice for diagnosing pyloric stenosis or intestinal duplication cyst, and evaluating the gallbladder and extrahepatic biliary system. Doppler sonography may be used to diagnose portal vein thrombosis.

Nuclear medicine scan or scintigraphy is done by performing imaging after a radioactive tracer is ingested or injected intravenously. A gastric emptying scan uses technetium-tagged formula fed to the infant and may be used to detect aspiration (with swallowing or from gastric reflux) and measures gastric emptying time in patients with feeding intolerance. A Meckel's scan is performed by intravenous injection of Tc-99m pertechnetate, which avidly accumulates in gastric mucosa, and is the study of choice in patients suspected of having a Meckel's diverticulum causing lower GI bleeding. A hepatobiliary hydroxy iminodiacetic acid (HIDA) scan, also known as hepatobiliary scintigraphy, is performed by administering radioactive tracer intravenously and obtaining images over 4 hours and then 24 hours later. The HIDA scan is used to evaluate liver, gallbladder, and bile duct pathology. At some institutions, phenobarbital is given for 5 to 7 days prior to a HIDA scan to improve accuracy (Kwatra et al., 2013).

Esophageal pH Probe

An esophageal pH probe test is performed by placing a thin, flexible electrode with one or two pH sensors in the distal esophagus; data is collected by a portable recorder. After 24 to 48 hours, the probe is removed, and data are analyzed. The diagnosis of acidic GER depends on a complex scoring system based on the number of reflux episodes, the number of episodes greater than 5 minutes, the duration of longest episode, and, most importantly, the percentage of time in reflux. It can be used to diagnose GER. It is also used to document the association of any symptom with reflux; symptoms that may be associated with reflux include apnea, bradycardia, oxygen desaturation, cough, or irritability. Since formula neutralizes acid, this test has to be done while the patient is taking bolus feedings 3 hours apart. The patient must also be off any acid-suppressive and promotility treatment for 1 to 2 days preceding, and during the study period. In cases where an esophageal pH probe study has to be done while the patient is receiving continuous feeding, or acid-suppressive treatment cannot be stopped, the formula can be acidified by adding citric acid, or an impedance probe can be used. An impedance probe detects any reflux, acidic or alkaline, but it is thicker than a standard pH probe.

Endoscopy

Diagnostic and therapeutic endoscopy is now feasible even in micropreemies with the rapid evolution of fiber optics and digital imaging processors. Endoscopy can be performed at bedside; small babies may need to be intubated. Table 8.3 shows the common indications for endoscopy in infants.

TABLE 8.3

INDICATIONS FOR ENDOSCOPY

Upper Endoscopy	
Diagnostic Indication	**Entities Diagnosed**
Persistent vomiting without obstruction Hematemesis/upper gastrointestinal bleeding Chronic diarrhea	Esophagitis, gastritis, gastric mucosal hypertrophy, ulcer, small bowel villous abnormalities
Therapeutic Indications	**Procedure Performed**
Feeding problems Upper gastrointestinal bleeding Dysphagia Esophageal stricture (after TE fistula repair)	Percutaneous Endoscopic Gastrostomy (PEG) tube placement Control of bleeding Dilation of stricture
Colonoscopy	
Diagnostic Indications	**Entities Diagnosed**
Hematochezia Constipation	Colitis (allergic) Hirschsprung's disease (rectal biopsy)

TRACHEAL ESOPHAGEAL FISTULA AND ESOPHAGEAL ATRESIA

Background

Esophageal atresia (EA) is defined as a complete interruption in continuity of the esophagus. Tracheoesophageal fistula (TEF) is a pathologic connection between the esophagus and trachea. The five major types of TEF are summarized in Figure 8.1.

Other congenital anomalies that may be associated with EA and TEF include vertebral, intestinal atresia, anorectal malformations (ARM), cardiac, renal, and limb anomalies. VACTERL (vertebral, anorectal, cardiovascular, tracheoesophageal, renal, and limb anomalies) syndrome is diagnosed when three or more of these anomalies are present. Approximately 19% of babies with EA and TEF have VACTERL syndrome (Bruch, Kunisaki, & Coran, 2016). Five percent of these neonates will also have chromosomal anomalies such as trisomy 13, 18, and 21. Other conditions that may be associated with EA and TEF include CHARGE (coloboma, heart defect, atresia choanae, retarded growth and development, genital abnormality, and ear abnormality) syndrome, Potter's syndrome, and pyloric stenosis (Bruch et al., 2016).

The survival rate of infants with EA with or without TEF based on birth weight (BW) and cardiac anomalies has been studied. Infants with no cardiac anomalies and a BW of greater than 2,000 g have a 100% survival rate, while infants with a BW of less than 2,000 g were found to have an 82% survival rate. Infants with a major cardiac anomaly and a BW of greater than 2,000 g have a 72% survival rate, while infants with a BW of less than 2,000 g had a survival rate of 27% (Bruch et al., 2016; Okamoto et al., 2009).

Diagnosis

Most neonates with EA and TEF present soon after birth with difficulty swallowing even their normal production of saliva. The swallowing problems can result in choking, coughing, gagging, and/or cyanosis, particularly during feedings. Difficulty with advancing a NG tube should raise suspicion of esophageal pathology, and be followed by a plain radiograph that includes views of the neck, chest, and abdomen. Coiling of the NG tube tip in the vicinity of the proximal esophagus supports the diagnosis of EA. Absence of bowel gas on plain abdominal radiograph is suggestive of EA without a distal fistula, while the presence of gas throughout the small and large bowel suggest a distal TEF. Further mapping of a proximal fistula can be done by radiographic contrast study or rigid bronchoscopy depending on institutional availability. Neonates who have TEF without EA (H-Type) may present beyond the newborn period (Bruch et al., 2016). In these babies, a NG tube may terminate in the stomach, but the baby will have persistent coughing and choking with feeds.

Additional findings may be associated with EA and TEF. Limb and anorectal anomalies may be observed on physical examination. Vertebral anomalies can be detected by plain radiography. Abdominal ultrasonography and echocardiogram may reveal renal abnormalities or a tethered spinal cord, and cardiac anomalies, respectively.

Management

Management should be in collaboration with a pediatric surgery team. Prior to surgery, steps should be taken to minimize the risk of oral pulmonary aspiration. The neonate should be placed supine with the head elevated at a 30° to 45° angle. An oral or nasal esophageal tube should be placed for continuous low suction. Oral secretions can be thick and sticky, causing frequent clogging of the suction tubing. Thus, tubes may need to be routinely flushed or changed. **Quality and Safety: Patency of the tube should be checked if symptoms of increased choking, gagging, or respiratory problems arise. Intravenous broad-spectrum antibiotics should also be started.** Specific details on the variations in surgical approaches have been well described (Bruch et al., 2016; van der Zee, Tytgat, & van Herwaarden, 2017).

Postoperatively, the baby should be managed with parenteral nutrition (PN), antibiotics, and acid suppression. Anastomoses site leakage can be a complication after surgery, and should be considered if there are acute clinical or vital sign changes. If a chest tube is in place, anastomoses site leakage may present as persistent or increased drainage. Frequent oropharyngeal suctioning and elevating the head of the bed will reduce the risk of aspiration. For oral suctioning, the catheter should be inserted to a predetermined depth that is well above the surgical site to avoid any potential trauma. The timing and initiation of gastric feedings should be determined in collaboration with the surgical team. An esophagram on postoperative days 5 to 7 can be considered to look for anastomotic leaks prior to starting oral feedings. Infants who have a gastrostomy tube or a transanastomotic tube ending in the stomach can be fed 2 to 3 days after surgical repair (Bruch et al., 2016).

Postoperative complications may include GER (40%–70%), anastomoses site leak (17%), anastomosis site stricture (40%–50%), fistula recurrence (5%–12%), and esophageal dysmotility (75%–100%; Berseth & Poenaru, 2005; Kovesi & Rubin, 2004).

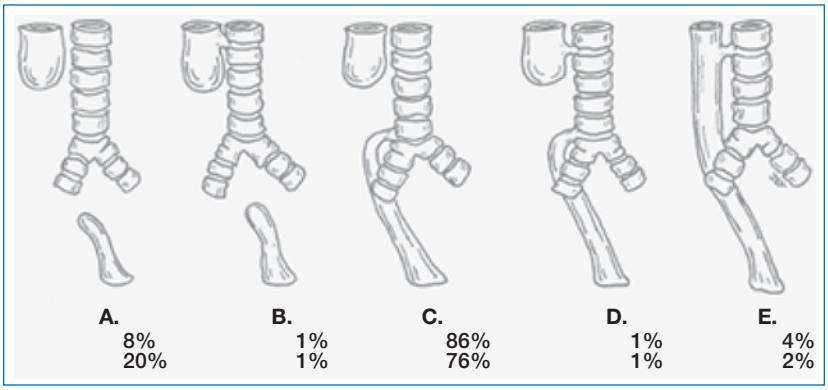

FIGURE 8.1 Diagram of the main types of esophageal atresia (EA) with or without a tracheoesophageal fistula (TEF). Type A is EA without a TEF and is often called pure EA. Shown are the blind upper and lower esophageal pouches next to the ringed windpipe (trachea) and the branches (bronchi) that lead to each lung. Type B has a connection (fistula) between the upper pouch and the trachea (a TEF). Type C is by far the most common form of EA and has a fistula between the lower esophagus and the trachea (one form of TEF) with a blind upper pouch. A rare form (1%) is type D with two TEFs, one between both the upper and lower esophageal segments and the trachea. Type E has only a TEF and no EA. This is usually referred to as an H- or N-shaped fistula and may be 2% to 4% of this group. The H-fistulas are divided surgically, and nothing further needs to be done to the esophagus, which is intact and reaches normally to the stomach.

GASTROESOPHAGEAL REFLUX

Background

GER is defined as the passage of gastric contents into the esophagus with or without regurgitation and vomiting (Rosen et al., 2018). In contrast, gastroesophageal reflux disease (GERD) is when GER leads to troublesome symptoms that affect daily functioning and/or result in complications (Rosen et al., 2018). Table 8.4 lists some of the symptoms and signs that may suggest GERD. It is often a challenge to distinguish between GER and GERD in infants, as there is no consistently reliable test that has been routinely recommended to diagnose GER/GERD (Rosen et al., 2018). The diagnosis therefore most often relies on clinical judgment. Since the common symptoms of GER are nonspecific, conditions other than GER should also be considered in evaluating any infant (Table 8.5).

Most episodes of GER are normal or physiologic, and usually go unnoticed. The precise prevalence of GER and GERD in infants is unclear. Based on esophageal pH monitoring studies, healthy infants may have up to 31 episodes of gastroesophageal acid reflux a day (Vandenplas, Goyvaerts, & Helven, 1991). The same study suggests that less than 10% of infants and children have GERD.

Three physiologic strategies limit GER and the development of GERD (Vandenplas & Hassall, 2002). First is the anatomic antireflux barrier that comprises the lower esophageal sphincter (LES), the diaphragmatic pinchcock, and the angle of His. These anatomic structures form a physical barrier that limits the frequency and severity of GER events. It is thought that inappropriate transient lower esophageal sphincter relaxation (TLESR) is the primary factor responsible for GER. The second physiologic strategy that limits the complications of GER is esophageal peristalsis and clearance, which removes any gastric content that enters the esophagus as a result of GER. Third is the epithelial layer architecture, including a protective mucous layer and tight epithelial cell junctions, which helps to reduce the esophageal injury that can result from contact with gastric contents. Compromise of one or more of these defense strategies can result in the symptoms or complications of GERD (Vandenplas & Hassall, 2002).

TABLE 8.4

CLINICAL PRESENTATION THAT MAY SUGGEST GERD

Symptoms	Signs
General	
• Persistent crying or irritability • Poor growth • Dystonic head posturing (Sandifer syndrome) • Sleeping problems	• Anemia
Gastrointestinal	
• Recurrent regurgitation • Hematemesis • Dysphagia • Feeding difficulties	• Esophagitis
Airway	
• Wheezing • Stridor • Cough • Hoarseness • Asthma refractory to therapy	• Apnea • Brief resolved unexplained events • Aspiration pneumonia • Recurrent pneumonias

TABLE 8.6

KEY HISTORY QUESTIONS IN EVALUATING INFANT GER/GERD

Feeding and diet history	• Duration of each feeding • Interval between feedings • Volume of each feed • Current and past formula(s) used • Method for mixing formula • Maternal diet history if infant using breast milk
Pattern of regurgitation, spitting up, or vomiting	• Nocturnal • Immediately post prandial • Long after meals • Undigested versus digested • Presence of red or brown material to suggest hematemesis
Family medical history	• Food allergies/intolerance • Environmental allergies • Asthma • Gastrointestinal problems • Metabolic or neurologic conditions
Social history	• Family psychosocial stressors • Mood and affect of caretakers • Exposure to tobacco
Medical history	• Concurrent medical problems • Other symptoms and signs, including red flags • Growth chart parameters—weight, length, head circumference

GER, gastroesophageal reflux; GERD, gastroesophageal reflux disease.

Pediatric gastroesophageal reflux clinical practice guidelines: Joint recommendations of the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition. *Journal of Pediatric Gastroenterology and Nutrition, 66*(3), 516–554. doi:10.1097/MPG.0000000000001889

Diagnosis

For most infants with recurrent regurgitation or spitting up, a detailed history (Table 8.6) and physical examination with attention to warning symptoms and signs (Table 8.7) that may suggest other causes is typically sufficient to make a clinical diagnosis of uncomplicated GER (Rosen et al., 2018). Neonates and infants in the hospital setting with GERD may pose a greater diagnostic challenge, as some of the symptoms and signs may be nonesophageal. Examples include apnea, bradycardia, and cyanosis during or unrelated to feedings.

Despite the frequency with which nonesophageal symptoms such as irritability and apnea trigger further investigation for or treatment of GER/GERD, a clear cause and effect relationship has not been well established (Abu Jawdeh & Martin, 2013; Heine, Jordan, Lubitz, Meehan, & Catto-Smith, 2006; Ramaiah, Stevenson, & McCallion, 2005; Zimbric, Bonkowsky, Jackson, Maloney, & Srivastava, 2012). Indeed, while proton pump inhibitors (PPIs) are the most effective acid suppression agents, several well-conducted studies in infants have not shown PPIs to be of benefit in reducing clinical symptoms (Davidson et al., 2013; Orenstein, Hassall, Furmaga-Jablonska, Atkinson, & Raanan, 2009; Writing Committee for the American Lung Association Asthma Clinical Research Centers, 2012).

Some infants who have symptoms of GER/GERD may require additional testing. However, there are no clear indications as to when further testing may be helpful. Broad guidelines for when to consider testing may include infants who have GER before the age of 1 week, infants who have red flag signs or symptoms, and infants with unexplained extraesophageal manifestations that may be related to GER (Rosen et al., 2018; see Table 8.7). Particular areas of ongoing controversy include the relationship of GER and respiratory disorders, and the relationship between GER and distressed behaviors in infants (Abu Jawdeh & Martin, 2013; Zimbric et al., 2012).

The current battery of tests available to evaluate for GER/GERD is outlined in Table 8.8. Routine testing beyond a thorough history and physical examination is typically not recommended unless red flag symptoms or signs are present (Rosen et al., 2018).

The 24 to 48 hour esophageal pH monitoring test with or without impedance is currently the only testing modality that enables correlation of intraesophageal events with clinical symptoms (Salvatore & Vandenplas, 2016). The test involves inserting a nasal esophageal catheter that remains in place for 24 to 48 hours. In the case

TABLE 8.7

RED FLAG SYMPTOMS AND SIGNS THAT SUGGEST DISORDERS OTHER THAN GERD

Symptoms and Signs	Comments
General • Weight loss or inappropriate weight gain • Lethargy • Fever • Excessive irritability/pain • Change in character or quantity of urine	• Suggesting various conditions, including systemic infections • May suggest urinary tract infection
Neurologic • Bulging fontanel/rapidly increasing head circumference • Seizures • Macrocephaly/microcephaly • Lethargy	• May suggest increased intracranial pressure—e.g., meningitis, brain tumor, or hydrocephalus
Gastrointestinal • Persistent forceful vomiting • Vomiting not associated with feedings • Bilious vomiting • Hematemesis • Chronic diarrhea • Rectal bleeding • Abdominal distension	• May suggest hypertrophic pyloric stenosis • May suggest increased intracranial pressure • Regarded as symptom of intestinal obstruction. Possible causes: Hirschsprung's disease, intestinal atresia, or midgut volvulus or intussusception • Suggests a potentially serious bleed from the esophagus, stomach, or upper GI tract, possibly GERD-associated, occurring from acid peptic disease, Mallory–Weiss tear, or reflux esophagitis • Indicative of obstruction, dysmotility, or anatomic abnormalities

TABLE 8.8

SELECTED STUDIES TO CONSIDER IN NEONATES AND INFANTS WITH SUSPECTED GERD

Study	What the Study Can Help Diagnose or Determine	Comments
Upper GI barium contrast	• Anatomic abnormalities of the esophagus, stomach, and upper small bowel • E.g., gastric outlet obstruction, small bowel obstruction, small bowel malrotation and volvulus, pyloric stenosis, esophageal stricture, esophageal extrinsic compression, duodenal stenosis/web, hiatal hernia, tracheal esophageal fistula	• Insufficient evidence to support use of barium contrast study for the primary diagnosis of GERD
Ultrasound	• Pyloric stenosis, hydronephrosis, ureteropelvic obstruction, gallstones	• No evidence to support use of ultrasound for the diagnosis of GERD
EGD	• Acid-related esophagitis, eosinophilic esophagitis, peptic ulcer disease, gastritis, duodenitis, *Helicobacter pylori* • Hiatal hernia	• Insufficient evidence to support use of EGD for the diagnosis of GERD • Based on expert opinion, EGD with biopsies can be considered to assess complications of GERD when an underlying mucosal disease is suspected or prior to escalating therapy
Scintigraphy	• Delayed gastric emptying, gastroparesis	• Insufficient evidence to support use to establish a diagnosis of GERD

(*continued*)

TABLE 8.8

SELECTED STUDIES TO CONSIDER IN NEONATES AND INFANTS WITH SUSPECTED GERD (*continued*)

Study	What the Study Can Help Diagnose or Determine	Comments
PPI trial	• Five trials in preterm and full-term infants show reduction in symptoms	• No evidence to support empiric trial of PPI for the diagnosis of GERD in infants
24- to 48–hour esophageal pH with or without impedance monitoring	• Correlation of GER episodes with clinical symptoms and signs (e.g., apnea, bradypnea, bradycardia, spitting up, cough, irritability) • Detection of acid- (pH) and nonacid- (impedance) related GER episodes • Efficacy of acid suppression therapy	• Insufficient evidence to support the routine use of pH and/or impedance monitoring for the diagnosis of GER in infants and children

EGD, esophagogastroduodenoscopy; GERD, gastroesophageal reflux disease; PPI, proton pump inhibitor.

Pediatric gastroesophageal reflux clinical practice guidelines: Joint recommendations of the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition. *Journal of Pediatric Gastroenterology and Nutrition, 66*(3), 516–554. doi:10.1097/MPG.0000000000001889

of pH monitoring, the catheter has sensors that detect changes in pH. The advantage of a dual pH/impedance catheter is that impedance sensors will detect any movement of air or liquid, regardless of pH. Thus, GER that is nonacidic will also be detected (Salvatore & Vandenplas, 2016). Since both acidic and nonacidic refluxate may contribute to clinical symptoms, dual monitoring may offer additional helpful information compared to pH monitoring alone.

Management

Beyond regurgitation and vomiting, the symptoms often attributed to GER/GERD are nonspecific and insensitive for establishing a diagnosis. This diagnostic uncertainty makes the decision whether to treat and how to treat GER/GERD equally challenging. Treatment options can be divided into pharmacologic and nonpharmacologic approaches.

Nonpharmacologic strategies should be considered in most infants with GER/GERD (Craig, Hanlon-Dearman, Sinclair, Taback, & Moffatt, 2004; Horvath, Dziechciarz, & Szajewska, 2008; Vandenplas & Sacre, 1987). Nonpharmacologic approaches include thickening feeds, modifying feeding volumes, elimination of cow's milk protein, and position changes (Bautista, Fullerton, Briseno, Cui, & Fass, 2004; Rosen et al., 2018; see Table 8.9). Despite the possible benefits to positioning in the treatment of GER, only the supine position is recommended by the National Health Service and the American Academy of Pediatrics as the safest position to reduce the risk of sudden infant death syndrome (SIDS; Moon, 2011).

Acid suppression therapy and prokinetic agents are two common medical management options. PPIs and histamine-2 receptor antagonists (H_2A) are the two most prescribed acid suppression agents. After reviewing the current evidence addressing the use of PPIs in infants, the GER guideline committee concluded that it is uncertain whether the use of PPIs or H_2As reduces crying/distress, visible vomiting/regurgitation, or signs and symptoms of GERD (Rosen et al., 2018). The working group subsequently recommended against the routine use of H_2A or PPI for the treatment of crying/distress or visible regurgitation in otherwise healthy infants. However, the same group determined that the current body of evidence does support the use of PPIs as first line for treating GERD-related erosive esophagitis (Rosen et al., 2018). Considering that few infants undergo endoscopy with biopsy, which is the gold standard for diagnosing erosive esophagitis related to GERD, clinicians are left with clinical symptoms as the main determinant whether acid suppression treatment is warranted.

If the decision is to proceed with treatment, a reasonable approach may be to begin with a time-limited trial with an H_2A agent. If there is no improvement in targeted symptoms, then a subsequent trial with a PPI can be considered. If target symptoms fail to improve or resolve with acid suppression therapy, the treatment should be discontinued. Practitioners should also be aware that while PPIs may effectively reduce esophageal acid reflux in neonates, they may not impact the symptoms associated with GERD (Davidson et al., 2013).

Prokinetic agents are a second class of drugs available to treat GER/GERD. Metoclopramide is one of the more commonly prescribed prokinetic agents in infants, although its effectiveness is far from satisfactory (Craig et al., 2004). Coupled with its unfavorable side effects profile including somnolence, irritability, galactorrhea, extrapyramidal reactions, and potentially permanent tardive dyskinesia, metoclopramide is not highly recommended in infants (Putnam, Orenstein, Wessel, & Stowe, 1992).

Over the past 10 years, there has been increasing use of erythromycin as prokinetic therapy. Erythromycin is an antibiotic that is also a motilin receptor agonist. Motilin is a physiologic hormone that increases GI motility when bound to the motilin receptor located throughout the GI tract. While there have not been sufficient studies for or against its effectiveness, there have been a limited number of studies to suggest that erythromycin ethylsuccinate (EES) may be helpful in some infants at reducing GER/GERD symptoms (Rosen et al., 2018).

For infants with GERD symptoms refractory to medical therapy, transpyloric tube feedings may be effective at improving feeding tolerance (Malcolm, Smith, Mears, Goldberg, & Cotten, 2009; Misra, Macwan, & Albert, 2007). Surgical intervention can be considered in rare cases in which medical management is not effective and the benefits of surgery outweigh the risks and potential long-term side effects (Rosen et al., 2018).

HYPERTROPHIC PYLORIC STENOSIS

Background

Hypertrophic pyloric stenosis (HPS) is the most common gastric surgical disorder in neonates (Seifarth & Soldes, 2016). HPS is characterized by progressive hypertrophy of the circular muscle that surrounds the gastric pylorus. The progressive hypertrophy culminates in a high-grade or complete gastric outlet obstruction (Seifarth & Soldes, 2016). The precise etiology and pathogenesis

TABLE 8.9

SUMMARY OF NONPHARMACOLOGIC OPTIONS FOR GER/GERD

Intervention	Comments	References
Thickened feedings	• May reduce observable regurgitation episodes, but may not affect the actual frequency of GER	Chao & Vandenplas, 2007; Corvaglia et al., 2006; Horvath et al., 2008; Iacono et al., 2002
Reducing feeding volumes	• Recommended based on expert opinion	• No RCT has looked at effects of reduced feeding volume
Elimination of cow's milk protein	• Some infants with cow's milk protein allergy may have regurgitation as their primary symptom • Trial of protein hydrolysate formula can be considered if CMPA is suspected (hematochezia, eczema, family history of allergic conditions) • Amino acid formulas should be reserved for infants with CMPA refractory to treatment with a protein hydrolysate formula	• No RCT specifically evaluating effects of eliminating CMP on GER • Some studies show reduced regurgitation in infants with CMPA treated with amino acid–based formula • For breastfed infants, eliminating cow's milk-containing products and beef from mother's diet can be considered
Positioning therapy	• Left lateral decubitus position may reduce total number of reflux episodes	Loots et al., 2014; Moon, 2011; Omari et al., 2004; Rosen et al., 2018

For each nonpharmacologic strategy, a minimum 2-week trial is recommended to assess for symptom improvement before considering other therapeutic options.

CMP(A), cow's milk protein (allergy); GER, gastroesophageal reflux; GERD, gastroesophageal reflux disease; RCT, randomized controlled trial.

Source: Adapted from Rosen, R., Vandenplas, Y., Singendonk, M., Cabana, M., DiLorenzo, C., Gottrand, F., . . . Tabbers, M. (2018). Pediatric gastroesophageal reflux clinical practice guidelines: Joint recommendations of the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition. *Journal of Pediatric Gastroenterology and Nutrition, 66*(3), 516–554. doi:10.1097/MPG.0000000000001889

of HPS is unclear. Several factors are thought to play a role in the development of HPS. There seems to a genetic predisposition based on studies demonstrating familial aggregation, first-born male predominance, and identification of several associated genetic loci (Olivé & Endom, 2019; Seifarth & Soldes, 2016).

Regional variations in the prevalence of HPS suggest environmental factors contribute to the development of HPS (Olivé & Endom, 2019). Other environmental factors that are thought to increase the risk for developing HPS include bottle feeding (McAteer, Ledbetter, & Goldin, 2013), maternal smoking (Svenningsson, Svensson, Akre, & Nordenskjöld, 2014), and exposure to macrolide antibiotics (Eberly, Eide, Thompson, & Nylund, 2015).

Diagnosis

Infants with HPS typically develop symptoms between 3 and 6 weeks of age. The predominant symptom is nonbilious forceful ("projectile") emesis that occurs almost immediately after feeding (Olivé & Endom, 2019). If the vomiting has gone on for some time, there may be evidence of brown coloration or blood streaks from vomiting-induced gastritis or esophagitis. The infant often exhibits a robust appetite even after vomiting episodes. The inability to tolerate feedings may result in dehydration, lethargy, and failure to thrive. Abdominal examination may reveal the hypertrophied pylorus as an olive-shaped mass at the lateral edge of the rectus abdominis muscle in the right upper quadrant of the abdomen (Olivé & Endom, 2019). Since adrenal crisis associated with congenital adrenal hyperplasia may also present with significant vomiting, examination for evidence of ambiguous genitalia should also be part of the physical examination (Olivé & Endom, 2019).

Laboratory abnormalities classically reveal hypochloremic, hypokalemic metabolic alkalosis (Olivé & Endom, 2019). The CBC is usually normal in infants with HPS. A mild unconjugated hyperbilirubinemia may also be present (Olivé & Endom, 2019). Abdominal ultrasound has a sensitivity and specificity of greater than 95% when performed by experienced technicians or radiologists (Niedzielski, Kobielski, Sokal, & Krakós, 2011). The diagnostic appearance on ultrasound is a target sign that represents the outer ring of low echo density musculature and the inner ring of high echo density mucosa (Seifarth & Soldes, 2016). Since HPS can evolve over time, a previous "normal" ultrasound should not preclude repeating the study if the infant's symptoms persist or worsen.

If ultrasonography is unavailable or inconclusive, an upper GI contrast study may be obtained. The most common signs on upper GI are an elongated and narrowed pyloric channel ("string" sign), two thin tracks of contrast along the pyloric channel from the compressed pyloric mucosa ("double-track" sign), a tapered point ending the pyloric channel ("beak" sign), and a prepyloric bulge of contrast ("shoulder" sign; Olivé & Endom, 2019).

Management

Pyloromyotomy is the surgical treatment for HPS. Prior to surgery, dehydration and electrolyte abnormalities should be corrected. Multiple boluses with 10 to 20 mL/kg of 0.9% normal saline may be required to correct the hypovolemia. Maintenance fluid then can be started with 5% dextrose in 0.45% to 0.9% saline at 1.5 to 2.0 times the maintenance rate depending on the degree of dehydration (Olivé & Endom, 2019). Once urine output is established, 10 to 20 mEq/L of potassium chloride may be added to the IV fluid mixture (Seifarth & Soldes, 2016). Electrolytes should be monitored every 8 to 12 hours until normalized. Surgery may be delayed for 24 to 48 hours in order to correct dehydration and electrolyte abnormalities (Hackam, Upperman, Grikscheit, Wang & Ford, 2019). Unlike other abdominal surgical conditions associated with

vomiting, continuous suction with a NG tube should be avoided so as not to exacerbate electrolyte abnormalities.

There are no guidelines on the timing and type of feedings to start after surgery. A common protocol used at some centers begins feedings within 4 to 8 hours after surgery. One-half to 1 oz of an electrolyte solution is started and progresses every 2 to 3 hours to 2 oz of breast milk or formula (Seifarth & Soldes, 2016). Most infants can be discharged within 48 hours after surgery (Seifarth & Soldes, 2016).

INTESTINAL ATRESIA

Background

Intestinal atresia (IA) is defined as a congenital defect of a hollow viscus resulting in complete or partial obstruction of the bowel lumen (Wesson, 2018). Duodenal atresias make up approximately 50% of intestinal atresias (Wesson, 2018). The classification scheme for duodenal atresia is summarized in Table 8.10. Duodenal atresia is hypothesized to be caused by a failure of luminal recanalization during weeks 8 to 10 of embryonic development (Schneider & Oldham, 2016). Up to 30% of infants with duodenal atresia may have associated chromosomal anomalies such as trisomy 21 (Best et al., 2012).

Jejunal and ileal atresia each make up 20% of IAs (Best et al., 2012). Unlike duodenal atresia, the pathophysiologic model for jejunal and ileal atresias begins with vascular compromise that leads to intestinal necrosis and subsequent reabsorption of the bowel tissue (Louw, 1959). Examples of causes of vascular compromise may include intussusception, segmental compromise of the mesenteric blood supply, volvulus, internal herniation, and gastroschisis (Wesson, 2018). Less than 5% of patients with jejunal or ileal atresia have associated chromosomal abnormalities (Best et al., 2012).

TABLE 8.10

CLASSIFICATION OF DUODENAL ATRESIA

Type	Description
I	• Intestinal lumen obstructed by a membrane • Membrane obstruction complete or fenestrated
II	• Fibrous band connecting two ends of duodenum
III	• Two blind-ending bowel loops; no mesentery in between • May be associated with biliary anomalies • Least common type

Classification of Jejunal Atresia

Type	Description
I	• Intraluminal web in continuity with muscle layers of proximal and distal segments • Least common type
II	• Fibrous cords connect proximal and distal bowel segments
III	• Significant mesenteric defects • Subtype IIIA—V-shaped mesenteric defect with intestinal discontinuity • Subtype IIIB—mesenteric defect with distal segment receiving entire blood supply in retrograde fashion via ileocolic or right colic artery. "Apple peel" or "Christmas tree" deformity • Associated with significant bowel loss • Most common type
IV	• Multiple atresias within a single length of bowel

Diagnosis

IA typically presents within the first 72 hours of life. These newborns may have abdominal distension, bilious or nonbilious vomiting, or fail to pass meconium (Wesson, 2018). A supine anteroposterior plain radiograph with either upright, lateral decubitus, or cross-table lateral views should be obtained in neonates and infants with suspected intestinal obstruction. Table 8.11 summarizes the possible findings on plain radiography.

Duodenal Atresia. Less than 50% of IAs are diagnosed prenatally (Haeusler, Berghold, Stoll, Barisic, & Clementi, 2002). Prenatal ultrasound of neonates with duodenal atresia may show polyhydramnios and/or dilation of the stomach and proximal duodenum (Grosfeld & Rescorla, 1993). The vomiting-associated duodenal atresia is typically bilious. Abdominal distension may or may not be present as vomiting may be sufficient to decompress proximal obstructions (Schneider & Oldham, 2016). Abdominal radiograph often reveals simultaneous gastric and duodenal distension (double bubble sign) with a paucity of air in the remainder of the bowel.

Jejunal Atresia. Prenatal ultrasound in neonates with jejunal atresia may show polyhydramnios and dilated loops of bowel (Phelps, Fisher, Partington, & Dykes, 1997). Infants may present with bilious vomiting, abdominal distension, and/or jaundice. Plain radiograph may show moderate to severely dilated bowel

TABLE 8.11

PLAIN RADIOGRAPH FINDINGS OF SELECTED INTESTINAL PATHOLOGIES

Diagnosis	Plain Radiograph Finding
Intestinal perforation	Abnormal accumulation of extraintestinal air Pneumoperitoneum Intraperitoneal calcification—(prenatal intestinal perforation, meconium peritonitis)
Duodenal atresia	Double bubble sign (dilation of stomach and duodenum) Absence or paucity of air in distal bowel Air-fluid level in duodenum
Jejunal or ileal atresia	Dilated loops of small bowel with air-fluid levels
Malrotation	Contrast study findings: Low-lying or displaced duodenojejunal junction and coiling of bowel with partial or complete obstruction

loops and air-fluid levels. A rectal contrast enema may reveal a microcolon in the setting of small bowel atresia.

Contrast Studies. If there is no evidence of perforation on plain radiograph, most infants should undergo an upper GI contrast study to look for malrotation or midgut volvulus. If plain radiographs and upper GI contrast studies do not provide a likely diagnosis, a contrast enema should be considered to further evaluate for IA or other causes of intestinal obstruction (Wesson, 2018).

Evaluation for other associated congenital anomalies should be considered as summarized in Table 8.12 (Kimble, Harding, & Kolbe, 1997).

Management

Definitive treatment for IA is operative. Preoperative therapy includes electrolyte and fluid resuscitation, antibiotics, and upper GI decompression via an orogastric or NG tube. An echocardiogram may be warranted to look for associated cardiac anomalies, particularly in patients with a murmur or trisomy 21.

Postoperatively, GI decompression is continued. PN may be required until oral feedings are started. Once the gastric aspirate appears clear and there is evidence of GI function, feeds can be started and carefully advanced until full enteral feeds are tolerated. Achieving full enteral feeds may take several weeks (Schneider & Oldham, 2016). Patients who require extensive bowel resection may take longer to tolerate enteral feeds or develop short bowel syndrome (SBS) requiring chronic PN therapy.

INTESTINAL MALROTATION

Background

Normal intestinal development in the fetus follows an orchestrated sequence of growth, elongation, and rotation followed by intestinal fixation to the body wall during fetal development (Table 8.13; Sato & Chang, 2016). Malrotation occurs when any step in this process fails to happen, resulting in abnormal intestinal rotation and fixation (Sato & Chang, 2016). The most catastrophic complication of malrotation occurs when the intestine twists along its mesenteric axis, resulting in volvulus, bowel ischemia, necrosis, and loss of bowel. Approximately 30% of infants with malrotation presenting before 1 month of age will develop volvulus (Fonkalsrud, 2003). Fifty percent of infants with malrotation are diagnosed in the first month of life and 90% by 1 year of age (Ford, Senac, Srikanth, & Weitzman, 1992; Nehra & Goldstein, 2011; Sato & Chang, 2016).

Other anomalies associated with intestinal malrotation include congenital diaphragmatic hernia, cardiac anomalies, abdominal wall defects (omphalocele, gastroschisis, prune belly syndrome), IA, EA, biliary atresia, Meckel's diverticulum, ARM, and Cornelia de Lang syndrome (Brandt, 2019).

TABLE 8.12

ADDITIONAL TESTING TO CONSIDER IN PATIENTS WITH INTESTINAL ATRESIA

Test	Consider in Neonates and Infants With. . .
Echocardiogram	Duodenal atresia Down syndrome
Chest radiograph	Infants with any small bowel atresia looking for vertebral anomalies
Renal ultrasound	Duodenal atresia
Cystic fibrosis mutation testing	Small bowel atresia and meconium plugs

Diagnosis

Since malrotation can quickly evolve into catastrophic volvulus, evaluation and treatment should be pursued emergently. Newborns and infants with malrotation typically present with one or

TABLE 8.13

FETAL EVENTS LEADING TO NORMAL POSITION OF THE INTESTINES

Stage	Event
I	• Fifth week of gestation • Herniation of primary intestinal midgut loop into umbilical cord base • Omphalomesenteric duct located at apex of midgut loop rotates 180° counterclockwise so that proximal prearterial half of loop passes posterior to SMA. • Prearterial segment gives rise to proximal duodenum (right of midline). • Distal prearterial segment that passes posterior and to the left of SMA becomes third and fourth portions of duodenum. • Distal duodenum normally fixed to left of aorta at ligament of Treitz after 270° counterclockwise rotation from original position. • Jejunoileal segment elongates to form remainder of small bowel. • Postarterial segment gives rise to cecum and right colon which undergoes a 270° counterclockwise rotation to move from the initial position on the left to the right of SMA before attaching to posterior wall of right iliac fossa.
II	• 10th–12th week gestation • Duodenojejunal junction has passed posterior to SMA and midgut rotated 180° counterclockwise • Small intestine initially remains to right of midline; cecum and ascending colon still anterior to SMA on return of the intestine to the abdominal cavity
III	• 12th week of gestation • Normal points of fixation: cecum in right iliac fossa, duodenojejunal junction at ligament of Treitz • Fixation of intestines to posterior body wall with a broad base extending from ligament of Treitz to cecum • Fixation prevents torsion of intestinal mesentery around its vascular supply

SMA, superior mesenteric artery.

Source: Adapted from Sato, T. T., & Chang, H. L. (2016). Abnormal rotation and fixation of the intestine. In R. Wyllie, H. S. Hyams, & M. Kay (Eds.), *Pediatric gastrointestinal and liver disease* (5th ed., pp. 640–647). Philadelphia, PA: Elsevier.

more of the following symptoms and signs: bilious or nonbilious vomiting, abnormal abdominal examination (distension, tenderness), and hemodynamic instability. Irritability, lethargy, feeding intolerance, reduced oral intake, and/or poor growth are nonspecific findings that may also suggest malrotation.

Emergency Alert: Late findings in babies with intestinal malrotation or volvulus include persistent bilious emesis associated with hemodynamic instability (tachycardia, hypotension, tachypnea), persistent abdominal distension, peritoneal signs, and poor vascular perfusion. Evaluation may reveal occult blood positive stools, metabolic acidosis, elevated serum lactate, and coagulopathy (Brandt, 2019; Nehra & Goldstein, 2011; Sato & Chang, 2016).

In a patient with suspected volvulus who is hemodynamically unstable, imaging should not delay surgical exploration (Brandt, 2019). Radiographic studies can proceed in hemodynamically stable patients. Initial plain abdominal radiography may reveal gastric or proximal bowel distension with a paucity of distal bowel air on plain abdominal radiographs. Upright anteroposterior or cross-table lateral views to look for pneumoperitoneum suggestive of intestinal perforation should also be obtained.

If there is no evidence of perforation on plain radiographs, an upper GI contrast study should be performed to confirm malrotation (Applegate, 2009). Malrotation may appear as a corkscrew or coiled spiral pattern with contrast imaging. The position of the duodenojejunal junction or ligament of Treitz on the right side of the abdomen also suggests malrotation (Applegate, 2009). Upper GI contrast studies have a sensitivity of over 90% for detecting malrotation (Sizemore, Rabbani, Ladd, & Applegate, 2008). For infants who undergo rectal contrast enema, the cecum may be positioned in the midline or to the left of the vertebra. However, it should be noted that in 20% of cases of malrotation, the cecum may appear in its normal anatomic location in the right lower quadrant (Applegate, 2009).

Ultrasound is a modality that is gaining increasing popularity. Normally, the superior mesenteric vein is to the right of the superior mesenteric artery (SMA). In the presence of malrotation, the superior mesenteric vein may be found ventral or to the left of the SMA (Sato & Chang, 2016; Weinberger, Winters, Liddell, Rosenbaum, & Krauter, 1992). It should be noted that a normal ultrasound does not eliminate the possibility of malrotation (Ashley, Allen, & Teele, 2001; Orzech, Navarro, & Langer, 2006).

Management

Prompt consultation with pediatric surgeons is paramount in all cases of suspected malrotation or volvulus. Preoperative management includes NG tube decompression and circulatory and electrolyte resuscitation. Broad-spectrum antibiotics should be considered since signs and symptoms of malrotation/volvulus can overlap with sepsis, or there may be concomitant systemic infection. Acid suppression with a H_2A blocker should be considered since vomiting or the presence of a NG tube may increase the risk for developing gastritis or esophagitis.

A general operative approach is shown in Box 8.1.

Recovery of GI function may be delayed postoperatively, particularly in the presence of volvulus; prolonged nasogastric decompression and PN may be required (Feitz & Vos, 1997; Sato & Chang, 2016). Some infants and children may have persistent postoperative vomiting or feeding intolerance with intestinal motility patterns that mimic neuropathic intestinal pseudo-obstruction (Devane et al., 1992). Prokinetic agents such as metoclopramide or erythromycin can be considered along with continued acid suppression therapy in postoperative infants with persistent symptoms of dysmotility. Neonates who require extensive bowel resection due to a delay in diagnosis may develop SBS necessitating chronic PN therapy.

Box 8.1

GENERAL OPERATIVE STRATEGY FOR MALROTATION AND VOLVULUS

- Delivery of the entire midgut and inspection of vascular mesentery
- Reduction of volvulus and evaluation of intestinal viability
- Division of Ladd's bands
- Broadening the base of mesenteric vascular pedicle
- Appendectomy
- Return of GI tract with small intestine in the right abdomen and the large intestine in the left abdomen.

ABDOMINAL WALL DEFECTS

Background

The prevalence of omphalocele and gastroschisis is approximately 3 to 4 per 10,000 live births (Friedman, Ananth, Siddiq, D'Alton, & Wright, 2016).

An omphalocele is a midline abdominal wall defect of variable size that is typically covered by a membrane of amnion and peritoneum that contains abdominal contents. The defect is at the base of the umbilical cord with the umbilical vessels inserting into the apex of the omphalocele sac. Sac contents may include stomach, small bowel loops, colon, and liver. The bowel may appear matted and edematous as a result of chronically being exposed to amniotic fluid. Larger omphaloceles may also contain the bladder, gonads, and spleen. The pathogenesis of omphaloceles begins during week 3 to 4 of fetal development when the embryo lengthens and folds onto itself to enclose various body cavities. Two lateral folds normally form and meet anteriorly in the midline at the umbilicus. Failure of the folds to meet in the midline results in an omphalocele (Stephenson, Lockwood, & MacKenzie, 2018).

Gastroschisis is an abdominal wall defect that is usually 5 cm or less and located to the right of the umbilical cord. The herniated abdominal contents usually include only the small bowel. The pathogenesis of gastroschisis is less clear. Several hypotheses have been proposed including failure of differentiation of the embryonic mesenchyme, rupture of the amniotic membrane at the base of the umbilical cord at the area of the right umbilical vein, and vascular compromise (deVries, 1980).

Diagnosis

The diagnosis of gastroschisis and omphalocele is usually made by prenatal ultrasound. Omphalocele can be differentiated from gastroschisis by the presence of a sac and a liver within the defect in most cases (Stephenson et al., 2018). Gastroschisis can be identified by free-floating loops of bowel within the amniotic fluid. Ultrasound may also detect associated anomalies such as IA and cardiac defects (Hughes, Nyberg, Mack, & Pretorius, 1989; Walther & Nathan, 2016; see Table 8.14). Both omphalocele and gastroschisis can be associated with elevated maternal serum alpha fetoprotein (Saller, Canick, Palomaki, Knight, & Haddow, 1994).

Omphalocele can be associated with chromosomal abnormalities such as trisomy 18 or 13, Turner syndrome, and triploidy. Structural anomalies may include other GI anomalies, cardiac

TABLE 8.14

COMPARISON OF GASTROSCHISIS AND OMPHALOCELE

	Gastroschisis	Omphalocele
Incidence	1 in 2,000 live births	1 in 5,000 live births
Defect location	Right periumbilical	Umbilical ring/central
Covering sac	Absent	Present (amnion and peritoneum)
Description	Free intestinal loops	Firm mass including bowel, liver, etc.
Umbilical cord	Normal insertion	Inserts into sac
Necrotizing enterocolitis	Common	Uncommon
Associated anomalies	• Gastrointestinal • Intestinal atresia • Malrotation • Cryptorchidism • Stenosis • Perforation • Volvulus	• Trisomy syndromes • Cardiac defects • Beckwith–Weidemann syndrome • Bladder exstrophy

Source: Adapted from Chabra, S., & Gleason, C. A. (2005). Gastroschisis. *NeoReviews, 6*(11), e493–e499. doi:10.1542/neo.6-11-e493; Walther, A. E, & Nathan, J. D. (2016). Newborn abdominal wall defects. In R. Wyllie, H. S. Hyams, & M. Kay (Eds.), *Pediatric gastrointestinal and liver disease* (5th ed., pp. 654–665). Philadelphia, PA: Elsevier.

defects, genitourinary anomalies, orofacial clefts, neural tube defects, and diaphragmatic defects (Stephenson et al., 2018). Other syndromes associated with omphalocele include Pentalogy of Cantrell, amniotic band sequence, schisis association, OEIS syndrome (omphalocele, exstrophy of the bladder, imperforate anus, spinal defects), Shprintzen syndrome, Carpenter syndrome, Goltz syndrome, Marshall–Smith syndrome, CHARGE syndrome, and Beckwith–Wiedemann syndrome (Stephenson et al., 2018).

Management

Presurgical management of infants with gastroschisis or omphalocele presents added challenges compared to infants with other surgical conditions. Infants with respiratory distress may require supplemental oxygen or ventilator support. Intravenous lines should preferentially be placed in the upper extremities due to possible inferior vena cava (IVC) compression during bowel reduction (Walther & Nathan, 2016). A nasogastric or orogastric tube should be placed to decompress the stomach and help minimize small bowel distension.

The omphalocele sac should be wrapped with saline-soaked gauze and an impervious dressing to reduce fluid losses and hypothermia. In neonates who have gastroschisis with eviscerated bowel, or a ruptured omphalocele, the bowel should be wrapped in saline-soaked gauze and placed in a central position; the infant should be placed on the right side to prevent vascular compromise from mesenteric kinking. The bowel is then wrapped in an impervious dressing, such as a plastic wrap (BMJ Best Practice, 2017; Walther & Nathan, 2016).

If the gastroschisis defect is small and there is evidence of vascular compromise, the defect should be enlarged to increase flood flow (Walther & Nathan, 2016). Infants should be placed in a warm environment to maintain core body temperature. Due to ongoing fluid losses, infants may require fluid volumes greater than maintenance amounts. Electrolytes should be followed closely and corrected as needed. Repositioning the baby may be needed if there are signs of vascular compromise to the bowel such as hypotension, tachycardia, or a dusky bowel appearance.

Surgical options for gastroschisis include primary reduction and fascial closure, silo placement with serial reduction, and delayed fascial closure, or primary or delayed reduction without fascial closure (BMJ Best Practice, 2017; Walther & Nathan, 2016). The main goal in managing omphalocele is the gradual reduction of the viscera into the abdominal cavity, followed by closure of the fascia and skin. Central venous access should be secured in anticipation of lengthy postoperative PN needs associated with intestinal dysmotility that is frequently encountered.

For neonates with omphalocele, the priority for abdominal wall repair is preservation of blood flow to the intestines and eviscerated organs (Stephenson, Lockwood, & MacKenzie, 2019). Small defects (2–3 cm) can usually be closed in the first 24 to 72 hours of life (Stephenson et al., 2019). Larger and more complex defects may require initial silo placement followed by gradual reduction and definitive closure (Pacilli, Spitz, Kiely, Curry, & Pierro, 2005). Depending on the size of the abdominal wall defect, it may take 3 to 7 days before sufficient reduction is achieved to allow closure of the fascia and skin. Serial Doppler ultrasound may be used to ensure sufficient blood flow to the organs during the omphalocele reduction process.

During the postoperative period, infants are at risk of developing abdominal compartment syndrome after fascial closure. Repeated physical examination, ventilator settings, intra-abdominal pressure measurements, heart rate, blood pressure, and urine output may provide clues indicating increased abdominal pressure (Stephenson et al., 2018). NG or orogastric decompression should continue until there is clinical evidence of bowel function and the abdominal examination is reassuring. PN should continue until a sufficient volume of enteral calories is reached. There is no clear consensus as to the optimal time for starting enteral feeds. Tolerance of full enteral feedings may take time due to the intestinal dysmotility commonly associated with gastroschisis. However, introducing even the smallest amounts of enteral feedings may help lower the risk of developing cholestasis as a result of delayed enteral feedings and PN. Oral stimulation should be provided as much as possible even during the slow process of advancing feeds to minimize the risk of developing feeding problems from the loss of the suck–swallow reflex (Walther & Nathan, 2016).

NECROTIZING ENTEROCOLITIS

Background

NEC is the most common GI emergency in neonates and carries a high rate of long-term complications (Gregory, DeForge, Natale, Phillips, & Van Marter, 2011). NEC occurs in 1 to 3 per 1,000 live births and increases with decreasing gestational age (Llanos et al., 2002; Thompson & Bizzarro, 2008). While NEC can occur at any age, approximately 90% occur in preterm infants who have been fed enterally (Kim, 2019a; Yee et al., 2012). Characteristics inherent to premature infants that most likely contribute to their increased risk for developing NEC are circulatory instability, permeable GI mucosal barrier that is prone to bacterial translocation, undeveloped local host defense mechanisms, and immature bowel motility and function (Kim, 2019b).

NEC can be localized in the case of segmental mucosal necrosis or extensive in the case of transmural necrosis of the small and large bowels. While the pathogenesis of NEC is not well defined, characteristic features most likely include ischemic injury leading to necrosis of the intestinal mucosa, unregulated mucosal inflammation, abnormal bacterial colonization particularly by gas-forming organisms, and dissection of gas into the muscularis layer of the intestines and portal venous system (Kim, 2018; Neu & Walker, 2011). The convergence of these pathogenic mechanisms culminates in multiorgan system failure (Iben & Rodriguez, 2016).

Diagnosis

Clinical evidence of NEC can be nonspecific such as increased gastric residual with feeds, poor feeding, apnea, lethargy, temperature instability, vomiting, change in stool character, occult blood positive stools, abdominal distension or tenderness, discoloration of abdominal skin, and/or bilious output from enteral feeding tubes (Kim, 2019a). Respiratory failure and signs of septic shock may also be present. Bacteremia is also common with NEC (Kim, 2019a). Laboratory findings may include leukocytosis, neutropenia, disseminated intravascular coagulation (increased prothrombin time, decreased fibrinogen, increased fibrin split products), acute anemia, thrombocytopenia or thrombocytosis, elevated C-reactive protein, hyperglycemia, electrolyte abnormalities (hyponatremia common), and acidosis (metabolic/respiratory; Kim, 2019a). Contrast enemas are contraindicated in suspected NEC due to the risk of perforation.

Successful management of NEC begins with early diagnosis that stems from being vigilant to clinical changes (Table 8.15). When NEC is suspected, screening assessment can include plain abdominal radiography, stool for occult blood and calprotectin, sepsis evaluation, CBC, coagulation studies, and serum chemistries (electrolytes, CO_2, BUN, Cr, glucose, lactate). Plain abdominal radiographs should include cross-table lateral and/or left lateral decubitus views to help detect pneumoperitoneum. Other abdominal radiographic signs can range from nonspecific findings such as a gasless abdomen, ascites, and dilated loops of bowel to ominous signs including pneumatosis intestinalis, portal venous air, or sentinel loops. Pneumatosis intestinalis is the result of gas dissecting into the bowel wall. Sentinel loops are bowel loops that remain in a fixed position on serial radiographs and may be evidence for necrotic bowel and/or perforation (Kim, 2019a).

Abdominal ultrasonography is likely to play an increasingly important role in the evaluation and diagnosis of NEC (Garbi-Goutel et al., 2014; Silva et al., 2007). A central echogenic focus with a hypoechoic rim may suggest necrotic bowel. Ultrasonography may also identify air in the liver parenchyma and portal venous system, fluid collections, and/or changes in bowel wall thickness and echogenicity associated with NEC. Doppler ultrasound can also detect abnormal bowel wall perfusion (Garbi-Goutel et al., 2014; Kim, 2019a; Silva et al., 2007).

TABLE 8.15

MODIFIED BELL STAGING CRITERIA FOR NEC

Stage	Classification	Systemic Signs	Intestinal Signs	Radiographic Signs
IA	Suspected NEC	Temperature instability, apnea, bradycardia, lethargy	Increased gastric residuals, mild abdominal distension, vomiting, guaiac-positive stool	Normal or dilated bowel loops, mild ileus
IB	Suspected NEC	Same as IA	Bright red blood from rectum	Same as above
IIA	Proven NEC—mildly ill	Same as above	Same as above, plus absent bowel sounds, with or without abdominal tenderness	Intestinal dilation, ileus, pneumatosis intestinalis
IIB	Proven NEC—moderately ill	Same as above plus: mild metabolic acidosis, mild thrombocytopenia	Same as above, plus absent bowel sounds, abdominal tenderness, with or without abdominal cellulitis or right lower quadrant mass	Same as IIA, plus portal venous gas, with or without ascites
IIIA	Advanced NEC—severely ill, bowel intact	Same as IIB, plus hypotension, bradycardia, severe apnea, combined respiratory and metabolic acidosis, disseminated intravascular coagulation, and neutropenia	Same as above, plus signs of generalized peritonitis, marked tenderness, and distention of abdomen	Same as IIB, plus definite ascites
IIIB	Advanced NEC—severely ill, bowel perforated	Same as IIIA	Same as IIIA	Same as IIB, plus pneumoperitoneum

NEC, necrotizing enterocolitis.

Necrotizing enterocolitis in the premature infant: Neonatal nursing assessment, disease pathogenesis, and clinical presentation. *Advances in Neonatal Care, 11*(3), 155–164. doi:10.1097/ANC.0b013e31821baaf4

Management

Management of NEC begins with bowel rest (nil per os—NPO), prompt initiation of broad-spectrum antibiotics, and abdominal decompression. Decompression via a NG tube set to low suction is continued until there is clinical improvement, and the abdominal distension and any pneumatosis that is present resolves. Since the period of NPO can range from 10 to 14 days, PN should provide complete nutritional requirements. Inotropic support, large volume fluid resuscitation, and ventilator support may be needed in some infants who become critically ill. Close monitoring and correction of electrolyte and metabolic abnormalities also will be required in many infants with NEC (Iben & Rodriguez, 2016; Kim, 2019a).

Since up to 30% of infants with NEC will have concomitant bacteremia (Ballance, Dahms, Shenker, & Kliegman, 1990; Holman, Stoll, Clarke, & Glass, 1997; Hunter, Upperman, Ford, & Camerini, 2008; Kim, 2018; Neu & Weiss, 1999), blood cultures should be obtained prior to antibiotic therapy. There are several broad-spectrum antibiotic combination options, but any regimen should include coverage of gram-negative and anaerobic organisms (Kim, 2018). **Quality and Safety: Antifungal therapy should additionally be considered if there is suspicion for intestinal perforation or if the neonate is critically ill.** The length of antimicrobial therapy is typically 10 to 14 days. Enteral feedings can be restarted after 10 to 14 days of NPO as the clinical picture improves. Enteral feeds are advanced slowly so as to reach full feeds over 7 to 10 days (Iben & Rodriguez, 2016). Given the potential for significant bowel injury with NEC, normal GI function including digestion, absorption, and motility may be slow to return.

A CBC with differential, electrolytes, creatinine, BUN, and acid-base tests should be obtained every 12 to 24 hours in the acute stages of managing NEC. The frequency of monitoring serum lactate, liver enzymes, and coagulation studies should be guided by the initial results of these studies. **Emergency Alert: Worsening or persistent low platelet count, metabolic acidosis, or increasing serum glucose are associated with worsening or persisting NEC (Kim, 2019b).** Plain radiographs taken every 6 to 12 hours in the initial acute phase of NEC is likely a prudent strategy. Radiographs should also be obtained as needed for any clinical change or deterioration.

The timing of surgical intervention, if necessary, requires clinical judgment and evaluation of the overall clinical condition in close consultation with pediatric surgeons. Indications for surgical intervention may include lack of clinical improvement with medical management, worsening clinical picture, free intra-abdominal air, or suspected bowel necrosis. **Emergency Alert: Worsening laboratory values (metabolic acidosis, thrombocytopenia, coagulopathy), inability to ventilate, persistent or worsening skin discoloration, protracted or refractory hypotension, persistent or worsening thrombocytopenia, or fixed bowel loops on plain radiography are signs that should trigger consideration of surgical management.** Surgical options include bedside placement of Penrose drain(s) with or without irrigation, or open laparotomy. The main aim of open laparotomy is removal of necrotic bowel, irrigation of contaminated abdominal cavity, and proximal diversion with the goal of preserving viable bowel (Iben & Rodriguez, 2016; Kim, 2018).

INTESTINAL FAILURE AND SHORT BOWEL SYNDROME

Background

At 27 weeks' gestation, the length of the average small bowel is 100 cm and increases to 200 cm by 40 weeks of gestation (Struijs, Diamond, de Silva, & Wales, 2009). By 3 years of age, the mean intestinal small bowel length is 350 cm. SBS is most commonly used to describe patients whose native bowel length or bowel function is insufficient to digest and absorb the appropriate nutrients and liquids for normal growth and hydration. However, the term SBS may be misleading in that the name implies a deficiency in the length of bowel, which may or may not be accurate depending on the underlying etiology. For example, infants who have a normal bowel length but depend exclusively on PN secondary to congenital villus pathology are often referred to as "SBS." A second and perhaps more accurately encompassing term is *intestinal failure* (IF).

IF is defined as the reduction of gut function below the minimum necessary for the absorption of macronutrients and/or water and electrolytes, such that intravenous supplementation is required to maintain health and/or growth (Pironi et al., 2015). The reduction of gut absorptive function that does not require intravenous supplementation to maintain health and/or growth can be considered as "intestinal insufficiency" (Pironi et al., 2015). Thus, IF is a broader umbrella term that encompasses SBS.

The ultimate goal for all infants with SBS who initially require PN is transition to full oral or enteral feedings. While there are no perfect predictors of weaning from PN, it is generally thought that longer bowel length, the presence of an intact ileum and ileocecal valve (ICV), the presence of a colon, and continuity of the GI tract represent favorable prognostic factors for weaning from PN (Andorsky et al., 2001; Goulet et al., 2005; Infantino et al., 2013; Quirós-Tejeira et al., 2004; Sondheimer, Cadnapaphornchai, Sontag, & Zerbe, 1998).

Intestinal adaptation refers to the physiologic and anatomic changes that the intestine undergoes over time that enables an increase in its digestive and absorptive functions (Kaufman, 2016). The large surface area, along with its high concentration of digestive enzymes and density of transport proteins, makes the jejunum the primary site for digestion and absorption of most macronutrients, micronutrients, and fluids. Thus, a functional or anatomic loss of the jejunum results in a corresponding loss of nutrient absorption.

The ileum also plays an important role in the absorption of fluids entering from the jejunum. In addition, it is the primary site for vitamin B_{12} absorption and bile acid reabsorption. Malabsorption of vitamin B_{12} results in macrocytic anemia, while malabsorption of bile acids causes fat and fat-soluble vitamin malabsorption. The ICV serves at least two key physiologic functions that likely contribute to intestinal adaptation. First, the ICV serves as a barrier that blocks the translocation of colonic bacteria into the small intestine where they can flourish and promote small intestine bacterial overgrowth (SIBO). SIBO is thought to contribute to further malabsorption of certain nutrients such as vitamin B_{12} and deconjugation of bile acids that contributes to fat malabsorption and diarrhea (DiBaise, Young, & Vanderhoof, 2006). The ICV is also essential in its role as a physiologic brake, slowing the transit from intestine to colon, and allowing more time for the intestine to carry out its digestive and absorptive functions. Indeed, the presence of an ICV is believed to improve the chances of weaning from PN (Goulet et al., 2005; Quirós-Tejeira et al., 2004).

The causes of IF can further be classified as short bowel syndrome, congenital diseases of enterocyte development, and severe motility disorders (D'Antiga & Goulet, 2013; Goulet & Ruemmele, 2006). In children, the most common cause of IF is SBS. Common causes of SBS in infants include NEC, midgut volvulus, gastroschisis, and IA (D'Antiga & Goulet, 2013; Goulet & Ruemmele, 2006).

Diagnosis

The diagnosis of neonates with SBS is usually straightforward. These patients typically have been diagnosed with NEC,

gastroschisis, omphalocele, intestinal volvulus, or IA, most often associated with surgical bowel resection. Symptoms of feeding intolerance such as massive diarrhea, abdominal distension, and vomiting are also common in patients with SBS.

Other causes of IF in the neonatal period such as congenital villus abnormalities and idiopathic pseudo-obstruction syndrome are less common. However, these causes may exhibit similar symptomatology of feeding intolerance and failure to grow in the neonatal period. Likewise, these babies will also require PN to survive.

In neonates who do require surgical intervention, it is helpful to note the quality, quantity, and location of remaining small bowel and colon on operative reports. A precise understanding of the remaining anatomy can guide management decisions as well as facilitate discussions regarding prognosis with family members.

Management

The mainstay of management of infants with SBS is PN. In order to provide an adequate amount of PN, a central venous catheter should be placed. The quantity of PN should be sufficient to support normal growth, normalization of electrolytes, and maintenance of euvolemia. Initially, it is common for infants with SBS to have excess fluid and electrolyte losses that will need to be accounted for in developing the PN recipe. PN is typically delivered over 24 hours initially. Once a maintenance PN program achieves appropriate growth, stable electrolytes, and euvolemia, the PN nutrition cycle can be compressed to 16 to 18 hours in most infants.

While PN may provide the majority of calories for infants with SBS, it is critical to offer and encourage oral or enteral feedings as much as tolerated. There is no standardized approach to enteral or oral feedings. Stamm and Duggan (2018) have proposed a strategy to feed infants with SBS. Breast milk is preferred when available. In the United States, if breast milk is not available many centers favor a protein hydrolysate or an amino acid–based formula. Hydrolysate and amino acid–based formulas have a theoretical advantage since they eliminate the need for most physiologic digestive processes that may be impaired in infants with SBS. In addition, these formulas may be less likely to trigger an immunologic response that infants with SBS may be at increased risk for developing.

Feedings are usually started at 10% to 20% of goal. After feedings are started, advancement can be considered if stool output is less than 10 stools/day (or <10 g/kg/day) or ostomy output is less than 2 mL/kg/hour, perianal skin irritation is manageable, and urine output is greater than 1 mL/kg/hour. The same authors recommend advancing feedings by 10 to 20 mL/kg/day to a maximum goal of 150 to 200 mL/kg/day. If stool output is 10 to 12 stools/day (or 10 to 20 g/kg/day) or ostomy output is 2 to 3 mL/kg/hour, and there is minimal or mild perineal erythema, then feeds can continue at the same rate without advancement. Intolerance to feedings is suggested by increased abdominal distension, greater than 12 stools/day or greater than 20 g/kg/day or ostomy output greater than 3 mL/kg/hour, moderate or severe perineal breakdown, or urine output less than 1 mL/kg/hour. Any of these signs of feeding intolerance should trigger reduction in the rate of feedings or holding the feeds altogether. When feeds are restarted after being held, restart can commence at 50% to 75% of the previous rate (Stamm & Duggan, 2018). Infants who do not have NG or gastric tube feedings should be offered oral feedings as tolerated.

In general, diarrhea or increased stool output related to oral or enteral intake can be tolerated as long as electrolytes and hydration can be maintained, and the irritant effects of the diarrhea on perianal skin is manageable. Vomiting or spitting up can be managed using a combination of acid suppression and/or prokinetic therapy. As long as oral or enteral feeding does not result in complications such as respiratory symptoms or excess irritability, feedings may continue. Even the smallest amounts of oral or enteral feedings are important. First, enteral feeding is thought to be protective against intestinal failure associated liver disease (IFALD), as oral intake and the passage of nutrient through the GI tract likely help stimulate physiologic hormones that promote hepatic bile flow. Second, infants who do not learn to suckle during infancy are more likely to develop long-term oral aversion, even once intestinal adaptation has occurred and PN is no longer needed. Trophic feedings may also help maintain intestinal mucosal integrity, lowering the risk of bacterial translocation and subsequent bacteremia.

Two complications common in infants requiring PN are IFALD and central catheter-related bloodstream infection (CRBSI). IFALD is suspected when bilirubin levels and/or liver enzymes (alanine aminotransferase, gamma glutamyl transferase, alkaline phosphatase) are persistently high in infants receiving chronic PN. The pathophysiology of IFALD is not well understood, but the cause is likely to be multifactorial. Three likely contributing factors include the toxic effects of PN on the liver, the lack of physiologic stimulation of bile flow associated with regular oral feedings, and the toxic effects of repeated episodes of CRBSI and its associated antimicrobial treatment.

Over the last 10 years, particular interest has been paid to the role of the lipid component of PN in contributing to IFALD. The standard lipid emulsion used in the United States is soy based and contains predominantly omega-6 fatty acids, which is the precursor to a host of pro-inflammatory cytokines that can contribute to IFALD (Nandivada et al., 2013). Alternative lipid emulsions such as fish oil–based products contain a higher proportion of omega-3 fatty acids that are believed to have anti-inflammatory effects. Omegaven® is a fish oil–based lipid emulsion that has been shown to mitigate the effects of IFALD in some infants (Gura et al., 2008; Nandivada et al., 2013). However, Omegaven® is currently available only under investigational study protocols. Smoflipid® is a mixture of soy oil, medium chain triglycerides, olive oil, and fish oil that contains a higher proportion of omega-3 fatty acid and has been recently approved by the United States Food and Drug Administration. However, data on its effectiveness in preventing or treating IFALD is limited (Belza et al., 2017).

Independent of the effects of bacteremia and antimicrobial treatment on the liver, CRBSI represents a leading cause of mortality and morbidity in infants with SBS (Chan & Wu, 2014). The ideal management of CRBSI involves treatment with antibiotic and removal of the central line in cases of severe sepsis or persistent bacteremia (Mermel et al., 2009). Unfortunately, infants only have approximately four (two subclavian and two internal jugular) standard sites for central venous access (Kaufman et al., 2001). Once a central line is removed, the vessel is at risk for scarring, rendering it unsuitable for subsequent access.

Thus, recurrent CRBSI may ultimately lead to loss of vascular access for PN. For patients whose vascular access is exhausted, intestinal transplantation is an option (Kaufman et al., 2001). However, the survival rate of long-term PN remains more favorable than intestinal transplantation. Therefore, management strategies aimed at preventing CRBSI are essential. There are no standard guidelines for the care and management of central lines in pediatric PN patients. At Loma Linda University Children's pediatric intestinal care and home parenteral nutrition program, when a central line is accessed or when a central line site dressing is changed, the site or catheter is cleansed with three alcohol and three chlorhexidine pads or swabs. Each pad or swab is applied for approximately 30 seconds. Care providers are asked to wear a mask and to perform vigorous handwashing for 30 seconds prior to accessing the line site or catheter.

SIBO is not an uncommon problem in babies with SBS. Symptoms of SIBO include abdominal distension, nausea and vomiting,

and increased stool output. Usually SIBO in infants is diagnosed based on clinical symptoms. Therapeutic options may include but are not limited to one of the following agents: metronidazole, trimethoprim-sulfamethoxazole, amoxicillin, or amoxicillin clavulanic acid.

Most infants with SBS have an increase in the production of gastric acid within the first 3 to 6 months after surgery. The increased risk for dyspepsia related to this hypersecretory state and a paucity of oral or enteral feedings can be mitigated by therapy with a H_2A such as ranitidine or famotidine. The agents can be administered enterally, orally, or be added to the PN mixture.

INTUSSUSCEPTION

Background

Intussusception is a common cause of intestinal obstruction that occurs when one segment of the intestine invaginates into an adjacent segment. Intussusception can involve any segment of small or large intestine, but ileocolic intussusception is most common. In most cases, a more proximal bowel segment invaginates into an adjacent distal segment. The majority of cases are idiopathic without an identifiable lead point, which is the part of the bowel or mesentery that prevents reduction of the involved bowel segment after it has telescoped. The proximal segment is referred to as the intussusceptum and the distal segment into which it telescopes is the intussuscipiens. Ileocolic intussusception accounts for approximately 90% of cases (Mandeville et al., 2012). Ileoileocolic, jejunojejunal, jejunoileal, and colocolic intussusceptions are also possible.

The telescoping of one segment of the intestine into an adjacent part is observed periodically during GI endoscopy. These telescoping episodes are a part of normal peristalsis, and typically self-reduce, returning bowel segments to their native states. The majority of these episodes are transient and unlikely to cause any clinical symptoms. Intussusception results when the mesentery of the intussusceptum bowel becomes "stuck" during one of these telescoping events. The consequences of intussusception are twofold: (1) partial or complete small bowel obstruction, and (2) progressive vascular compromise if untreated.

The majority of intussusception is idiopathic. However, in a subset of patients intussusception may be associated with viral or bacterial infections (Arbizu, Aljomah, Kozielski, Baker, & Baker, 2014; Bhisitkul, Todd, & Listernick, 1992; Nylund, Denson, & Noel, 2010). It has been proposed that infections cause hypertrophy of lymphatic tissues, which can serve as a lead point that traps bowel segments in the telescoped position, resulting in intussusception (Vo & Sato, 2019). The greater density of lymph tissue in the terminal ileum helps explain why the majority of intussusception involves the ileum.

Up to 25% of patients with intussusception have an underlying disorder (Vo & Sato, 2019). Some of these underlying disorders can include Meckel's diverticulum (St-Vil, Brandt, Panic, Bensoussan, & Blanchard, 1991), polyps (Hwang, Chu, Chen, & Chen, 2001), small bowel lymphoma (Abbasoğlu et al., 2003), vascular malformations (Morgan, Mylankal, el Barghouti, & Dixon, 2000), and vasculitis (Choong & Beasley, 1998).

Diagnosis

Intussusception presents between 6 and 36 months of age with over 50% presenting during infancy (Mandeville et al., 2012). Infants and toddlers with intussusception typically experience a sudden onset of colic and progressive abdominal pain that is episodic (Ross, 2010). During episodes, the infant or toddler may cry inconsolably and draw its legs up toward the abdomen. A period of lethargy may follow the episodes of pain, which may become more frequent over time. Vomiting is commonly associated with the pain episodes and may begin as nonbilious vomiting that progresses to bilious vomiting as the intussusception becomes fixed. Fever is not a typical feature of intussusception.

Between the episodes of pain, the infant or toddler can appear completely normal, which can make the diagnosis difficult to make in the early stages. The classic triad of intussusception including colicky abdominal pain, vomiting, and red "currant jelly" stools may not be evident until the later stages of the disease. The currant jelly stools are caused by a mixture of intestinal mucus and blood resulting from mucosal sloughing due to vascular compromise (Manning & Little, 2016). A sausage-shaped mass may be palpable on physical examination, but this finding is variable (Ross, 2010).

Abdominal ultrasound is noninvasive, safe, and often the test of choice to screen for intussusception. The sensitivity of the technique is nearly 100% when performed by experienced ultrasonographers and interpreted by radiologists familiar with diagnosing intussusception (Mandeville et al., 2012). The classic finding of intussusception on ultrasound is a "target sign," which forms when layers of intestines are trapped within intestine (Manning & Little, 2016).

Rectal enemas using air or contrast can be employed for diagnostic or therapeutic purposes in infants and children with suspected intussusception. A plain abdominal radiograph is performed prior to enemas to confirm the absence of pneumoperitoneum that may suggest intestinal perforation. The hydrostatic or pneumatic pressure from the enema relieves the intussusception in 70% to 80% of cases (Manning & Little, 2016). Contraindications to rectal enemas include evidence of intestinal perforation or peritonitis.

Management

Depending on the infant or toddler's clinical status, there are nonoperative and operative management options. Patients who are hemodynamically stable and have no concerns for intestinal perforation or peritonitis are candidates for nonoperative management. Even when the nonoperative approach is tried first, the surgical team should be consulted in case operative management is required emergently.

Intravenous resuscitation and broad-spectrum antibiotics should be initiated prior to nonoperative or operative management. A NG tube for decompression can be considered if there is gastric or abdominal distension or persistent vomiting. Nonoperative management typically involves a rectal enema using air and/or hydrostatic pressure. Ideally, the pressure should separate the proximal and distal segments of the intussusception. Nonoperative management is successful in 60% to 90% of cases (Heurn, Pakarinen, & Wester, 2014)

Surgical management is indicated in patients who are clinically unstable, have evidence of intestinal perforation or peritonitis, or in whom nonoperative reduction has been unsuccessful. Surgical options include an open or laparoscopic approach. The goal of either approach is to first attempt to manually reduce the involved intestinal segments. If manual reduction is unsuccessful or if a lead point is identified, then resection with primary anastomosis is performed (Heurn et al., 2014).

CONGENITAL AGANGLIONIC MEGACOLON (HIRSCHSPRUNG'S DISEASE)

Background

Normal intestinal motility depends on the coordinated contraction and relaxation of the longitudinal and circular muscle layers throughout the GI tract. Control of motility relies on the function of ganglia that innervate the muscle layers. HD or congenital aganglionic megacolon is a congenital motor disorder of the colon

caused by failure of neural crest cells to migrate completely to the muscular layers during fetal intestinal development (Heuckeroth, 2018). This migration failure results in missing ganglion cells in affected segments of the colon. Affected colonic segments fail to relax, resulting in a functional pseudo-obstruction (Heuckeroth, 2018).

The majority of patients with HD have short-segment disease that involves the rectum and distal sigmoid colon (Wesson & Lopez, 2019a). Twenty percent of patients have long-segment disease in which the aganglionosis extends from the rectum to the proximal sigmoid colon (Wesson & Lopez, 2019a). Approximately 5% of patients have total colonic aganglionosis that involves the entire colon. The small bowel is rarely affected by HD. Short-segment HD generally carries the best prognosis.

The incidence of HD is about 1 in 5,000 live births with a male predominance (Best et al., 2014; Suita, Taguchi, Ieiri, & Nakatsuji, 2005). The recurrence rate in siblings is between 3% and 17%, depending on whether the HD is short or long segment. Several chromosomal abnormalities are associated with HD. These abnormalities include trisomy 21, Bardet–Biedl syndrome, cartilage-hair hypoplasia, congenital central hypoventilation syndrome, familial dysautonomia, multiple endocrine neoplasia type 2, Mowat–Wilson syndrome, Smith-Lemli-Opitz syndrome, and Waardenburg syndrome (Wesson & Lopez, 2019a). Genitourinary abnormalities, visual and hearing problems, congenital heart disease, and ARM may also be found in about 20% of patients with HD (Wesson & Lopez, 2019a).

Diagnosis

Most patients with HD are diagnosed within the first 2 months of life, while up to 10% of patients may not be diagnosed until childhood (Arshad, Powell, & Tighe, 2012). Bilious or nonbilious vomiting, abdominal distension, and failure to pass meconium within 48 hours of life are common clinical presentations that should raise the possibility of HD (Tabbers et al., 2014). While delayed meconium passage is a hallmark feature, a history of meconium passage within 48 hours of life does not fully exclude the possibility of HD. A forceful expulsion of stool and gas may be seen during digital rectal examination as the examining finger dilates the affected rectosigmoid segment. **Emergency Alert: Infants with HD may also present with enterocolitis that can progress to toxic megacolon if untreated. Clinical evidence of enterocolitis includes fever, vomiting, diarrhea, and persistent abdominal distension.**

Plain radiographs may show dilated bowel proximal to the aganglionic segments and an absence of gas in the rectosigmoid region. Contrast enema, anorectal manometry, and rectal biopsy are the three most common modalities for diagnosing HD. Rectal biopsy and anorectal manometry have the highest sensitivity and specificity of over 90%. Contrast enemas have sensitivities and specificities of 70% to 80% (Peranteau & Mattei, 2016). Selection of which test(s) to use may be dictated by institutional availability of equipment and expertise to interpret the results.

Initial evaluation often involves a contrast enema to look for a transition zone. In patients with short- or long-segment HD, the transition zone represents a change from a normal caliber or narrowed aganglionic rectum to a more dilated proximal colon (Peranteau & Mattei, 2016). In patients with total colonic aganglionosis, the colon may appear normal in size, but dilated loops of distal small bowel may be seen. The rectosigmoid index is the ratio between the diameter of the rectum and the sigmoid colon. In children without HD, this ratio is greater than 1, while in children with HD the ratio may be less than 1 (Garcia et al., 2007). A high false negative rate for HD limits its use as a gold standard examination. Suction rectal biopsy and anorectal manometry are considered more sensitive for diagnosing HD (Heuckeroth, 2018).

Anorectal manometry involves inserting a pressure transducer with a balloon at its tip into the rectum. As the balloon is inflated, the transducer continuously measures the pressure of the anal sphincter. Normally, inflation of the balloon should trigger a reflex relaxation of the anal sphincter. In patients with HD, this reflex anal relaxation is absent.

Rectal biopsy is performed to confirm the diagnosis of HD before surgical intervention. The procedure is performed by inserting a suction rectal biopsy instrument 2 to 3 cm into the rectum, applying negative pressure via an attached syringe to suction in intestinal mucosa into a side hole at the end of the device, and then triggering a blade within the biopsy device that excises a small piece of tissue (Noblett, 1969; Peranteau & Mattei, 2016). Samples should contain tissue that includes submucosa to be interpretable. The procedure is convenient, can be done at bedside, and does not require sedation or local analgesia. Uncommon complications include bacteremia, refractory bleeding, and bowel perforation (Peranteau & Mattei, 2016; Rees, Azmy, Nigam, & Lake, 1983). Histologic features of HD include absence of ganglion cells, hypertrophy of nerve fibers, and increased acetylcholinesterase staining (Peranteau & Mattei, 2016).

Management

Surgery is the definitive treatment for HD. Most surgery for HD is nonemergent. After fluid resuscitation, a NG or orogastric tube should be placed for intermittent or continuous suction, and broad-spectrum antibiotics should be started. Twice-daily rectal irrigations and daily digital rectal examinations are also used at some centers (Wesson & Lopez, 2019b). Surgery usually involves resection of the aganglionic portion of the colon and rectum followed by creation of a neorectum using ganglionated normal proximal bowel.

HD-associated enterocolitis is a form of severe infectious colitis unique to patients with HD that can occur before or after surgery (Wesson & Lopez, 2019b). Risk factors for enterocolitis include a family history of HD, trisomy 21, long-segment disease, and prior episodes of enterocolitis (Frykman & Short, 2012; Peranteau & Mattei, 2016). Common symptoms and signs of enterocolitis include abdominal distension, explosive diarrhea, vomiting, fever, lethargy, rectal bleeding, and shock (Frykman & Short, 2012; Peranteau & Mattei, 2016). Plain radiography with lateral decubitus or cross-table lateral views may show dilated proximal bowel, absence of air in the sigmoid or rectum, and air-fluid levels. Treatment of enterocolitis generally includes broad-spectrum antibiotics that target intestinal flora, rectal irrigation with normal saline, and fluid resuscitation. The patient should be kept NPO until there is evidence of clinical improvement or resolution of signs and symptoms. The duration of antibiotic treatment ranges from 5 to 14 days depending on the severity of the enterocolitis. Contrast enemas should be avoided in patients with enterocolitis due to the increased risk of intestinal perforation.

SMALL LEFT COLON

Background

Neonatal small left colon, also known as micro left colon, is characterized by uniform narrowing of the left colon from the splenic flexure to the anus. Neonatal small left colon is thought to be the result of functional immaturity of the colon (Ngo, Stanescu, & Phillips, 2018). There is dilatation of the colon proximal to the splenic flexure with a cone-shaped transitional zone between dilated and narrow areas.

Approximately 40% of patients with small left colon are infants of mothers with diabetes (Ngo et al., 2018). The exact cause of micro left colon is unknown but is thought to represent a colonic motility problem. Normal colonic motility is achieved at term by myenteric plexuses that innervate smooth muscles of the colon. These myenteric plexuses migrate to the colon in a cephalocaudal direction between 5 and 12 weeks of gestation; they mature to normal function as gestation progresses. Failure of migration leads to the absence of ganglion cells as observed in HD; immaturity of migrated myenteric plexuses leads to decreased motility and micro left colon. Histologic examination of the colon in such patients reveals morphologically immature plexuses.

Diagnosis

Infants with small left colon present with signs and symptoms of a lower intestinal obstruction, namely, abdominal distension, bilious vomiting, and failure to pass meconium. Plain radiographs of the abdomen reveal multiple gas-filled loops of dilated small bowel and proximal colon, with decreased air in the distal colon or rectum (Ngo et al., 2018). These features are indistinguishable from HD or meconium plug syndrome. Very rarely, significant distal obstruction with marked dilation proximally may lead to cecal perforation. Contrast enema (barium or Gastrografin) reveals a uniformly small left colon, cone-shaped transition zone in the splenic flexure, and dilated proximal colon (Ngo et al., 2018). HD may have similar findings. A distinguishing feature of micro left colon in contrast to HD is that following contrast enema, infants evacuate the contrast promptly and begin passing stools spontaneously with resolution of lower intestinal obstruction. In some cases, rectal biopsy may be needed to rule out HD. In micro left colon, rectal biopsy reveals the presence of ganglion cells, albeit immature; ganglion cells are absent in HD.

Management

Initial management is similar to that of any intestinal obstruction (diagnosed by plain radiographs): decompression by NG tube, maintenance of hydration, and correction of electrolyte imbalance. Contrast enema is both diagnostic and therapeutic. Oral feedings should be started as soon as the patient starts having bowel movements after an enema and gradually advanced as tolerated. The baby should be diligently monitored for abdominal distension, vomiting, or decreased stool, as these may be harbingers of the recurrence of obstruction. Small left colon spontaneously resolves in the neonatal period, and the long-term outlook is good with usually normal bowel movements.

MECONIUM ILEUS

Background

Meconium ileus (MI) is an obstruction of the distal ileum due to an accumulation of abnormally thick meconium (Carlyle, Borowitz, & Glick, 2012). In the past, a majority (almost 90%) of infants with MI were thought to have CF (Boczar, Sawicka, & Zybert, 2015). However, several studies have since reported 30% to 50% of children with MI do not have CF (Paradiso, Briganti, Oriolo, Coletta, & Calisti, 2011). Non-CF causes of MI include HD, prematurity, and low birth weight.

In CF patients, MI is the result of thick meconium, which in turn is the result of exocrine pancreatic insufficiency—a lack of hydrolytic enzymes results in meconium with an abnormally high content of protein and mucus glycoprotein, resulting in a very viscous meconium (Atlas & Rosh, 2016). It is also postulated that abnormally high fat content in the distal ileum increases neurotensin secretion, causing slowing of intestinal motility and resulting in MI (Carlyle et al., 2012). The histologic hallmark of MI is distension of the goblet cells of the intestinal mucosa.

Diagnosis

Neonates with MI usually present within the first 12 to 24 hours of life. The presentation of MI may be divided into two forms: simple or complicated. In simple MI, the distal ileum is obstructed by very viscid meconium, the proximal small bowel is dilated and thick-walled, and the colon is narrow and empty (microcolon). Complicated MI cases have additional features such as intestinal volvulus, atresia, necrosis, perforation, meconium peritonitis, and meconium pseudocyst.

Affected infants develop signs and symptoms of small bowel obstruction including abdominal distension, bilious vomiting, and absence of stool. Physical examination of the abdomen may reveal a doughy or putty-like ball of meconium that is movable. Rectal examination reveals a normal anal sphincter tone and an empty rectal vault without meconium or stool.

Plain radiographs may show a dilated proximal small bowel and a "soap bubble" or ground-glass appearance in the right lower quadrant (Ngo et al., 2018). Contrast enema shows microcolon. In complicated MI, plain radiographs may show ascites, peritoneal calcifications, or pneumoperitoneum. A sweat chloride test and DNA analysis for CF mutations should be done in all patients suspected of having MI; neonatal screening for CF may be helpful, but the lack of immediate results limits its usefulness in the first few days of life.

Management

The initial treatment is stabilizing the patient with respect to hydration and electrolytes. In simple MI, mildly hypertonic Gastrografin or Hypaque with acetylcysteine is delivered into the distal ileum (during contrast enema) under fluoroscopy to break up inspissated meconium (Carlyle et al., 2012). The loosened meconium is then passed by normal peristalsis. Maintaining adequate hydration is very important, as fluid from the intravascular space is drawn into the intestinal lumen with the hyperosmolar agent. Generally, 4 mL of half-normal saline solution is given for every 1 mL of retained enema. Surgery is indicated if the previous measures fail in simple MI or if the patient has complicated MI (Carlyle et al., 2012). Inspissated meconium is removed surgically by simple enterotomy. A temporary ileostomy may be needed in some cases.

Elemental formula feedings are started when intestinal function is deemed adequate. If the patient has CF, pancreatic enzymes should also be started with feedings. Pulmonary toilet should be initiated as soon as possible, and parents should be referred to a genetic counselor if CF is diagnosed. The long-term prognosis depends on the underlying etiology; non-CF patients have better outcomes than CF patients.

MECONIUM PLUG

Background

Meconium plug syndrome causes distal colonic obstruction and is caused by thick meconium; there is no pancreatic enzyme deficiency. Obstruction is relieved by the passage of meconium and there are no long-term consequences. It is important to distinguish meconium plug syndrome from HD and micro left colon.

The most likely cause of meconium plug syndrome is abnormal gut motility associated with immaturity or hypotonia; about 13% of

patients have HD (Keckler et al., 2008). Premature infants and infants with hypotonia are especially prone to developing a meconium plug. Infants of diabetic mothers are also at increased risk of developing a meconium plug, which is considered a variant of micro left colon.

Diagnosis

Meconium plug patients usually present with signs and symptoms of distal bowel/colonic obstruction; there is gradually increasing abdominal distension, bilious vomiting, and failure of meconium passage. Plain radiographs reveal multiple dilated small bowel loops. Contrast enema reveals a normal caliber colon (as compared to micro left colon) and dilated bowel proximal to the meconium plug.

Management

Supportive measures including NG tube for decompression and maintenance of hydration and electrolytes balance should be started as soon as possible after birth. Contrast enema usually results in dislodgement of the plug and relief from obstruction (Cuenca, Ali, Kays, & Islam, 2012). Once the plug is evacuated, distension has resolved, and normal intestinal function has returned, feedings can be started and advanced as tolerated. Rectal biopsy should be considered in all patients with meconium plug syndrome, especially if constipation continues after relief of the obstruction from the initial meconium plug. Overall, the prognosis is good and complete recovery is expected.

IMPERFORATE ANUS/ANORECTAL MALFORMATION

Background

ARM includes a spectrum of congenital malformations involving the anus and rectum; many are associated with a fistula between the rectum and urogenital system or between the rectum and perineum (Herman & Teitelbaum, 2012). ARM is thought to result from abnormal development of the urorectal septum, which separates the anorectum from the urogenital system, or failure of the migration of the anus. ARM may occur in isolation, as part of the VACTERL association, or other anomalies involving the sacrum, lower spinal cord, or kidneys (Bulas, 2018).

For clinical purposes, ARM is classified according to the lesion location in relation to the internal anal sphincter or levator ani muscle complex. In low lesions, the rectal pouch ends below the internal anal sphincter and opens into the perineum as a narrow opening (anal stenosis, type I) or a fistula (type II). In high lesions, the rectal pouch ends above the internal anal sphincter and communicates externally through a fistula (type III) to the urinary bladder, urethra, or vagina; in rare cases, there may not be any external communication (type IV), causing complete obstruction. In high lesions, the internal sphincter is either absent or very malformed, and there are associated sacral abnormalities. In both types of lesions, the external sphincter is almost always present.

The incidence of ARM in the general population is about 1 in 5,000 live births; it increases to 1 in 100 for siblings of affected individuals (Bischoff, Levitt, & Pena, 2016). The cause of abnormal urorectal septum development or arrested migration of the anus is not known. It seems, however, that both environmental and genetic factors are involved. The mildest form of low lesions presents as anal stenosis, where the anus and rectum are patent but very narrowed; the anus therefore looks very small; it may be missed, as the newborn may be able to pass pasty or loose stools. Other low lesions may be associated with a thin membrane covering the anal opening or a complete absence of an anal opening; in these cases, stool is passed through a fistula in the perineum. In high lesions, there is no anal opening and stool is passed with urine via a fistula to the bladder, urethra, or vagina.

Diagnosis

ARM presents with a variable degree of GI obstruction because of failed or incomplete passage of stool. Symptoms include abdominal distension, poor feeding, vomiting, and delayed or absent passage of meconium. In low lesions, perineal examination will reveal a very small anus or no discernible anal opening, ectopic anal opening, fistula, or bulge in the perineum. In high lesions, there is no anal opening or fistula externally; there may be stool mixed with urine or excreted from the vagina. Careful perineal examination is mandatory and diagnostic in identifying and categorizing ARM.

Management

The treatment of ARM depends on the nature of the defect; it is imperative to define low versus high lesions. As mentioned earlier, careful perineal examination is all that is needed for diagnosis. Prone cross-table lateral x-ray film at 12 to 16 hours after birth may reveal a dilated rectal pouch that ends blindly above the perineum, but it is unreliable for determining the level of the lesion; the larger the distance from the perineum (more than 1.5 cm), the more likely it is to be a high lesion. An ultrasound, CT, and MRI of the pelvis may be able to better define the level of the lesion, and one or more of these modalities may be used prior to a surgical approach.

A pediatric surgeon needs to be involved in the management of ARM as soon as the defect is identified. Anal stenosis (type I, low lesion) is treated by repeated anal dilation using Hegar dilators. The infant can be discharged once it is able to pass stool and there are no signs of obstruction; daily anal dilation is continued at home, as parents are trained prior to discharge. The other simple low lesion, where the anal opening is covered by a thin membrane, requires minimal surgical therapy. The membrane is ruptured or excised and repeated anal dilation is performed as previously noted.

Low lesions with a perineal fistula are corrected by posterior sagittal anorectoplasty, in which the rectal pouch is brought down through the external sphincter (identified using a nerve stimulator) and sutured to the skin at the anal opening. Any fistulous connection is removed. Postoperatively, the infant may need gentle rectal irrigation until stool passes. Anal dilation using the Hegar dilator is usually started after 2 weeks, depending on the pediatric surgeon, and continued at home.

High lesions may require complex reconstructive surgery. These patients have significant intestinal obstruction and require stabilization before surgery. Gastric decompression is achieved with NG tube placement, and dehydration or an electrolyte imbalance is rectified. Usually, correction of the defect is done in two stages. Initially a left-sided colostomy is done as soon as possible for decompression and fecal diversion. If there is any fistula, it is excised. In the second stage, definitive repair is accomplished in 3 to 12 months by abdominal perineal pull-through surgery, where the rectal pouch is pulled through the levator ani muscle sling and the external sphincter and the subsequent anastomosis is done at skin level. The timing of definitive surgery depends on adequate growth and nutritional status of the patient.

Postoperative care of neonates depends on the type of surgery performed. Care of anoplasty patients requires gentle cleaning with saline and monitoring for infection at the suture site and mucosal prolapse. Parents need to be trained in care of the wound site as well as possible dilation as needed. As there is a risk of recurrence of fistulas, patients should be observed for the passage of any stool mixed with urine and for any new opening in the perineum. Once the site is healed, feedings can be started. Initially, a stool softener

may be required to prevent formed stool. If the patient required a colostomy, then daily inspection of the colostomy is mandatory to ensure proper functioning and site integrity. Parents need to be trained in taking care of the colostomy.

All children with an imperforate anus should have an ultrasonography or MRI of the lumbosacral spinal cord to rule out tethering of the spinal cord. The urinary system should also be investigated by ultrasonography for any lesions.

The long-term outcome is measured in terms of achieving continence and a normal stool pattern. Patients with anal stenosis have a very good prognosis, and some may need stool softeners for a long time. For all other patients, there may be late complications, including rectocutaneous anastomosis stricture, recurrent rectourinary fistula, mucosal prolapse, constipation, and fecal incontinence. In general, children with low lesions (below the levator ani complex) achieve normal continence, while only a minority (about one-third) with high lesions achieve continence before school age. The overall mortality rate of patients with anorectal malformation is 15%; death is largely due to complex surgical intervention and is more likely from associated anomalies. About 75% of patients have good outcomes in achieving normal bowel movements and continence.

SUPPORT OF FAMILY WITH AN INFANT WITH A GI SYSTEM DISORDER

The birth of an infant with a congenital anomaly or one who is acutely ill elicits feelings of loss, guilt, and confusion for parents. Nurses and other health professionals must expect grief reactions and be prepared to help the family cope with the crisis. Strategies to cope include support for early contact between parents and infant and open lines of communication to provide factual information of the infant's condition and plan of care. Healthcare providers also need to patiently reinforce information on an ongoing basis as the family begins to process and accept the diagnosis. Understanding of the disease process is essential for parents to cope with the prognosis and ongoing healthcare needs. Encourage the parents to hold their infants to provide skin-to-skin (kangaroo) care as early as possible. Encourage them to express their concerns before they are discharged home.

SUMMARY

The GI system is vital to human growth and development and ultimately long-term survival. The vast majority of conditions that cause GI dysfunction in the infant are the result of congenital anatomic malformations. Additionally, any condition or situation that leads to ischemia and bacterial overgrowth places an infant at risk for NEC and resultant long-term sequelae. The input and support of a variety of nursing, medical, and other specialists are required for optimal outcomes of the infant's physiologic well-being and the parents' psychosocial stability. The major purposes of this chapter were to present the embryologic development of the GI tract and resultant anatomic structure and to describe common causes of neonatal dysfunction with implications for care.

CASE STUDY

■ Identification of the Problem.

An 18-day-old, 38 weeks' gestation male infant presented to the ER with history of poor feeding, poor stooling pattern, abdominal distention, and listlessness. He was admitted with a diagnosis of failure to thrive and had an orogastric tube placed and Pedialyte started. He was transferred to a tertiary care NICU for inability to establish IV access.

■ Assessment: History and Physical Examination

- 38-week gestation male infant born by normal spontaneous vaginal delivery (NSVD) to a 28-year-old, G4, P3003 mother who had an unremarkable pregnancy. Serologies negative, BW 3,220 g and Apgar scores of 8 at 1 minute and 9 at 5 minutes of life
- At birth admission, infant required observation in the hospital for failure to stool. A contrast enema on day of life (DOL) 2 showed movable stool in the colon and no anatomic problems. He was discharged home on DOL 4 after passing two stools.
- On DOL 16, his mother brought him to the hospital because he was irritable, lethargic, and feeding poorly. He was evaluated and sent home.
- On DOL 18, he presented to the ER with listlessness and abdominal distention and was admitted for failure to thrive. Weight at admission was 2,930 g. Unable to secure IV access, he was transferred to a NICU.
- Vital signs: Temp 37, HR 147, respiratory rate (RR) 40, BP 86/55 67, CRT 2 seconds, abdominal girth 36 cm

Physical examination on admission to the NICU:

- GENERAL: irritable active infant with good perfusion, slightly pale, OG tube in place
- HEENT: anterior fontanel soft, flat with sutures approximated, eyes clear with + red reflex
- CARDIOVASCULAR: RRR, no murmur noted, pulses 2+ and equal
- RESPIRATORY: on room air with bilateral clear breath sounds
- ABDOMEN: grossly distended, tender to the touch, BS audible, anus is patent and normally placed
- GENITOURINARY: normal male genitalia
- NEUROLOGIC: lethargic, irritable

Evaluation after transfer to NICU included laboratory work with electrolytes, CBC/differential, C-reactive protein (CRP), blood culture. Peripheral IV placed and PN and antibiotics were started. A Replogle tube was placed to low constant wall suction.

■ Differential Diagnosis

- Hirschsprung's disease
- Jejunoileal atresia
- Meconium ileus
- Meconium plug syndrome
- Small left colon syndrome

■ Diagnostic Tests

Laboratory Tests:

- CBC/differential: WBC 7.5, segmented cells 10, bands 24, hematocrit 45, platelet 326,000/mm^3
- CRP: 11.7
- Electrolytes WNL
- Blood cultures remained negative

Imaging Tests:

- Contrast enema DOL 2: showed movable stool in the colon and no anatomic problems
- Abdominal radiographs: revealed extremely gaseous, distended bowel with no air in the rectum

- Contrast enema (repeated secondary to no rectal air): normal-caliber colon with a transition zone noted at the level of the mid- to distal descending colon
- Rectal biopsy: absence of ganglion cells

HD presents similar to jejunoileal atresia, MI, meconium plug syndrome, and small left colon syndrome. A contrast enema can be helpful in diagnosing the disease by determining the caliber of the colon. Microcolon is typically seen with jejunoileal atresia and MI. Normal or enlarged colon is seen with HD, meconium plug, and small left colon syndrome. Retention of contrast material 24 hours after examination is suggestive of HD. Final diagnosis can be made by rectal biopsy through the anus with histologic examination of the specimen. Absence of ganglion cells in the submucosa confirms the diagnosis of HD.

■ Working Diagnosis

- Term infant with HD: based on absence of ganglion cells
- Colitis due to tender abdomen
- Clinical sepsis due to elevated CRP, shifted CBC, and lethargy

■ Development of Management Plan

- Gastric decompression
- Maintenance fluid support
- Continuous monitoring of vital signs and abdominal girth every 6 hours
- Antibiotics
- Surgical consult

■ Implementation and Evaluation of Effectiveness

Implementation of Management Plan

- Gastric decompression was initiated immediately.
- IV access was obtained on admission.
- PN started for total fluid volume ~ 140 to 150 mL/kg/day, AA at 3 g/kg/day, IL at 3 g/kg/day.
- Laboratory work sent for sepsis workup and electrolytes.
- Ampicillin, gentamicin, and Flagyl were started.
- Abdominal radiograph was obtained.
- Electrolytes were obtained daily until stable, then every 2 to 3 days.
- CBC/diff obtained daily until WNL, then PRN.
- Pediatric surgery consulted and performed normal saline enemas until surgery could be performed.
- After diagnostic workup was completed, decision made to attempt colon endorectal pull-through, although family was informed that a colostomy may be necessary if sequential histologic examinations made during surgery showed higher colonic involvement.
- Social work services was consulted to provide support to family.

Effectiveness of Management Plan

- Abdominal girth improved within 2 hours.
- A laparoscopic subtotal proctocolectomy–right colon endorectal pull-through was successfully performed.
- Ventilated 3 days postoperatively and then successfully extubated to room air.
- Ampicillin and gentamicin were discontinued postoperatively.
- Treated with Rocephin and Flagyl for 5 days postoperatively and will be discharged home on Flagyl for 1 to 2 months.
- Pain was controlled with morphine and Ativan PRN.
- PN was provided at 140 mL/kg/day with 3 g/kg/day protein and intralipids at 3 g/kg/day.
- Enteral feeds were begun on the fifth postoperative day and advanced slowly with full feeds reached in 4 days.

■ **Outcome.** He was discharged to home on room air, on full feedings, and Flagyl. Follow-up was with his pediatrician in 1 week and pediatric surgeon in 2 weeks after discharge.

EVIDENCE-BASED PRACTICE BOX

Establishing a timely diagnosis without adding to patient morbidity is a pillar of good medical practice. Ultrasonography is the preferred diagnostic test in several GI and non-GI conditions including pyloric stenosis, intussusception, cholelithiasis, hydronephrosis, ovarian cysts, and testicular torsion. The performance and interpretation of the majority of ultrasound examinations at most institutions rely on technicians and specialists who are not directly involved in the day-to-day care of patients. Depending on the institution, these individuals may or may not always be readily available.

Point-of-care ultrasonography (POCUS) is a bedside technology that allows healthcare providers to integrate clinical examination findings with real-time sonographic imaging (Marin et al., 2015). POCUS has several important advantages. First, the technology comes to the patients wherever they may be. Second, ultrasound and the performance of ultrasonography is one of the safest radiographic testing modalities. Finally, technologic innovations have dramatically improved portability and simplicity of use for POCUS (www.lumify.philips.com/web). While POCUS has been available since the 1990s, its clinical use in the realm of medical education and clinical practice has steadily increased only in recent years (Bornemann, Jayasekera, Bergman, Ramos, & Gerhart, 2018). Efforts are ongoing to define the conditions and diagnostic protocols for which POCUS can be used, and to develop training programs for nonspecialists who wish to use POCUS (Blanco & Volpicelli, 2016; Bornemann et al., 2018; Hoeffe, Desjardins, Fischer, Carriere, & Gravel, 2016). The use of POCUS in pediatrics is increasingly being recognized, paving the way for its implementation in training programs, and gradually into clinical practice (James, Alsani, Fregonas, Seguin, & Tessaro, 2016; Marin et al., 2015).

PARENT VOICES

Laurel Kapferer, MS

Our son Grayson was born via emergency C-section at 34 weeks. He had suffered IUGR, and at the time of his birth, he weighed only 2 lb 14 oz. Grayson was a very curious, aware, feisty baby with a larger than life personality. He would always interact with us and enjoyed skin-to-skin contact, being sung to, stories, his binky, and having his head rubbed gently.

During the first few days in the NICU, Grayson was progressing well. He was breathing on his own and regulating his own temperature. We thought for sure he would be home in no time. All that changed when Grayson was 6 days old. His color became pale and ashy, and his personality was completely different. That entire day he was crying and fussy. Nothing would comfort him. Later on in the day, Grayson developed a small pink area on his abdomen; x-rays later that day confirmed that he had developed necrotizing enterocolitis. Very quickly, his abdomen became distended and purple. He was eventually transferred to another hospital where his condition continued to worsen. His disease quickly progressed; we were told that Grayson's blood would not clot and surgery would not be possible. Eventually, Grayson's intestines were perforated which led to sepsis.

My husband and I held our son in our arms as he took his last breaths. Less than 18 hours after Grayson was diagnosed with NEC, he lost his life. This disease progressed rapidly and before we even could understand what it was, our son was gone.

Every moment that parents have with their children is precious, especially in the NICU. Things can turn around so quickly and there is not always a happy ending. It is so critical that as nurses you do everything you can to support families bonding with their babies, and that you help them create special moments to hold onto. When we knew that Grayson was losing his battle, we were able to get hand and foot prints, a lock of hair, pictures. In the end, those items along with his blankets, hats, binkies, bracelets, and our memories are all we have left of our son. In those times where it is clear that a child may not be making it home, please be mindful not to throw anything away. Instead, hold on to it for the family. We are so grateful that the NICU nurses thought to do this for us. Having items that were Grayson's, that he touched, and in some way connected with, mean the world to us now.

Jennifer M. Driscoll

Our daughter, Lilian Hope, was born 7 weeks premature, weighing only 2 lb 12 oz and 15 inches long. Lily's lungs were her main problem, as they are for many preemies, because the lungs are the last thing to develop. On the day she was born, she was doing well but still needed a CPAP machine to help her breathe. As the day progressed, her condition worsened. She was given nitric oxide, put onto a ventilator to breathe for her, and an oscillator to vibrate the lungs to help the flow of oxygen. Due to the force of the ventilator and oscillator, an air sac in her lungs burst and she had a chest tube inserted. Additionally, she had an erratic blood pressure and jaundice, and needed multiple blood transfusions. But the miracle continued as she began to gain strength inside herself; she came off the oscillator after 7 days and took out the ventilator herself. By day 8, we were able to hold her for the first time. She ended up only needing to stay in the NICU at Lehigh Valley Hospital for 24 days and was able to come home at a mere 3 lb 11 oz.

Aside from Lily's lung issues at birth, Lily suffered with severe GI issues from the time she was discharged from the NICU until age 5. Lily was bottle-fed because my milk never came in. This was beneficial for her in some ways because we were able to monitor how much she was eating and supplement with high-calorie formula and formula

(*continued*)

(*continued*)

that was geared toward preemies. Unfortunately for her, she would have severe vomiting and lose what seemed like an entire bottle, often during a feeding, or just after she was done, and it would literally fly from her mouth across the room with very severe force. We saw many specialists because she would experience discomfort with the reflux, but it was hard to keep giving this tiny, fragile baby so much medication. Finally, once she began some solid foods, the reflux slowed down; however, it immediately led to other motility issues for her. Over her next few years, she would experience failure to thrive, worsened motility issues, and an eventual emergency surgery at Children's Hospital in Philadelphia. It took her one full year under the care of a specialist to work through those issues and begin to stabilize, which was by age 5.

CHAPTER 9

Metabolic System

Susan Kau and Stephanie Hoe

INTRODUCTION

Metabolism is a sequence of chemical reactions that takes place in cells of the body. These reactions are responsible for the breakdown of nutrients and the generation of energy. Inborn errors of metabolism (IEM), also known as EM, are a group of disorders that causes blockages in metabolic pathways, which can lead to clinically significant consequences. Chemical compounds called enzymes are responsible for the reactions that happen to make metabolism. There are also cofactors, also known as compounds, that help these enzymes carry out their reactions. A few examples of metabolism include breaking down the carbohydrates, protein, and fats in food to release energy as well as transforming excess nitrogen into waste products that get excreted in urine.

EMs are a heterogenous group of monogenic diseases that can affect the metabolic pathways. Most EMs are named for an enzyme that is not working properly. Depending on the enzyme's job, its absence means toxic chemicals may build up, or an essential product may not be produced. The code or blueprint to produce an enzyme is usually contained on a pair of genes. Most people with inherited metabolic disorders inherit two defective copies of the gene—one from each parent. Both parents are carriers of the bad gene, meaning one normal copy and one defective copy. A mutation in the gene causes it to not function properly or not function at all. These can be inherited from their parents or occur spontaneously.

The likelihood that someone else in the family has the same EM depends on several factors:

- Inheritance pattern of EM
- Whether at-risk family member is a male or female
- Rest of family history (how many family members have previously been tested or diagnosed with disorder already)

When discussing how genetic conditions are passed on in a family, it is important to understand that we have two copies of most genes, with one copy inherited from our mother and one copy inherited from our father. This is not the case for genes that are on our sex chromosomes (the "X" and the "Y" chromosomes). These are different in men and women: men only have one X chromosome and therefore one copy of genes on that chromosome, while women have two X chromosomes and therefore two copies of genes on that chromosome. A father passes on his X chromosome to all his daughters and his Y chromosomes to all his sons. A mother passes on an X chromosome to each child. The recommendation is to talk to a metabolic specialist or genetics specialist for family members who may be at risk for having an EM and for coordination of genetic testing if deemed appropriate.

The earlier an infant develops symptoms of an EM, the more severe the disorder. Severity of symptoms is generally based on several factors: position of the defective enzyme within the metabolic pathway, whether or not there is any functional enzyme or cofactor being produced, and other genetic or environmental factors. EMs are considered multisystemic diseases and infants may present with a variety of symptoms dependent on the specific metabolic pathway. Symptoms of substrate and intermediary metabolism develop once a significant amount of toxic metabolites accumulates following the initiation of feeds and may include the following: poor feeding, vomiting, diarrhea, temperature instability, tachypnea, apnea, bradycardia, poor perfusion, irritability, involuntary movements, posturing, abnormal tone, seizures, and altered level of consciousness. For EM of energy deficiency, symptoms usually develop within 24 hours and are usually present at birth. Neonates with EMs that result in defects in energy production usually have dysmorphic features, skeletal malformations, cardiopulmonary compromise, organomegaly, and severe generalized hypotonia. For those infants with errors of substrate and intermediary metabolism, physical examination findings are usually unremarkable. Acute decompensation in the neonate includes certain forms of tyrosinemia, organic acidemia, urea cycle defects, fatty acid oxidation defects, and galactosemia. An infection in an infant with an EM can result in a metabolic crisis (McGuire, 2017). This condition can result in death but more research needs to be done in this area; a National Institutes of Health (NIH)-funded study *Metabolism, Infection, and Immunity in Inborn Errors of Metabolism* is being conducted by Dr. Peter McGuire. The inherited metabolic disorders manifesting in the early neonatal period are the focus of this chapter.

GENERAL PRINCIPLES: THE NEONATE WITH A METABOLIC DISORDER

Pathophysiology of EMs

The genetic mechanisms through which biochemical disease is inherited include autosomal dominant, autosomal recessive, sex-linked recessive, or a mutation in mitochondrial DNA

(Cederbaum, 2018). The genetic mutation leads to an absent or defective gene product or enzyme, causing either an accumulation of precursors before a blocked step in a metabolic pathway, a deficiency of a critical metabolic product, or both. In disorders involving the intermediary metabolism of small molecules (such as maple syrup urine disease, MSUD), the accumulated molecules give rise to an "intoxication syndrome" because of the profoundly toxic nature of these substances and their effect on the central nervous system (CNS). Disorders involving energy metabolism (such as pyruvate dehydrogenase, PDH, deficiency) lead to a failure of energy production or utilization with a broad range of symptoms and physiologic consequences. Other disorders, such as lysosomal storage diseases, involve complex molecules, and symptoms that arise from these disorders are permanent, progressive, and independent of intercurrent events.

Clinical Manifestations of EMs

Most neonates who are eventually diagnosed with EMs appear essentially normal at birth and have no history of antepartum or intrapartum complications. The placenta and maternal circulation protect the fetus from the damaging effects of toxins. Birth is followed by a symptom-free interval of variable duration. Some metabolic disorders are unmasked by the ingestion of formula, milk, or fructose. Others are unrelated to feeding or may be brought on by fasting, infection, or stress.

Metabolic disease in the newborn can be clinically silent, indolent, or acute (Cederbaum, 2018). Five common presentations have been described (Leonard & Morris, 2010):

- Neurologic presentation—acute encephalopathy, seizures, lethargy
- Hypoglycemia
- Acid–base abnormalities—particularly metabolic acidosis and respiratory alkalosis
- Cardiomyopathy and cardiac arrhythmias
- Acute liver disease

The earlier an infant develops symptoms of an EM, the more severe the disorder. Severity of symptoms is generally based on several factors: position of the defective enzyme within the metabolic pathway, whether or not there is any functional enzyme or cofactor being produced, or other genetic or environmental factors. EMs are considered multisystemic diseases and infants may present with a variety of symptoms depending on the specific metabolic pathway involved.

A complete family history should be obtained to determine if other individuals in the family have had similar symptoms or the same disorder, or if there is a history of unexplained infant death, sudden infant death syndrome (SIDS), mental retardation, or consanguinity (Leonard & Morris, 2010).

Diagnosis of EMs

The trigger for a metabolic workup varies with the situation. In infants initially suspected of having sepsis, a metabolic workup might be initiated when laboratory results to investigate infection fail to confirm infection. **Emergency Alert: Persistent metabolic acidosis with an increased anion gap, hypoglycemia, significant hyperammonemia, unexplained hepatic dysfunction, or ketonuria should always raise suspicion of EM** (Leonard & Morris, 2010). Although only a minority of EMs are associated with dysmorphism, the possibility of metabolic disease should not be discounted in the neonate with congenital malformations or unusual features.

The initial laboratory investigation of a suspected EM includes a broad range of tests of both blood and urine (Box 9.1). Nonspecific screening tests do not provide a diagnosis; at best, they will support a strong suspicion of a metabolic disorder and suggest a specific category of disease (e.g., organic acidemia, fatty acid oxidation disorders—FAOD). Interpretation of results can be tricky. Conditions of sampling can profoundly affect results. Blood and urine samples must be obtained prior to the initiation of therapy, and, whenever possible, both should be collected when the infant is symptomatic (Mussa, Porta, Hoffmann, & Sarafoglou, 2017). Extra blood and urine samples should be obtained and frozen for later testing. It is important for health professionals to understand

Box 9.1

GENERAL SCREENING TESTS FOR ERRORS OF METABOLISM

Blood Tests

Glucose
Complete blood count with differential
Blood gases
Electrolytes (and anion gap[a])

Liver function tests

Blood urea nitrogen and creatinine
Total and direct bilirubin
Prothrombin time and partial thromboplastin time
Uric acid
Ammonia
Lactate
Pyruvate
Amino acids
Free fatty acids
Ketones (3OH-butyrate, acetoacetate)
Creatinine phosphokinase
Newborn metabolic screen/blood acylcarnitine analysis
Cerebrospinal fluid glycine (to rule out nonketotic hyperglycinemia)

Urine tests

Glucose
Ketones
pH
Reducing substances
Ferric chloride reaction
Dinitrophenylhydrazine reaction
Amino acids
Organic acids
Odor
Orotic acid (if blood NH_4 elevated)

[a]Anion gap is (sodium − [chloride + bicarbonate]). Normal is less than 15 mEq/L.

the limitations of laboratory testing, which tests are appropriate under what conditions, and how the infant's symptoms relate to such testing (Rice & Steiner, 2016).

Quality and Safety: Secondary metabolic derangements can interfere with test interpretation, and biochemical abnormalities might be present only during acute episodes. Laboratory abnormalities can also be transient; a result within the reference range does not necessarily rule out a metabolic disorder. Studies may need to be repeated at specific times. Clinicians might be falsely reassured by screening tests that are inadequate to exclude certain conditions. Therefore, consultation with a metabolic specialist is recommended. Furthermore, a clinical history and as much information as possible about the infant's symptoms and the suspected diagnosis should be provided to the referral laboratory to improve the accuracy of testing and interpretation of results.

Postmortem Diagnosis. If a neonate with a possible metabolic disorder dies suddenly, it is of great importance to continue to try to establish the proper diagnosis for purposes of genetic counseling and future antenatal diagnosis. In addition to standard blood and urine samples, a sample of cerebrospinal fluid (CSF) should be obtained if possible, and whole blood and bile should be collected on filter paper. The routine state newborn screening card should be completed and sent. If the family declines a full autopsy, tissue biopsies should be obtained. Tissue samples of value are skin, liver, kidney, and muscle.

Neonatal Screening. Newborn screening was first introduced as a public health program in the United States in the early 1960s, and has expanded to other countries around the world, with different testing menus in each country. Both prenatal and newborn screenings have improved healthcare. The conditions included in the newborn screening programs around the world vary greatly, based on the legal requirements for screening programs, prevalence of certain diseases within a population, political pressure, and availability of resources for both testing and follow-up of identified patients.

The development of tandem mass spectrometry (MS/MS) has greatly improved the presymptomatic detection of a large number of EMs. With MS/MS, it is possible to measure 30 or 40 different metabolites in less than 2 or 3 minutes, using a single dried blood spot. MS/MS works by applying a charge to the compounds in solution, sending them through an electromagnetic field, sorting them out, and weighing them according to their mass-to-charge ratio. Expanded newborn screening using MS/MS is mandated in some states as part of the routine newborn screening program. It is also available to parents who wish to purchase it from a number of private laboratories at a nominal cost. Currently, MS/MS screens only for disorders of intermediary metabolism, including amino acid disorders, organic acid disorders, and FAODs. A normal neonatal screen, even an expanded newborn screen by MS/MS, does not rule out an error of metabolism in a suspicious clinical setting. **Quality and Safety: If newborn screening tests are still pending when a neonate manifests potential signs and symptoms of metabolic disease, clinicians should contact the screening laboratory promptly to determine whether a diagnosis can be provided or to expedite results** (Yudkoff, Summar, & Haberle, 2017).

Management of the Newborn With an EM

Treatment of EMs is tailored to the specific disorder once a diagnosis is made. In general, the goals of treatment are to minimize or eliminate the buildup of toxic metabolites that result from the block in the metabolic pathway while maintaining growth and development. This may be done by using diets, supplements, and medications.

As soon as it becomes apparent that the infant has some type of metabolic disorder, it is important to consult a metabolic specialist/geneticist. In addition to general supportive measures as indicated by the infant's symptoms, both general and specific treatments should be initiated. **Quality and Safety: Oral feedings and amino acid solutions (all protein sources) are withheld, and 10% glucose solution with electrolytes is administered temporarily until the precise diagnosis is ascertained.** A glucose infusion rate of at least 5 mg/kg/minute (and higher if tolerated, aiming for 120–150 kcal/kg/day) is administered, because many metabolic disorders are exacerbated by tissue catabolism (Cederbaum, 2018). **Quality and Safety: Intralipids are withheld until disorders of fatty acid oxidation have been ruled out. Acute hypoglycemia, metabolic acidosis, dehydration, hypovolemia, and electrolyte imbalances are corrected as part of the overall supportive management of a metabolic disorder. If the infant is to be transferred to a referral center, reliable vascular access should be secured prior to transport.** Hemodialysis or extracorporeal membrane oxygenation (ECMO) may be required for emergency management of some EMs. Liver transplantation can be lifesaving in some EMs. Many disorders with rapid neonatal or prenatal onset are lethal, and all that can be offered are palliative and symptomatic care.

Interactions with parents and other family members are critically important, not only at the time of diagnosis, but throughout the course of care (Box 9.2). EMs occur in newborn infants with a broad range of racial/ethnic backgrounds. It is important to provide culturally sensitive care, which includes access to interpreter services, exploration of the family's sociocultural background, and bidirectional communication as well as decision making in the best interest of the child (Stockler, Moeslinger, Herle, Wimmer, & Ipsiroglu, 2012).

UREA CYCLE DISORDERS

Urea cycle disorders (UCDs) are caused by inherited defects in genes encoding enzymes or membrane transporters involved in ureagenesis. All are transmitted as autosomal recessive traits except ornithine transcarbamylase (OTC) deficiency, which is X-linked, and the most common of the primary defects. In aggregate, the prevalence of UCDs is believed to be approximately 1 per 10,000 live births, if partial defects are included.

Box 9.2

NURSING IMPLICATIONS FOR FAMILIES OF INFANTS WITH ERRORS OF METABOLISM

Nurses should support the families of these infants in the following ways:

1. Assuring that the programs are implemented safely and effectively
2. Facilitating education of the nursing workforce, and developing and contributing to programs of research focused on newborn screening
3. Educating parents with appropriately timed discussion of results. Parental teaching that includes materials providing descriptions of how screening results will be communicated to the family and what they should expect if retesting is needed (Arnold et al., 2006; Davis et al., 2006).

Pathophysiology

The hepatic urea cycle is the mechanism used by the body to detoxify and eliminate ammonia generated from nitrogen waste. Five enzymatic reactions make up the urea cycle, leading to the incorporation of ammonia into urea and enabling its excretion in the urine (Figure 9.1). The first two steps, the carbamoyl phosphate synthetase (CPS) and OTC reactions, take place in the mitochondria and lead to the synthesis of citrulline. In a subsequent cytosolic reaction, citrulline is converted to argininosuccinate, which is hydrolyzed to arginine and fumarate. Arginine is then hydrolyzed to urea and ornithine is regenerated.

A block of the urea cycle can result from a deficiency of any one of the first five enzymes in the urea cycle pathway: carbamoyl phosphate synthetase I (CPSI deficiency), OTC deficiency, argininosuccinic acid synthetase (citrullinemia), argininosuccinic acid lyase (argininosuccinic aciduria), arginine, a cofactor producer, N-acetylglutamate synthase (NAGS) deficiency, or a transport protein (Yudkoff et al., 2017). The outcome of a block in the urea cycle is an accumulation of precursor metabolites, including ammonia, which have no effective alternate clearance pathway. The neonate, with an immature liver and tendency toward catabolism, is poorly equipped to handle the excess metabolites and rapidly succumbs to the neurotoxic effects of high ammonia levels. Hyperammonemic encephalopathy results from osmotic swelling in the brain caused by glutamine accumulation in cerebral astrocytes, where glutamine synthesis is increased in response to high ammonia levels. The developing brain is much more susceptible to the deleterious effects of excess ammonia than the adult brain, leading to irreversible cortical atrophy, ventricular enlargement, demyelination, or gray and white-matter hypodensities in survivors, the extent of which depends on the magnitude and duration of ammonia exposure and the degree of brain maturation (Braissant, 2010).

Clinical Manifestations

Infants with complete urea cycle enzyme defects such as OTC and CPSI deficiency are usually born at term, with no prenatal complications, because the maternal circulation prevents a buildup of toxic ammonia (Yudkoff et al., 2017). Affected newborns are initially healthy, but shortly after receiving their first protein feedings, they begin to show signs of clinical decompensation and hyperammonemic encephalopathy. **Emergency Alert: The earliest signs of ammonia toxicity are irritability, hypotonia, hypothermia, lethargy, poor feeding, vomiting, and hyperventilation.** A mild respiratory alkalosis with tachypnea is a common early finding that should prompt measurement of a plasma ammonia level. Neurologic deterioration is progressive, with loss of tone and reflexes, eventually leading to respiratory failure and coma. Hepatomegaly may also be present. Without treatment, most infants will die from complications such as cerebral or pulmonary hemorrhage, or neurologic or cardiac problems.

Diagnosis

The hallmark of a UCD is an elevated blood ammonia level. A plasma ammonia level of 150 µmol/L (>260 mcg/dL) or higher in neonates, with a normal anion gap and a normal blood glucose level, is a strong indicator of a UCD (Yudkoff et al., 2017). The exception is arginase (ARG) deficiency, which does not typically cause a rapid rise in plasma ammonia level. A normal ammonia level in a healthy infant is less than 65 µmol/L. Blood sampling and handling techniques can affect results. Blood for ammonia levels should be collected by arterial or venous sampling and kept on ice, and plasma should be separated within 15 minutes of collection. Hemolysis, delayed processing, and exposure to room air can falsely elevate ammonia levels. Blood taken by capillary puncture

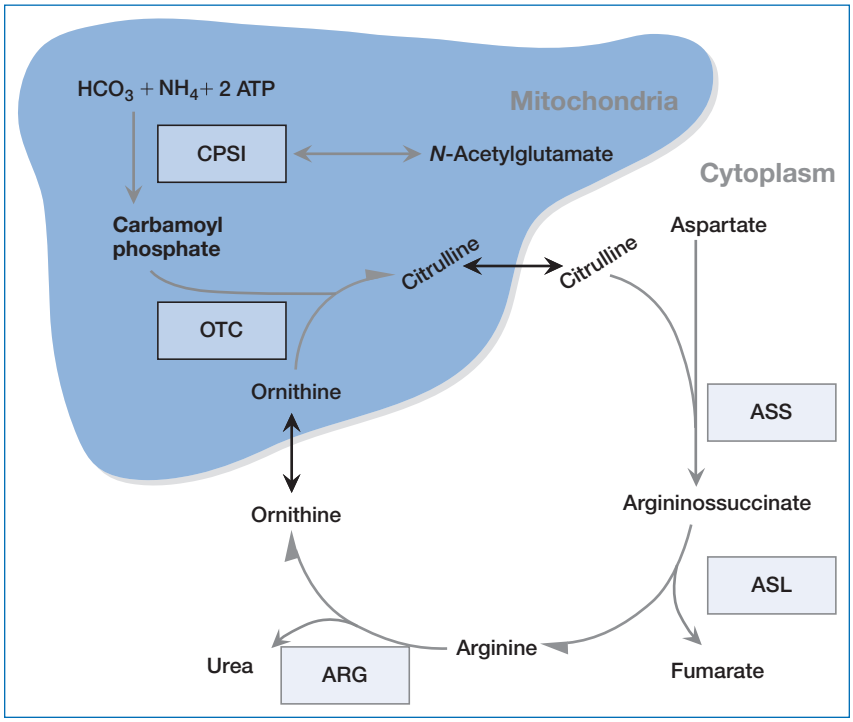

FIGURE 9.1 The urea cycle and alternative pathways of nitrogen excretion. Nitrogen is converted to ammonia (NH_4) and transported to the liver, where it is processed via the urea cycle, composed of five enzymes in the direct pathway: (1) carbamoyl phosphate synthetase I (CPSI); (2) ornithine transcarbamylase (OTC); (3) argininosuccinic acid synthetase (ASS); (4) argininosuccinic acid lyase (ASL); (5) arginase (ARG).

Source: Adapted from Ah Mew, N., Kimpson, K. L., Gropman, A. L., Lanpher, B. C., Chapman, K. A., & Summar, M. L. (2017). In M. P. Adam, H. H. Ardinger, R. A. Pagon, & S. E. Wallace (Eds.), *GeneReviews®* [Internet]. Seattle: University of Washington, Seattle. Retrieved from https://www.ncbi.nlm.nih.gov/books/NBK1217

is not appropriate for measurement of blood ammonia levels because of hemolysis (Leonard & Morris, 2010). If the ammonia level of a newborn with a suspected UCD is only modestly elevated, it should be repeated after several hours because the level can rise rapidly.

Blood gases, electrolytes, glucose, and other routine clinical laboratory tests should be obtained. Metabolic acidosis with a normal anion gap is sometimes present in UCDs, but not as often as in disorders of organic acid metabolism. Blood urea nitrogen (BUN) is low, but this is not specific or sensitive for UCDs. Liver function tests are important to rule out possible causes of hyperammonemia related to liver disorders or dysfunction (Merritt & Gallagher, 2018).

To arrive at a more precise diagnosis, quantitative plasma and urinary amino acids are necessary. Plasma glutamine, alanine, and asparagine, which serve as waste storage forms of nitrogen, may all be elevated. Plasma arginine is low in all UCDs of neonatal onset. The amounts of citrulline, argininosuccinic acid, and arginine in plasma and orotic acid in urine are usually sufficient to differentiate among UCDs. Measuring enzyme activity in tissue (liver, cultured skin fibroblasts, or RBCs) at a later point in time provides a definitive diagnosis that may be desirable for genetic counseling or future prenatal testing. Molecular genetic testing using linkage analysis or mutation scanning is available for OTC and CPSI deficiencies as well as citrullinemia, allowing for diagnostic confirmation, carrier detection, and prenatal diagnosis. Three UCDs (citrullinemia, argininosuccinate lyase deficiency, and ARG deficiency) can also be detected by the amino acid panels of expanded newborn screening programs employing MS/MS.

Differential Diagnosis of Hyperammonemia. Several other EMs can cause hyperammonemia in the newborn, notably the organic acidemias, propionic acidemia, methylmalonic acidemia (MMA), the FAODs, medium chain acyl-CoA dehydrogenase deficiency (MCAD), systemic carnitine deficiency, and long-chain FAODs, although the last group is also associated with hypoglycemia. Hyperammonemia is also a feature of pyruvate carboxylase deficiency (PCD) and PDH deficiency. In transient hyperammonemia of the newborn (THAN), very high plasma ammonia levels, often matching those of UCDs, exist for which no underlying cause can be found. THAN is usually associated with prematurity and has no genetic basis, nor does it recur in infants who survive the initial episode (Merritt & Gallagher, 2018). A simple algorithm can be useful to determine the cause of hyperammonemia (Figure 9.2).

The uniform newborn screening panel was updated to include more UCDs (U.S. Department of Health and Human Services [HHS], 2018). To date, no screening is available for OTC, CPS1, or NAGS deficiency.

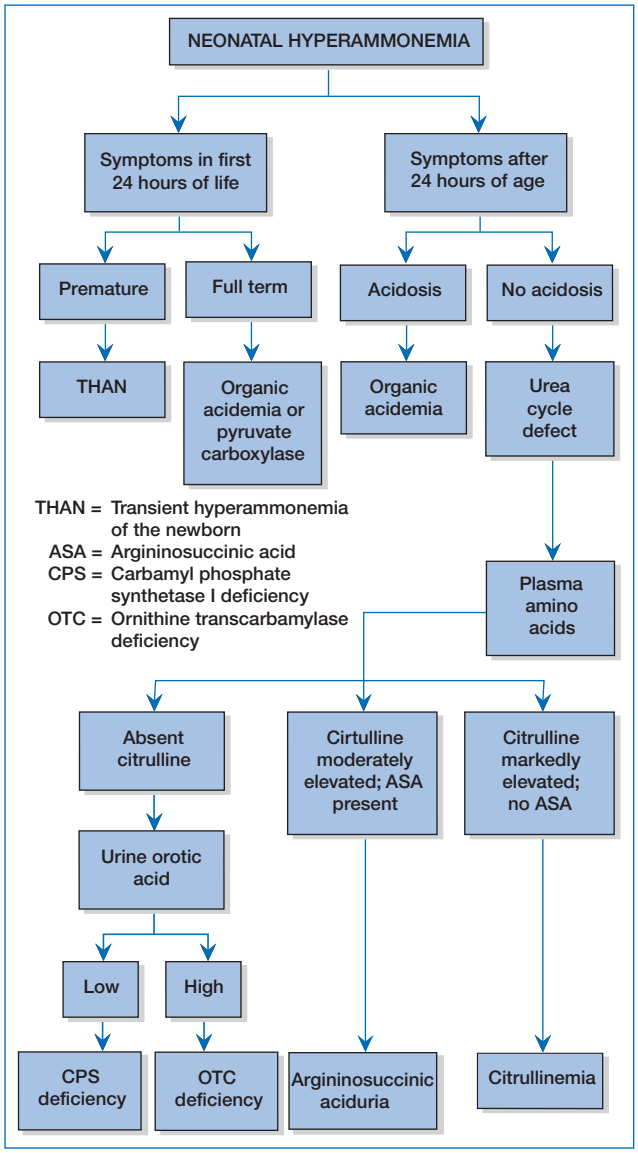

FIGURE 9.2 Algorithm to differentiate among conditions that produce neonatal hyperammonemia.

Management

The emergency treatment of an infant with a suspected UCD has three simultaneous requirements: (1) physical removal of ammonia from the circulation; (2) reversal of catabolism; and (3) scavenging of excess nitrogen (Yudkoff et al., 2017). **Quality and Safety: Dietary protein intake should cease and be replaced by high-energy intake with a protein-free formula or by intravenous glucose and lipid infusion started, if enteral feeding cannot be tolerated.** Protein intake is stopped only temporarily, however, because failure to supply essential amino acids will eventually result in catabolism and further ammonia production. Within 48 hours, 1 to 1.5 g/kg/day of protein should be restarted, with 50% as essential amino acids. Fever, if present, must be aggressively treated. The kidneys remove ammonia poorly, so plasma ammonia levels are monitored closely and ammonia concentrations greater than 500 µmol/L must be reduced promptly with hemodialysis or hemofiltration. Peritoneal dialysis is much less effective in clearing ammonia from the body. For this reason, it is recommended that neonates with symptomatic hyperammonemia be transferred without delay to a neonatal facility capable of providing effective toxin removal.

Compounds that conjugate to amino acids, providing an alternate route for the excretion of nitrogen, can be given to lower the nitrogen burden, and therefore the ammonia burden, of an infant with a UCD. These agents (called "scavenger drugs" or diversion therapy) include N-carbamylglutamate (which activates CPSI and stimulates ureagenesis), sodium benzoate (which is conjugated with glycine to form hippurate), and sodium phenylbutyrate (which is oxidized in the liver to phenylacetate and then with glutamine and excreted in the urine). N-carbamylglutamate has been effectively used to treat NAGS deficiency (Daniotti, la Marca, Fiorini, & Filippi, 2011). Serum potassium levels must be monitored closely when these drugs are used. A preparation

combining both sodium phenylbutyrate and sodium benzoate is also available. In babies with citrullinemia and argininosuccinic aciduria, nitrogen can be excreted by increasing losses of citrulline and argininosuccinic acid, respectively. Arginine supplementation enhances the excretion of these metabolites by replenishing the supply of ornithine. However, high doses of the intravenous preparation L-arginine-HCl can cause metabolic acidosis and must be administered via central line because it can cause tissue necrosis if extravasation occurs.

A neonate in acute hyperammonemic coma caused by a suspected UCD should be given loading doses followed by continuous infusions of the ammonia-scavenging drugs (L-arginine-HCl, N-carbamylglutamate, sodium benzoate, and sodium phenylacetate), and drug levels should be monitored to reduce the risk for toxicity. Dietary protein is reintroduced in low amounts (0.5 g/kg/day) to encourage an anabolic state, while continuing diversion therapy to control ammonia levels. Alternative therapies that have been used with variable success for neonatal UCDs include liver and hepatocyte transplantation.

Prognosis. Even with the most vigorous intervention, UCDs of neonatal onset are often fatal, and the few survivors have a high rate of neurologic disability (Braissant, 2010). In a recent series, a mortality rate of 32% was found in infants with UCDs who were symptomatic within the first 30 days of life (Summar, Dobbelaere, Brusilow, & Lee, 2008). OTC deficiency is typically the most severe and lethal defect, particularly among males. The extent of permanent neurologic impairment in survivors is related to the duration of the hyperammonemic coma, plasma ammonia level at diagnosis, and other unidentified factors. Neonatal onset is associated with the worst prognosis (Braissant, 2010). Neurologic outcomes can be improved with early orthotopic liver transplantation (Campeau et al., 2010).

DISORDERS OF AMINO ACID METABOLISM

Amino acids play a role in literally all metabolic and cellular functions. As the constituents of protein, amino acids are used for the synthesis of new protein and as a source of carbon skeletons for generating glucose and ketone bodies. Amino acids are classified as nonessential or essential, depending on whether they can be synthesized by the body or must be obtained from dietary sources.

The disorders of amino acid metabolism, also called aminoacidopathies, arise from deficiencies of enzymes required to metabolize specific amino acids or amino acid transporters. The effects of the aberrant metabolism are highly disease specific. In some aminoacidopathies, clinical symptoms are caused by the relatively rapid accumulation of toxic metabolites that are substrates for the dysfunctional enzyme (Leonard & Morris, 2006). In other amino acid disorders, damaging effects of the enzyme deficiency are more gradual and chronic in nature.

The most well-known disorder of amino acid metabolism, perhaps of all the errors of metabolism, is phenylketonuria (PKU). The clinically and biochemically heterogeneous disorders of amino acid metabolism are inherited primarily as autosomal recessive traits.

Nonketotic Hyperglycinemia (NKH)

Pathophysiology. NKH (also known as glycine encephalopathy) is a disorder of glycine metabolism that is generally fatal in its neonatal form. Glycine, a glucogenic amino acid, is normally metabolized by a complex of enzymes known as the glycine cleavage complex, consisting of four proteins encoded on four different chromosomes. A defect in any of these enzymes interferes with the cleavage of glycine, resulting in a steep rise in glycine concentration in the blood and CSF. The exact pathophysiology of NKH is not known, but it is believed to be related to glycine's role as a neurotransmitter (Gibson, Van Hove, Willemsen, & Hoffman, 2017).

Clinical Manifestations. In classic neonatal NKH, symptoms usually start soon after birth and are not related to feedings. The clinical picture is dominated by neurologic decompensation: rapidly increasing stupor, lethargy, unresponsiveness, apnea, and sustained seizures that are difficult to control (Gibson et al., 2017). Myoclonic jerking and hiccupping (from diaphragmatic spasms) are also common. Within 1 to 3 days, the infant becomes comatose and death ensues. Babies who survive have intractable seizures and uniformly poor neurologic outcomes.

Diagnosis. Glycine is elevated in plasma, urine, and CSF. The CSF-to-plasma glycine concentration ratio of affected infants is greater than 0.09 (normal is <0.04). The diagnostic workup fails to find evidence such as metabolic acidosis, ketosis, hyperammonemia, or abnormal organic acids in blood or urine suggestive of another EM. Electroencephalographic (EEG) tracings typically show a burst suppression pattern with hypsarrhythmia (random, high-voltage slow waves and spikes that arise from multiple foci and spread to all cortical areas). Confirmation of the exact enzyme deficiency is made by enzyme assay of a liver sample or by molecular analysis.

Management. No consistently effective therapy has been discovered for classic neonatal-onset NKH. Attempts to reduce plasma glycine levels with sodium benzoate, and manage seizures with anticonvulsants, have not changed the poor neurodevelopmental outcomes of NKH (Gibson et al., 2017).

Hereditary Tyrosinemia

Hereditary tyrosinemia type I, also called hepatorenal tyrosinemia or fumarylacetoacetate hydrolase (FAH) deficiency, is a severe autosomal recessive metabolic disorder affecting the liver, kidney, and nervous system.

Pathophysiology. Tyrosine is derived from the metabolism of dietary phenylalanine, and from catabolic processes. Tyrosine degradation requires a series of enzymes, the last of which is FAH. A deficiency of this enzyme characterizes tyrosinemia type I (Morris & Chakrapani, 2017). The offending compounds in tyrosinemia type I are fumarylacetoacetate and maleylacetoacetate, both of which accumulate in the cells of the liver and kidney and cause cell death by apoptosis. Although hepatocytes are quickly regenerated, liver function can deteriorate rapidly in babies with tyrosinemia type I (Cederbaum, 2018).

Clinical Manifestations. Patients with hereditary tyrosinemia type I may come to clinical attention in the newborn period or within the first 3 weeks of life. Newborns present with evidence of liver dysfunction including firm hepatomegaly, splenomegaly, bleeding from coagulation defects, jaundice, and ascites (Morris & Chakrapani, 2017). Renal tubular dysfunction and hypophosphatemic rickets are common.

Diagnosis. The diagnostic workup includes liver function tests, which typically show elevated transaminases, and prolonged PT and PTT. Plasma tyrosine, phenylalanine, methionine, bilirubin, and serum alfa fetoprotein (AFP) may be elevated. The urine organic acid analysis reveals increased excretion of succinylacetone. The diagnosis can be confirmed by enzyme analysis of cultured skin fibroblasts or molecular studies. Hereditary tyrosinemia is included in the recommended uniform newborn screening panel (HHS, 2018).

Management. Hereditary tyrosinemia type I is now treated with nitisinone, a potent inhibitor of 4-hydroxyphenylpyruvate dioxygenase (Morris & Chakrapani, 2017). The response is monitored with urine succinylacetone, liver function tests, clotting studies, renal tubular function, and serum AFP. Most patients respond within a week with improved liver and renal function.

Dietary management involves feeding the infant a phenylalanine- and tyrosine-free formula, or breastfeeding, with phenylalanine supplementation sparingly, if needed (Morris & Chakrapani, 2017). Some infants will require a liver transplant to avoid the development of hepatocellular carcinoma.

Transient Tyrosinemia

Transient tyrosinemia in the newborn is the most common disorder of tyrosine metabolism.

Pathophysiology. Transient tyrosinemia is most likely caused by immaturity of 4-hydroxyphenylpyruvic acid dioxygenase (4HPPD), a vitamin C–dependent enzyme in the tyrosine degradation pathway. Risk factors include prematurity (hepatic immaturity), low vitamin C intake, and excessive protein intake. In some infants, transient tyrosinemia may be precipitated by endogenous catabolism. Tyrosinemia peaks in the first 14 days of life and resolves by 1 month of life (Morris & Chakrapani, 2017).

Clinical Manifestations. Lethargy and poor feeding may be seen in neonates with hypertyrosinemia, particularly in preterm infants.

Diagnosis. Transient hypertyrosinemia is identified by positive newborn metabolic screen.

Management. All infants with an elevated tyrosine on initial newborn screen should have a repeat screen done, with confirmatory testing for those who remain abnormal (see Hereditary Tyrosinemia). This is usually a self-limited disorder that does not require therapy. Therapies include a low-protein diet and supplemental vitamin C as a cofactor to increase the activity of 4HPPD and accelerate the fall in tyrosine concentration.

Phenylketonuria

Classic PKU is an autosomal recessive disorder caused by mutations in both alleles of the gene for phenylalanine hydroxylase, found on chromosome 12. Classic PKU occurs in about 1 in 10,000 to 13,000 live births (Hertzberg, Hinton, Therrell, & Shapira, 2011). Although PKU rarely manifests clinically in the newborn period, it is discussed here because it is important for neonatal caregivers to be able to provide accurate information to parents about key genetic conditions for which their newborn infants are being screened.

Pathophysiology. The effect of the inactive phenylalanine hydroxylase enzyme is an inability to metabolize phenylalanine, resulting in hyperphenylalaninemia. Following ingestion of adequate amounts of breast milk or formula, blood phenylalanine levels gradually increase. Phenylketonuric compounds are excreted in the urine, one of which (phenylacetic acid) imparts the musty or mousy odor characteristic of PKU. If dietary therapy is not implemented at birth, mental retardation can occur.

Clinical Manifestations. Biochemical manifestations of PKU are present in the newborn, but there are no outward clinical signs or symptoms. A musty odor may be detectable in the infant's urine around the end of the first week of life, if plasma phenylalanine levels reach 10 to 15 mg/dL.

Diagnosis. **Quality and Safety: Early diagnosis is critical because PKU is a preventable cause of mental retardation.** Plasma phenylalanine in the normal infant is less than 2 mg/dL. In infants with PKU, the plasma phenylalanine level usually exceeds 4 mg/dL by 24 hours of age and is 20 to 40 mg/dL by the end of the first week of life. PKU is a pioneer among metabolic disorders; it was the first disorder for which a screening test was developed in 1961 (the Guthrie test, a bacterial inhibition assay), and the first disorder to be screened for using MS/MS. MS/MS has dramatically decreased the number of false positive screening results, as well as further clarifying the prevalence of variants of hyperphenylalaninemia in the population.

Management. PKU is currently treated with a low-phenylalanine diet; however, compliance can be a long-term problem and dietary treatment can be associated with other nutritional deficiencies. Enzyme substitution with recombinant phenylalanine ammonia lyase is being explored as an alternative form of therapy (Cleary, 2010).

DISORDERS OF ORGANIC ACID METABOLISM

The organic acid disorders are disorders of intermediary metabolism resulting from a deficient enzyme or transport protein, the lack of which causes a block in a metabolic pathway. The block occurs in a step after deamination of the amino acid, and the resulting metabolites are organic acid derivatives. An organic acid is distinguished from an amino acid in that it contains no nitrogen. Because these disorders lead to an accumulation of organic acids in the urine, they are often referred to as "organic acidurias."

Maple Syrup Urine Disease

MSUD, a branched-chain organic aciduria, is a disorder resulting from one or more mutations in the gene encoding the enzymes that catalyze the branched-chain amino acids (BCAA) leucine, isoleucine, and valine. The name MSUD refers to the intensely sweet, maple sugar odor of the cerumen, skin, and urine that accompanies the disorder (Box 9.3). The incidence of MSUD is about 1 in 200,000 in the general population, but in the Old Order Mennonites of southeastern Pennsylvania the frequency is 1 in 358 births (Puffenberger, 2003).

Pathophysiology. The second common step in the degradation of a BCAA involves the enzyme branched-chain ketoacid dehydrogenase (BCKAD) complex. This enzyme catalyzes the conversion of the 3-ketoacid derivatives of the BCAA into their decarboxylated coenzyme metabolites within the mitochondria (Hoffmann, Burlina, & Barshop, 2017). A deficiency of BCKAD results in an accumulation of the three BCAAs and their metabolites.

The neurotoxicity of MSUD is secondary to the accumulation of the ketoacid of leucine, 2-oxoisocaproic acid, in the plasma and organs. Leucine intoxication impairs the volume-regulating mechanisms in the brain, liver, muscle, and pancreatic cells. A fall in serum sodium precipitates a redistribution of water in the intracellular spaces of the brain, causing cerebral edema. The brains of newborns with MSUD exhibit severe cytotoxic edema with involvement of myelinated white matter on MRI (Kilicarslan, Alkan, Demirkol, Toprak, & Sharifov, 2012).

Clinical Manifestations. The neonate with classical MSUD is usually born at term after an uncomplicated pregnancy and delivery. A short symptom-free interval occurs after birth. During this time, the usual postnatal endogenous protein catabolism causes a progressive rise in BCAA levels, with concomitant metabolic acidosis.

By about 48 hours of age, the untreated infant begins to show signs of the disorder. The earliest and most specific sign is the

Box 9.3

UNUSUAL ODORS ASSOCIATED WITH EMS

Disorder	Odor
Maple syrup urine disease	Maple syrup—burnt sugar
Tyrosinemia type I	Cabbage or rancid butter
Multiple acyl-CoA dehydrogenase deficiency	Sweaty socks—rancid cheese
Phenylketonuria	Mousy—musty
Propionic acidemia	Cat urine
Isovaleric acidemia	Sweaty socks—rancid cheese
Ketoaciduria	Fruity
3-Methylglutaconic aciduria	Tomcat urine
Trimethylaminuria	Fish

unique maple syrup odor of the cerumen. Other early signs and symptoms of MSUD are feeding difficulties, irritability, lethargy, and dystonia. Over the ensuing hours, neurologic deterioration predominates, as drowsiness and lethargy progress to coma. Periods of lethargy and hypotonia alternate with muscular rigidity, hypertonia, and seizures. Opisthotonic posturing is a characteristic feature of classic MSUD (Hoffmann et al., 2017).

Diagnosis. Early diagnosis and management are essential to prevent permanent brain damage. MSUD is diagnosed by plasma amino acid assay. An elevated leucine level and a high leucine-to-alanine ratio are diagnostic of MSUD. A dinitrophenylhydrazine (DNPH) test of the urine, which screens for the presence of alpha-ketoacids, will be positive. Urine should also be tested for ketones, which are typically present. Ketonuria is never normal in the neonate and should always suggest the possibility of an EM. Urinary organic acid analysis should also be performed.

By the time of diagnosis on clinical grounds, many infants with MSUD are severely encephalopathic and require emergency therapy to lower the BCAA levels. Newborn screening by MS/MS allows for detection of elevated BCAA concentrations in blood in patients with classic MSUD before the onset of severe encephalopathy. All states include MSUD on their newborn screening panels. Unfortunately, these specimens are often collected after 24 hours of age, and results are not reported until infants are 6 to 10 days of age. An infant with classic MSUD would already be seriously ill by that time.

Management. The aims of treatment of MSUD are to rapidly lower the plasma leucine level and achieve stable, long-term metabolic control with a carefully monitored low-BCAA diet. Hemodialysis, hemofiltration, or ECMO are used to remove toxins. High-energy enteral or parenteral nutrition, with close monitoring of BCAA levels, is the dietary therapy used in the newborn period to augment toxin removal. Even after the infant is in good metabolic control, however, common infections and injuries can rapidly induce biochemical disturbances requiring prompt changes in management to prevent a metabolic crisis (Cederbaum, 2018).

Isovaleric Acidemia

Isovaleric acidemia (IVA) is a disorder of leucine metabolism caused by mutations in the gene encoding the enzyme isovaleryl-CoA dehydrogenase, mapped to chromosome 15. IVA has an incidence of about 1 in 67,000 live births (Ensenauer et al., 2011). The disorder has both an acute and chronic form; the acute form manifests in the neonatal period as catastrophic disease.

Pathophysiology. Isovaleryl-CoA dehydrogenase catalyzes the third step in the catabolism of the BCAA leucine in the inner mitochondrial matrix (Grünert et al., 2012). A deficiency of isovaleryl-CoA dehydrogenase leads to accumulations of highly toxic free isovaleric acid, 3-hydroxyvaleric acid, and N-isovalerylglycine. Excess organic acids in the bloodstream inhibit gluconeogenesis and ureagenesis, predisposing the infant to both hypoglycemia and hyperammonemia, and causing fulminant metabolic acidosis (Grünert et al., 2012). Hypoglycemia stimulates the release of free fatty acids, which are transported into the mitochondria where they are oxidized to produce ketones, the source of ketosis in infants with IVA, and other organic acidemias. These organic acids also arrest maturation of hematopoietic precursors, leading to leukopenia and thrombocytopenia (Hoffmann et al., 2017; Wilcken, 2010).

Clinical Manifestations. Infants with IVA become extremely ill in the first week of life. Early symptoms are poor feeding, vomiting, lethargy, and hypothermia. Clinical evidence of dehydration is often present. **Emergency Alert: Untreated infants progress to coma, and less than half survive the initial metabolic crisis.** IVA can be recognized by the unpleasant "sweaty feet" or "rancid cheese" odor of body fluids. Hepatomegaly is present in some infants.

Diagnosis. The diagnosis of IVA is based on the presence of isovalerylglycine and its metabolites in urine, and of isovalerylcarnitine in plasma. Plasma organic acid analysis also reveals markedly elevated N-isovalerylglycine and 3-hydroxyvaleric acid. A secondary carnitine deficiency can develop. Both ketosis and metabolic acidosis, with an elevated anion gap, are present. Secondary derangements include hyperammonemia, thrombocytopenia, neutropenia, and anemia. IVA can be detected by MS/MS using filter-paper blood-spot samples and is included on the recommended uniform newborn screening panel (HHS, 2018).

Management. Infants who are extremely ill as a result of accumulation of isovaleric acid will need exogenous toxin removal with hemodialysis, hemofiltration, or ECMO (Cederbaum, 2018). Supplementation with L-glycine is also effective for IVA. Glycine promotes the formation of isovalerylglycine, which is excreted more efficiently than free isovaleric acid. L-Carnitine is given to replace lost carnitine and to provide substrate for the formation of isovalerylcarnitine, a nontoxic by-product that can be excreted in the urine (Cederbaum, 2018). If metabolic acidosis is severe, bicarbonate therapy is indicated. **Quality and Safety: Adequate fluids are mandatory to promote excretion of isovaleric acid because the primary route of elimination is the kidney.** Urine output must be carefully monitored. Initially, until the diagnosis is confirmed, protein is removed from the diet and a high-energy intake of glucose and intralipid is administered. Nutritional support is subsequently provided in the form of leucine-free amino acid mixtures followed

by a reduced leucine diet. It is important to reintroduce a balanced nutritional intake, including protein, as soon as possible to promote an anabolic state in these infants.

Propionic Acidemia

Propionic acidemia (PA) is a severe autosomal recessive disorder caused by mutations in the genes that encode the two nonidentical subunits (alpha and beta) of the propionyl-CoA carboxylase enzyme. Its estimated incidence is less than 1 in 100,000 births.

Pathophysiology. Propionyl-CoA carboxylase is involved in the metabolism of BCAA, odd-chain fatty acids, and cholesterol (Daniotti et al., 2011). Propionyl-CoA carboxylase is necessary for the synthesis of nicotinamide adenine dinucleotide, the main substrate of the mitochondrial respiratory chain (Romano et al., 2010). Propionate is a product of catabolism of amino acids (isoleucine, valine, threonine, and methionine), oxidation of odd-chain fatty acids, and gut bacterial activity. A deficiency of propionyl-CoA carboxylase results in an accumulation of toxic organic acid metabolites in the mitochondria causing severe ketoacidosis (see also Isovaleric Acidemia).

Clinical Manifestations. The clinical features of PA typically manifest shortly after birth, beginning with poor feeding, vomiting, lethargy, and hypotonia (Chapman et al., 2012). Ketonuria and metabolic acidosis develop in most infants, and severe intracellular dehydration may develop. Seizures often follow. Hepatomegaly may stem from steatosis. Infants with PA are susceptible to bacterial infections as a result of neutropenia and thrombocytopenia. The odor imparted to body fluids by propionic acid has been likened to "cat urine." Cardiomyopathy of uncertain pathogenesis is associated with PA (Romano et al., 2010) and may be associated with rapid deterioration and death in infants with this disorder. Magnetic resonance spectroscopy confirms compromised aerobic metabolism within brain tissue during acute metabolic decompensation (Davison et al., 2011). Neurologic sequelae of PA include encephalopathy, hypotonia, seizures, extrapyramidal symptoms, optic nerve atrophy, and stroke-like episodes (Johnson, Le, & Palacios, 2009).

Diagnosis. In most cases, there is a marked elevation of free propionate in the blood and urine. However, these findings are occasionally absent, and in those cases, significant elevations of other propionate metabolites, such as propionyl-carnitine, beta-hydroxypropionate, and methylcitrate, help to establish the diagnosis. However, propionyl-carnitine is not specific for PA; it can be elevated in MMA and disorders of vitamin B_{12} transport and synthesis (Chapman et al., 2012). Plasma glycine is also increased, but plasma carnitine is low. The diagnosis of PA can be confirmed either with analysis of enzyme activity in leukocytes or fibroblasts, or with specific mutation analysis. PA can be detected by MS/MS using filter-paper blood-spot samples and is included on the recommended uniform newborn screening panel (HHS, 2018), allowing presymptomatic diagnosis for some infants (Chapman et al., 2012).

Management. PA is unique in that the urinary excretion of the toxin, propionic acid, is negligible, and no alternate route can adequately remove the toxin from affected newborns. Emergency treatment to remove toxins using hemodialysis or hemofiltration is imperative. Initially, protein intake is stopped and a high-calorie intake of glucose and intralipid or nonprotein formula is substituted to suppress catabolism. Protein is reintroduced in small quantities after a few days of protein restriction. Secondary hyperammonemia may respond to administration of N-carbamylglutamate (Ah Mew et al., 2010; Kasapkara et al., 2011), sodium benzoate, sodium phenylacetate, or a combined preparation to provide an alternate route for excretion of nitrogen. In some cases, dramatic response to N-carbamylglutamate has obviated the need for hemodialysis (Fillippi et al., 2010). Blood ammonia levels should be followed closely. Carnitine supplementation, to prevent carnitine deficiency and to augment excretion of propionate, has also been used in the early management of infants with PA. In addition, because propionyl-CoA is a biotin-containing enzyme, biotin and cobalamin are given to evaluate for a vitamin-responsive disorder.

Antimicrobial therapy with oral broad-spectrum antibiotics, such as metronidazole or neomycin, inhibits anaerobic colonic flora, thereby suppressing propionate production in the gut. Infants with PA are immune-compromised and easily susceptible to infection; therefore, strict measures to avoid exposure to microbes must be observed. Laboratory indicators of infection must be monitored closely. Infants with PA should also be assessed for evidence of cardiac failure secondary to cardiomyopathy. Long-term dietary management consists of a low-protein, high-energy diet centered on the proportion of valine, a direct precursor to propionyl-CoA. Discharge teaching should include the importance of seeking medical attention immediately for any sign of illness or infection, because even a minor illness can lead to rapid deterioration in an infant with PA.

Methylmalonic Acidemia

MMA is really a group of disorders representing inherited deficiencies of the activity of methylmalonyl-CoA mutase, a vitamin B_{12}–dependent enzyme. MMA is one of the more common organic acidemias, occurring in about 1 in 25,000 to 48,000 infants. About half of the mutations causing MMA are in the genes encoding this enzyme; other mutations can occur in genes required for provision of cobalamin cofactors. In the most severe form of MMA, enzyme activity is completely absent.

Pathophysiology. Methylmalonyl-CoA mutase is normally responsible for the conversion of methylmalonyl-CoA to succinyl-CoA, a Krebs cycle intermediate. The lack of methylmalonyl-CoA mutase activity results in an intracellular accumulation of methylmalonic acid, impairing mitochondrial oxidative metabolism. A secondary inhibition of propionyl-CoA results in an accumulation of propionic acid and its metabolites. These compounds have inhibitory effects on many intermediary metabolic pathways, leading to hypoglycemia, hyperammonemia, and hyperglycinemia. Conjugation with carnitine results in a relative carnitine deficiency.

Clinical Manifestations. Most infants with MMA begin showing symptoms before the end of the first week of life. Lethargy, hypotonia, and vomiting with signs of dehydration are followed by respiratory distress, acute encephalopathy, and eventual coma. Untreated infants develop hypoglycemia, hyperammonemia, anion gap metabolic acidosis, and ketosis. MMA is similar to PA in that many infants become neutropenic and thrombocytopenic.

Diagnosis. Plasma methylmalonic acid and propionyl-carnitine are increased in MMA. The presence of C4-dicarboxylic acylcarnitine distinguishes MMA from PA. Urine organic acid analysis demonstrates greatly increased methylmalonic acid and its precursors, methylcitric acid and beta-hydroxypropionate. MMA is detected by MS/MS in states that have adopted the recommended uniform newborn screening panel (HHS, 2018). Among the many other nonspecific laboratory findings in MMA are metabolic acidosis, hyperammonemia, hyperglycinemia, leukopenia, anemia,

thrombocytopenia, and ketonuria. Molecular genetic testing is available for prenatal diagnosis.

Management. Infants who are severely moribund and those with extreme hyperammonemia (>600 µmol/L) are likely to have very high levels of toxic organic acids that must be removed expeditiously with hemodialysis or hemofiltration. Severe hyperammonemia can also be treated with N-carbamylglutamate (Tuchman et al., 2008), sodium benzoate, or sodium phenylacetate or a combined preparation to provide an alternate pathway for nitrogen removal. The acute metabolic crisis of MMA is further managed with protein restriction and administration of intravenous glucose and intralipid. Adequate fluid intake will enhance the elimination of methylmalonic acid, which is relatively efficiently removed from the body by the kidneys. Blood gases should be monitored to evaluate the degree of metabolic acidosis, and sodium bicarbonate may be required to control severe metabolic acidosis. In the event that the infant has a cofactor-responsive disease, pharmacologic doses of vitamin B_{12} are given. Because excess propionate is also a problem in MMA, broad-spectrum antibiotics are given to inhibit anaerobic flora and reduce intestinal propionate production. Supplemental carnitine is used to replace carnitine depletion and promote urinary propionylcarnitine elimination.

Like infants with PA, those with MMA are at high risk for infection owing to compromised immunity reflected by neutropenia and thrombocytopenia. Close monitoring of clinical and laboratory indicators of infection is warranted. These infants must also be monitored for evidence of cardiac failure related to cardiomyopathy. The discharge planning needs of infants with MMA are similar to those of infants with PA. Parents or other caretakers must be aware that even a minor illness or infection in their baby with MMA can represent a potential metabolic crisis and requires prompt medical attention.

FATTY ACID OXIDATION DISORDERS

FAODs are a subset of organic acid disorders that are among the most common of the known inherited disorders of metabolism. The population frequency of FAODs is estimated to be 1 in 8,000 to 16,000, although a number of neonates die before the diagnosis is made. An FAOD can be caused by a deficiency of any of the enzymes involved in cellular uptake, transport, and mitochondrial oxidation of fatty acids. To date, more than 20 defects and their gene mutations have been discovered (Rector & Ibdah, 2010). The most common is MCAD. Short, long, and very long chain forms of this enzyme deficiency also exist (SCAD, LCAD, very long chain acyl-CoA dehydrogenase [VLCAD]), as well as carnitine transporter defects, and deficiencies of the mitochondrial trifunctional protein (MTP) complex. The FAODs are considered treatable, and the prognosis for many FAODs has improved in recent years (Wilcken, 2010).

Pathophysiology

The fatty acids are the largest source of energy in the body and are the preferred fuels of the liver, heart, and skeletal muscles. Neonatal brown fat uses fatty acids to sustain nonshivering thermogenesis. When glucose levels are low during long periods between feedings, glucagon secreted by the pancreas stimulates adipose cell lipase to liberate free fatty acids. These fatty acids are oxidized to provide energy through the mitochondrial beta-oxidation pathway. Fatty acid oxidation also provides the substrate for hepatic ketogenesis. Fatty acids as a source of energy are particularly critical for the neonate who has limited stores of glycogen and a high metabolic rate; thus, any perturbation in the fatty acid oxidation pathway can rapidly lead to metabolic decompensation.

Fatty Acid Oxidation. Three subsystems are required for the production of energy in the normal fat oxidation process (Figure 9.3): (1) the carnitine cycle, (2) the mitochondrial inner membrane system, and (3) the mitochondrial matrix system (Vockley, Longo, Andresen, & Bennett, 2017). In the first step, L-carnitine and fatty acids are taken up by the cell, and fatty acids are conjugated to fatty acyl-CoAs in the cytoplasm by enzymes of the outer mitochondrial membrane. Medium- and short-chain fatty acids can penetrate the inner mitochondrial membrane for beta-oxidation, but longer chain fatty acids of dietary fat (those with carbon lengths of 14–20) must be actively transported into the matrix via the carnitine cycle. Activated acyl-CoAs are converted to carnitine esters by carnitine palmitoyltransferase I (CPT1), transported across the mitochondrial membrane by carnitine-acylcarnitine translocase, and reactivated by carnitine palmitoyltransferase II (CPT2).

Within the mitochondrion, long-chain acyl-CoAs are degraded by enzymes in the inner membrane system in a recurring cyclic sequence of four reactions (Vockley et al., 2017). These are catalyzed by VLCAD and the MTP complex encompassing the three enzymes required for a single cycle of beta-oxidation: enoyl-CoA hydratase, L to 3-hydroxy acyl-CoA dehydrogenase (LCHAD), and thiolase. In each full cycle, the fatty acid is progressively shortened by two carbons from long to medium, and finally to short-chain acyl-CoAs. The final system, the mitochondrial matrix, oxidizes shorter chain length fatty acids resulting from the enzymatic steps in the inner membrane system. L-Carnitine is not required for the latter process. The result of the beta-oxidation system is generation of acetyl-CoA, used by the liver to produce ketone bodies and as a major source of cellular ATP.

Defective Fatty Acid Oxidation. Inborn errors of fatty acid oxidation result in a buildup of toxic metabolites both proximal and distal to the block, and an insufficient yield of substrate for energy production. A deficiency of any of the enzymes required for fatty acid transport or metabolism can result in a failure of fatty acid oxidation. The primary physiologic consequence is inadequate ATP and ketone body generation, and a failure of energy production. This becomes apparent during periods of increased energy demand, such as a prolonged period of fasting, fever, or other illness. Under normal circumstances, when glycogen stores are depleted in the newborn, free fatty acids are released as a source of energy. However, the neonate with a FAOD is unable to use fatty acids for fuel and rapidly becomes hypoglycemic. As a result of hypoketogenesis, the brain is without an alternate fuel source. Without early treatment, neurologic morbidity and mortality are high. A second consequence of FAODs is the accumulation of fatty acids and their derivatives, which can have toxic effects. When their oxidation is blocked, fatty acids are stored in the cytosol as triglycerides, resulting in muscular, hepatic, and cardiac lipidoses. Skeletal muscle tissue begins to break down (rhabdomyolysis), causing a skeletal myopathy characterized by muscle weakness. In defects downstream from CPT1 in the carnitine cycle, the acylcarnitine that accumulates has detergent-like properties that may disrupt the integrity of muscle membranes. In the heart muscle, accumulated long-chain fatty acyl-CoAs can produce electrophysiologic abnormalities, including arrhythmias and cardiac arrest.

Clinical Manifestations

Affected neonates are almost always born at term. A fasting stress sufficient to reveal the disorder can result with early breastfeeding, especially in infants who do not nurse well (Jameson & Walter,

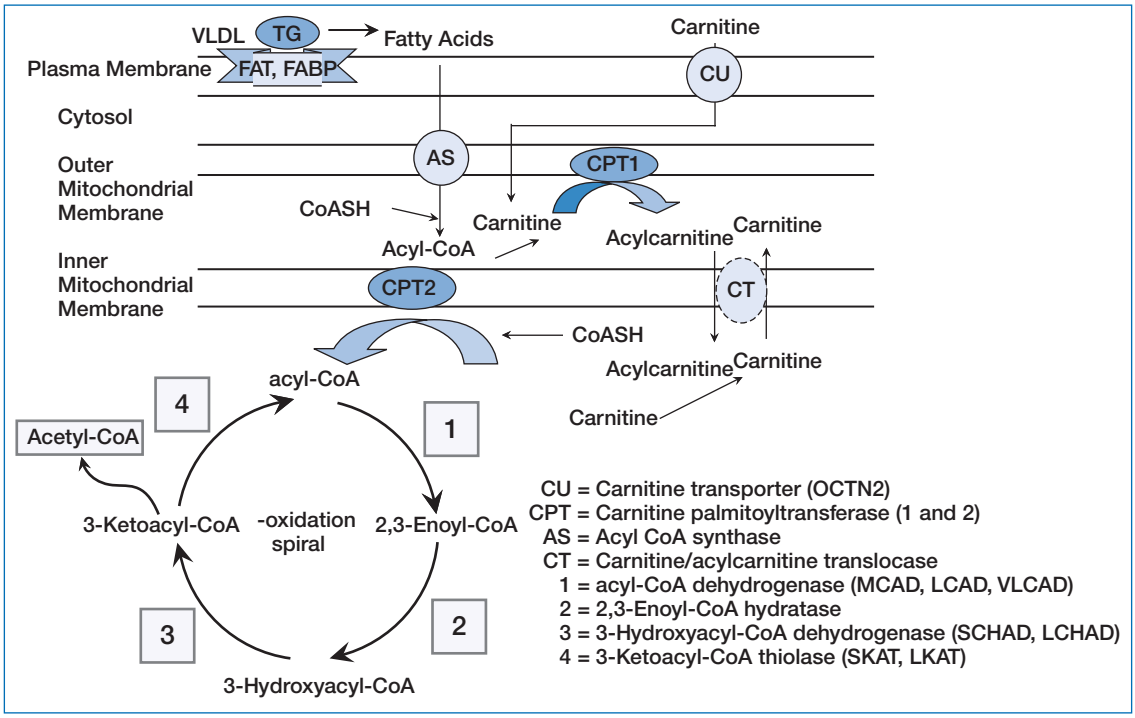

FIGURE 9.3 The mitochondrial fatty acid oxidation pathway. This schematic representation shows the uptake of fatty acids and carnitine into the cell, transfer of fatty acid from the cytosol into mitochondria, and the fatty acid beta-oxidation spiral.

LCAD, long chain acyl-CoA dehydrogenase; LCHAD, long-chain 3-Hydroxyacyl-CoA dehydrogenase; LKAT, long-chain 3-Ketoacyl-CoA thiolase; MCAD, medium chain acyl-CoA dehydrogenase deficiency; OCTN2, organic cation/carnitine transporter 2; SCAD, short chain acyl-CoA dehydrogenase; SCHAD, short-chain 3-Hydroxyacyl-CoA dehydrogenase; SKAT, 3-Ketoacyl-CoA thiolase; VLCAD, very long chain acyl-CoA dehydrogenase.

Human placenta metabolizes fatty acids: Implications for fetal acid oxidation disorders and maternal liver diseases. *American Journal of Physiology, Endocrinology & Metabolism, 284*, E1098–E1105. doi:10.1152/ajpendo.00481.2002

2010). Mitochondrial FAODs in the neonate present with three clinical phenotypes that, depending on the disorder, can be seen individually or in combination: hypoketotic hypoglycemia, cardiomyopathy, and skeletal myopathy (Rector & Ibdah, 2010). Neonates with MCAD, the most common of the FAODs, usually present with glucose instability, but there have been reports of acute life-threatening episodes and even sudden death (Rector & Ibdah, 2010).

Neonates with VLCAD are similarly intolerant to fasting and develop hypoglycemia without ketosis. Moreover, VLCAD can be associated with evidence of cardiomyopathy, including cardiomegaly, ventricular arrhythmias, or unexplained cardiac arrest. Other physical findings that have been reported in neonates with disorders of fatty acid oxidation include hypotonia, seizures, irritability or lethargy (mimicking acute encephalopathy), hepatomegaly, and associated congenital malformations such as cystic renal dysplasia.

Diagnosis

A FAOD must be considered in any infant with an unexplained nonketotic hypoglycemia, hepatic dysfunction, isolated arrhythmia, or cardiomegaly. The initial screen for FAOD includes urine organic acid analysis, as well as plasma and urine free and total carnitine, collected during a period of acute decompensation. A strong clue to a FAOD is urinary excretion of dicarboxylic acids, compounds not normally found in the urine (Rector & Ibdah, 2010). Plasma carnitine levels will be markedly reduced.

To reach a specific diagnosis of mitochondrial fat oxidation, a plasma acylcarnitine profile must be obtained (Rector & Ibdah, 2010). Using whole blood samples on filter paper and MS/MS, the acylcarnitine intermediates formed as a result of the enzymatic block somewhere in the fat oxidation cycle can be quantified. A plasma acylcarnitine profile reveals accumulation of acyl-CoA conjugates proximal to the defect. When MS/MS screening is not available, the most useful indirect laboratory tests in neonates with suspected FAODs are glucose, electrolytes, BUN, creatinine, lactate, ammonia, transaminases, and creatine kinase. Elevated creatine kinase and myoglobinuria reflect rhabdomyolysis. Plasma carnitine levels are markedly reduced, except in CPT1 deficiency (Vockley et al., 2017). Additional laboratory results may show hyperammonemia, metabolic acidosis, and increased uric acid and transaminases. A liver biopsy performed during the acute phase usually reveals microvesicular and macrovesicular fatty infiltration.

Family and perinatal history can be particularly important to the diagnosis of a FAOD. Many infants diagnosed with a FAOD have a history of a sibling who died of SIDS. In addition, an association has been found between acute fatty liver of pregnancy (AFLP) or HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome in the mother and fetal deficiency of long-chain 3-hydroxyacyl coenzyme A dehydrogenase (LCHAD), one of the enzymes in the MTP complex. When a woman is carrying an affected fetus, the placenta and fetus are unable to oxidize fatty acids, leading to transfer of accumulated fatty acid intermediates to the maternal circulation. For unclear reasons, in some women these fatty acids overwhelm the maternal liver and contribute to HELLP syndrome and maternal hepatic fat deposition (AFLP).

The newborn infants of women with AFLP or mothers who are known carriers for FAODs should be evaluated immediately after birth with blood-spot acylcarnitine profiles, and treated as if they have a FAOD until test results are known.

Neonatal Screening and Confirmatory Testing for FAOD. The key to preventing the morbidity and mortality associated with FAOD is through presymptomatic diagnosis, allowing early

treatment and avoidance of metabolic crisis. Neonatal screening for FAODs by MS/MS analyzes acylcarnitines from dried blood spots and can identify 22 different abnormalities. However, an abnormal acylcarnitine profile can represent more than one FAOD, so more specific testing is required. Using cultured skin fibroblasts (or amniocytes) that have been incubated with deuterium-labeled fatty acid precursors and excess L-carnitine, MS/MS can rapidly detect any enzyme defect from translocase through SCAD. This method is possible because the enzymes of fatty acid oxidation are also expressed in the skin and other cells. Mutational analysis, if available, can also provide a definitive diagnosis (Vockley et al., 2017).

Management

The primary goal is to provide nutrition that will control endogenous lipolysis and prevent tissue catabolism. This involves a high-carbohydrate, low-fat diet. The newborn should feed every 3 to 4 hours, with close monitoring of blood sugar level. Breastfeeding mothers should receive lactation assistance to ensure successful breastfeeding with evidence of milk transfer. If hypoglycemia persists or the infant is unable to tolerate enteral feeding, glucose should be administered intravenously. Closely monitor for cardiac conduction disturbances.

The nurse is in a key position to prevent stressors, such as hypothermia or pain, that could precipitate a metabolic crisis, and to assess the infant for signs of intercurrent illness that might require additional therapy. Discharge teaching should emphasize the need to avoid prolonged periods of fasting and to seek medical attention if the infant shows signs of illness (fever, vomiting, diarrhea, refusal to eat, lethargy, or any other change in normal behavior). A consult should be made with a neonatal nutritionist or dietary specialist to arrange teaching for the family about the infant's postdischarge dietary regimen. The infant's diet will continue to be high in carbohydrate and restricted in fat. Supplementation with l-carnitine has not been shown to be beneficial (Spiekerkoetter et al., 2010).

Multiple Acyl-CoA Dehydrogenase Deficiency (Glutaric Aciduria Type II)

Pathophysiology. Multiple acyl-CoA dehydrogenase deficiency (MADD), formerly known as glutaric aciduria type II, is a disorder caused by a defective electron transfer flavoprotein (ETF) or electron transfer flavoprotein dehydrogenase (ETF-QO). MADD impairs both fatty acid oxidation and oxidation of branched amino acids lysine and glutaric acid. The heart, liver, and kidneys become infiltrated with fat.

Clinical Manifestations. Two different neonatal presentations have been described for MADD; both involve overwhelming illness with rapid progression to coma and death (Vockley et al., 2017). One presentation is a neonate, often preterm, with dysmorphic facial features, polycystic kidneys, and hepatomegaly. Within the first 24 to 48 hours of life, the infant develops hypotonia, metabolic acidosis, severe nonketotic hypoglycemia, and a distinctive "sweaty feet" odor of body fluids. The alternate neonatal presentation is the infant without congenital anomalies, but with similar symptoms and metabolic aberrations. Neither group lives longer than a few weeks; the few babies who survive generally succumb at a few months of age to cardiac failure.

Diagnosis. MS/MS rapidly detects elevated acylcarnitines (C4, C5, C8, C10, and C16). Quantitative urine organic acid analysis usually reveals a pattern of elevated organic acids: lactic, glutaric, 2-hydroxyglutaric, ethylmalonic, adipic, suberic, sebacic, and other acids, some in very high amounts. The same organic acids are increased in the plasma. Volatile acid (isovaleric, acetic, isobutyric, propionic, butyric) concentrations in plasma are excessive, accounting for the characteristic odor associated with the disorder. Plasma carnitine may be low. Mutations have been identified in the genes for flavoproteins ETF and ETF-QO.

Management. There is no effective treatment other than supportive care (fluids, glucose, sodium bicarbonate) for the rapid-onset, severe neonatal presentation. For the rare infant who survives the initial crisis, management involves frequent feedings with avoidance of fasting, and a diet low in fat and protein and high in carbohydrates. Some patients also respond to riboflavin.

CONGENITAL LACTIC ACIDOSES

The congenital lactic acidoses (also called primary lactic acidoses) are a group of disorders of lactate metabolism caused by defects in the mitochondrial respiratory or electron transport chain, the tricarboxylic acid (Krebs) cycle, or in pyruvate metabolism.

Lactic acid is the major end product of anaerobic glycolysis, accumulating when production of pyruvate exceeds utilization. The brain's dependence on oxidative metabolism makes it particularly susceptible to damage in disorders of oxidation that lead to lactic acidosis.

Pyruvate Dehydrogenase Deficiency

PDH complex disorders are the most common inborn errors of pyruvate metabolism. Most cases of PDH are caused by mutations in the X-linked *PDHA1* gene, which encodes the E1 alpha subunit of the PDH enzyme complex (Brown, 2012).

Pathophysiology. PDH complex efficiently and irreversibly converts pyruvate, a product of glucose metabolism, to acetyl-CoA. Acetyl-CoA is one of two essential substrates needed to generate citrate for the energy-producing tricarboxylic acid cycle (also called the citric acid cycle or Krebs cycle). Thus, PDH provides the link between glycolysis and the tricarboxylic acid cycle. PDH complex activity is regulated primarily by reversible phosphorylation (inactivation) of the enzyme's E1 alpha subunit. A deficiency in the PDH complex limits the production of acetyl-CoA, and in turn the production of citrate, blocking the tricarboxylic acid cycle and creating an energy deficit. Persistent glycolysis without pyruvate oxidation leads to the accumulation of lactate because excess pyruvate is reduced to lactate in the cytoplasm. Tissues with high-energy requirements, such as those of CNS, are vulnerable to injury when cellular energy production is impaired.

Clinical Manifestations. The nonspecific early signs and symptoms of PDH deficiency develop soon after birth and are similar to those of other metabolic disorders. Poor feeding, lethargy, and tachypnea are followed by progressive neurologic deterioration, apnea, seizures, and coma. Fulminant lactic acidosis is present in infants with profound deficiencies of the PDH complex, and these patients often die early in the neonatal period. Infants with severe disease may have prenatal onset leading to structural brain abnormalities including microcephaly. MRI may show ventricular dilatation, cerebral atrophy, hydrancephaly, partial or complete absence of the corpus callosum, and periventricular leukomalacia (Sharma, Sharrard, Connolly, & Mordekar, 2012). Patients with PDH complex deficiency can also present with Leigh syndrome.

Diagnosis. Lactic acidosis is an important biochemical marker for mitochondrial dysfunction. Hyperlactatemia, with an elevated

lactate–pyruvate ratio, is predictive of early demise (Patel, O'Brien, Subramony, Shuster, & Stacpoole, 2012). Lactate and pyruvate are also often elevated in the CSF of babies with this disorder. Plasma and urine amino acid analysis reveal hyperalaninemia. A definitive diagnosis of enzyme activity requires testing of leukocytes, fibroblasts, or tissue samples, or DNA analysis.

Collaborative Management. No effective treatment has been found to date for any of the PDH complex defects that manifest in the neonatal period. Therapies include alternate dietary regimens or vitamins such as thiamine that might stimulate residual enzyme activity or circumvent the enzyme defect. Because infants with PDH complex deficiency oxidize carbohydrates poorly, a ketogenic (high-fat, low-carbohydrate) diet has been used to provide an alternate energy source for acetyl-CoA production (Patel et al., 2012). These diets may reduce hyperlactatemia and improve short-term neuromuscular function in infants with PDH complex deficiency. Cofactor supplementation with thiamine, carnitine, and lipoic acid is another facet of the management of these infants.

Recently, dichloroacetate (DCA) has been used to treat PDH complex deficiency. DCA is believed to activate PDH complex activity by inhibiting PDH kinase. PDH complex is thereby "locked" in its unphosphorylated, catalytically active form (Patel et al., 2012).

Pyruvate Carboxylase Deficiency

PCD is a disorder of energy metabolism that exists in three different forms. The most severe of these is a neonatal-onset form known as type B, a disorder with a high mortality rate. All forms of PCD have a frequency of about 1 in 250,000 live births and are recessively inherited.

Pathophysiology. Pyruvate carboxylase is a biotin-containing mitochondrial enzyme responsible for the ATP-dependent carboxylation of pyruvate. This enzyme also catalyzes the conversion of pyruvate to oxaloacetate, an essential substrate in gluconeogenesis, glycogen synthesis, lipogenesis, and other metabolic pathways (Marin-Valencia, Roe, & Pascual, 2010). The absence of pyruvate carboxylase activity results in malfunction of the citric acid cycle and gluconeogenesis, thereby disrupting energy metabolism in the brain. A deficiency of aspartic acid, derived from oxaloacetate, disrupts the urea cycle as well, leading to a simultaneous failure of nitrogen excretion.

Clinical Manifestations. In PCD with neonatal onset, the earliest signs and symptoms begin at 72 hours of life and include severe truncal hypotonia and tachypnea associated with profound metabolic acidosis. Seizures, abnormal eye movements, and coma can occur. Hyperammonemia, hypoglycemia, ketosis, and ketonuria are frequent findings. Renal tubular acidosis can also accompany PCD.

Diagnosis. The diagnosis of PCD is based on the measurement of urinary organic acids and blood acylcarnitine profile. In type B PCD, the lactate–pyruvate ratio may be high (≥25). Plasma citrulline and lysine are elevated along with the ammonia level. Serum transaminases may also be elevated. The diagnosis can be confirmed by enzyme analysis of hepatic cells or leukocytes.

Management. PCD is a progressive disorder with no specific therapy. Some infants have biotin-responsive disease, so pharmacologic doses of biotin are administered and the response is evaluated. Therapeutic options that involve replenishment of citric acid cycle intermediates to interrupt the hyperactive catabolic cascade associated with the disorder and enhance ATP production are being explored (Marin-Valencia et al., 2010).

DISORDERS OF CARBOHYDRATE METABOLISM

Galactosemia

Galactosemia is an inherited disorder of carbohydrate metabolism caused by a deficiency in one of the three enzymes of the galactose metabolic pathway: galactose-1-phosphate uridyl transferase (GALT), galactokinase (GALK), or UDP-galactose-4-epimerase (GALE). GALT deficiency, affecting the second step in the galactose metabolism, accounts for more than 95% of galactosemias; thus, it has become synonymous with classic galactosemia.

Galactosemia has an estimated prevalence of 1 in 40,000 to 60,000 live births (Berry, 2012). At least 24 different mutations have been identified to date in the human GALT gene, located on chromosome 9.

Pathophysiology. Infants with galactosemia are unable to metabolize the sugar galactose, derived from the disaccharide lactose, the major carbohydrate of mammalian milk. In normal galactose metabolism, galactose is first converted to galactose-1-phosphate by GALK, which is in turn converted by the GALT enzyme to uridyl diphosphate (UDP) glucose. The severe form of galactosemia features near total deficiency of GALT enzyme activity in all cells of the body. In the absence of GALT, ingestion of lactose-containing substances produces toxic levels of galactose-1-phosphate within cells. Surplus galactose is reduced to galactitol or oxidized to galactonate, metabolites that also have a direct toxic effect on the liver and other organs.

Clinical Manifestations. Most patients present in the neonatal period or in the first week or two of life. After ingestion of galactose (either cow's milk–based formula or breast milk), vomiting, diarrhea, poor weight gain, jaundice, hepatomegaly, and hypoglycemia become evident. In some infants, CNS symptoms, such as lethargy and hypotonia, predominate. Untreated infants will go on to develop cataracts secondary to the accumulation of galactitol. Sepsis, usually caused by *Escherichia coli*, is often the presenting problem, owing to low neutrophil bactericidal activity. Liver dysfunction is progressive, and many infants die during the first week of life from liver failure. In those who do survive, neurologic complications are frequent.

Two related disorders of galactose metabolism are GALK and GALE deficiencies. In GALK deficiency, galactose cannot be phosphorylated into galactose-1-phosphate. The chief clinical finding in GALK deficiency is cataract formation. In GALE deficiency, most patients are asymptomatic and have normal growth and development.

Diagnosis. A galactose assay, measuring blood galactose, RBC galactose-1-phosphate, and GALT enzyme activity, is used to diagnose classic galactosemia. GALT activity is low or absent. Galactose and galactose-1-phosphate are elevated. DNA analysis for the common mutations associated with GALT deficiency can also be done. Urine is positive for reducing substances. Galactosemia is included on all routine state newborn screening panels, allowing presymptomatic diagnosis.

Management. Galactosemia is treated by feeding a soy-based formula, containing no galactose. **Quality and Safety: Breastfeeding is not permitted. Other sources of galactose, including medications containing galactose, must also be avoided.** Dietary restriction of galactose in the newborn will reverse the hepatic, renal, brain, and immune dysfunction and reduce the accumulated galactose metabolites. Additional measures include monitoring for and treating sepsis and coagulopathy. Despite dietary treatment,

long-term neurodevelopmental outcomes have not been uniformly favorable. An important part of discharge education is dietary teaching to assist the family to maintain dietary control as the infant grows and develops and help them identify occult sources of galactose in foods and other substances.

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) is an inherited inability to digest fructose (fruit sugar) or its precursors (sugar, sorbitol, and brown sugar). This autosomal recessive disorder has a frequency of approximately 1 in 22,000 births.

Pathophysiology. Fructose is a naturally occurring sugar that is used as a sweetener in many foods, including many baby foods. A deficiency of activity of the enzyme fructose-L-phosphate aldolase impairs the body's ability to convert fructose-L-phosphate to glyceraldehyde and dihydroxyacetone phosphate. The outcome is an accumulation of fructose-L-phosphate in the liver, kidney, and small intestine, which inhibits glycogen breakdown and glucose synthesis and causes severe hypoglycemia following ingestion of fructose. This disorder can be life threatening to infants.

Clinical Manifestations. In the neonate, the onset of clinical symptoms follows ingestion of cow's milk formula and resembles that for galactosemia. Signs and symptoms include pallor, lethargy, poor feeding, irritability, vomiting, and hypoglycemia. Jaundice, hepatomegaly, and evidence of progressive liver disease may follow. In exclusively breastfed infants, symptoms will be delayed until the time of weaning to fruits and vegetables.

Diagnosis. The diagnosis of HFI is usually now by molecular analysis, rather than enzyme analysis or fructose tolerance testing (Merritt & Gallagher, 2018). Urine is positive for reducing substances.

Management. Management of HFI centers on removal of all sources of fructose and sucrose from the diet. All intravenous solutions and other medications must also be free of fructose, corn syrup, and sorbitol. Supportive care includes management of liver failure, kidney dysfunction, and coagulopathy, if present. The infant's parents will benefit from consultation with a dietary specialist to learn about long-term dietary management.

Fructose 1,6-Bisphosphatase Deficiency

Fructose 1,6-biphosphatase deficiency is a rare disorder of carbohydrate metabolism.

Pathophysiology. Fructose 1,6-bisphosphatase catalyzes the irreversible splitting of fructose 1,6-biphosphate into fructose 6-phosphate and inorganic phosphate. The enzyme's activity is highest in gluconeogenic tissues such as the liver and kidney. Fructose 1,6-biphosphatase deficiency is, therefore, a disorder of gluconeogenesis, resulting in glucose deprivation to the CNS.

Clinical Manifestations. In fructose 1,6-biphosphatase deficiency, hypoglycemia is precipitated by fasting, not by fructose ingestion (Merritt & Gallagher, 2018). Lactic acidosis and ketosis result from accumulating lactic, 3-hydroxybutyric, and acetoacetic acids. Hyperventilation followed by apnea may result from profound acidosis. Although the acidosis and hypoglycemia may be treated and the infant recovers from the acute attack, if the underlying disorder is not recognized, the infant can have many acute metabolic attacks and develop hepatomegaly and failure to thrive before the diagnosis is finally made.

Diagnosis. Definitive diagnosis is made by liver biopsy and assay of hepatic enzymes. Mutational analysis is available and can be used instead of biopsy.

Management. Acute management involves glucose administration with intravenous solutions and correction of acidosis with sodium bicarbonate. Frequent feedings, avoidance of fasting, and limitation of fructose and sucrose in the diet usually prevent further episodes. Dietary restriction includes the many prescription and over-the-counter medications with a syrup base containing sucrose. Stress management (e.g., during times of fever, infection, or vomiting) is critical because illness can induce a metabolic attack.

Glycogen Storage Disease

Glycogen storage disease (GSD) is a group of inherited enzyme defects that affects the glycogen synthesis and degradation cycle. Liver and muscle, having the most abundant quantities of glycogen, are usually the most severely affected tissues (Hendriksz & Gissen, 2010). More than 10 different types of GSD have been identified with a collective incidence of about 1 in 20,000 births. Glycogen storage disease type I (GSD-I, also known as von Gierke's disease), the disorder most likely to have neonatal onset, occurs in about 1 in 100,000 births and has two main subtypes (Ia, Ib). GSD-II, known as Pompe's disease, is classified as a lysosomal storage disease.

Pathophysiology. GSD-Ia, the most common subtype, is the result of a deficiency of the hepatic enzyme glucose-6-phosphatase (G6Pase), an enzyme situated in the endoplasmic reticulum of the cell. Normally, G6Pase hydrolyzes glucose-6-phosphate to glucose and phosphate. An accumulation of glycogen in the liver, kidney, and intestines results from a deficiency of G6Pase. In the normal neonate, blood glucose falls during the first postnatal hours as the neonate uses circulating glucose obtained from the mother, but then rises as endogenous glucose production begins. In the neonate with GSD-I, blood glucose continues to decline because endogenous glucose production is severely compromised. Instead, the phosphorylated intermediate compounds of glycolysis produce an excess of lactate, resulting in hyperlactacidemia. Secondary metabolic derangements typical of GSD-I include hyperuricemia and hyperlipidemia.

Clinical Manifestations. The neonate with GSD-I cannot cope with the normal postnatal drop in blood sugar. Despite a plentiful supply of glycogen, the neonate is unable to mobilize free glucose and becomes hypoglycemic. The abdomen may appear distended from birth as a result of an enlarged liver. Acute, nonspecific clinical deterioration is related to the buildup of lactic acid in the body.

Diagnosis. Definitive diagnosis of GSD-I is accomplished with molecular genetic testing. Typical laboratory findings in GSD-I include increased plasma lactate and metabolic acidosis with an increased anion gap. Ketosis and ketonuria will be found during hypoglycemia. Other routine tests that should be obtained are liver function tests, plasma uric acid, triglycerides, creatinine, coagulation studies, and complete blood count (CBC) with differential. Abdominal ultrasonography is performed to determine liver and kidney size.

Management. The goals of treatment of GSD-I are to prevent hypoglycemia and correct secondary biochemical abnormalities. Frequent feedings or continuous gastric feedings may be necessary to maintain normoglycemia and supply the brain with a steady source of glucose, even during the night. Blood glucose levels must be monitored closely. Pharmacologic therapy to address hyperuricemia and prevent the development of gout may be necessary. Very severely affected infants will require a liver transplant. Parent teaching about long-term nutritional management, prevention of hypoglycemia, and special considerations during stress or other illnesses is critically important.

PEROXISOMAL DISORDERS

Peroxisomal disorders are complex developmental and metabolic disorders caused by defects in peroxisome biosynthesis. Two of the better known disorders, Zellweger syndrome (ZS) and neonatal adrenoleukodystrophy (NALD), are now recognized as belonging to a continuous spectrum of disorders, of which ZS is the most severe. ZS has a reported incidence of about 1 in 25,000 to 50,000 births.

Pathophysiology

Peroxisomes are subcellular organelles that synthesize bile acids, cholesterol, and plasmalogens (a type of phospholipid found in myelin sheaths of nerve fibers). Peroxisomes are also critical in the beta-oxidation of very long-chain fatty acids. Peroxisomal disorders arise from either a defect in peroxisomal biosynthesis or a single peroxisomal enzyme or protein (Scott & Olpin, 2010). Individuals with peroxisome biogenesis defects such as ZS and NALD synthesize peroxisomes normally, but display defects in the import of peroxisomal enzymes into the lumen of the organelle (Merritt & Gallagher, 2018). Biochemical abnormalities include impaired degradation of peroxide, very long-chain fatty acids, pipecolic acid, and phytanic acid and impaired synthesis of plasmalogens, bile acids, cholesterol, and docosahexaenoic acid. In ZS, the extent of progressive multisystemic disease is profound; in NALD, the systemic involvement is milder, but the cerebral demyelination is more pronounced.

Clinical Manifestations

Infants with ZS present with characteristic facial dysmorphism including a high forehead, hypoplastic supraorbital ridges, flat occiput, low and broad nasal bridge, epicanthal folds, high arched palate, small nose with anteverted nares, micrognathia, large fontanelles, wide sutures, and eye abnormalities (Scott & Olpin, 2010). Typically, they have profound hypotonia, an absence of neonatal reflexes, and seizures. The disease affects every organ of the body, particularly the liver, kidney, and brain, resulting in hepatomegaly, renal cysts, white-matter abnormalities, and neuronal migration defects.

Diagnosis

Diagnosis of peroxisomal biosynthesis defects is based on indirect evidence of the defect. Initial tests for an infant with a suspected peroxisomal disorder include plasma very long-chain fatty acids, and plasmalogens in erythrocytes. Affected infants have elevated transaminases, bile acid intermediates, hypercholesterolemia, and increased iron and transferrin concentrations and are often hypoglycemic. A suspected peroxisomal disorder is confirmed by molecular studies if possible (Scott & Olpin, 2010).

Management

Currently, no successful treatment for the peroxisomal disorders is available. Management is supportive care and symptomatic therapy. The median life expectancy of ZS patients is less than 1 year. Milder forms of peroxisomal disorders may respond to dietary therapy.

LYSOSOMAL DISORDERS

The lysosomal disorders are a diverse group of inherited conditions caused by dysfunctions in enzymes (called hydrolases) responsible for the degradation of complex macromolecules, such as glycogen, sphingolipids, glycoproteins, and glycosaminoglycans (Wraith, 2010). In these disorders, a complex substrate that is normally degraded by a series of lysosomal enzymes fails to undergo degradation owing to a deficiency or malfunction of one of these enzymes (Figure 9.4). Catabolism of the substrate into soluble end products is incomplete, and insoluble intermediates that are unable to escape from the organelle accumulate within the lysosome (Wraith, 2010). More than 50 lysosomal disorders are recognized, with a collective incidence of 1 in 7,000 to 10,000 births.

Niemann–Pick Type C

Pathophysiology. Niemann–Pick type C (NP-C) is a disorder of intracellular cholesterol transport that leads to an accumulation of unesterified cholesterol in lysosomes (Thomas, Lam, & Berry, 2018). Unesterified cholesterol, sphingomyelin, phospholipids, and glycolipids are stored in excess in the liver and spleen, and glycolipids are increased in the brain.

Clinical Manifestations. Neonatal-onset NP-C is characterized by conjugated hyperbilirubinemia, ascites, hepatosplenomegaly, and hypotonia (Thomas et al., 2018). Hydrops fetalis is a rare presentation. Respiratory failure can occur owing to lipid infiltration of the lungs (Wraith, 2010).

Diagnosis. The diagnosis of NP-C requires specialized testing that must be coordinated with a metabolic laboratory. In general, the diagnosis is made on the basis of filipin staining of cultured fibroblasts and cholesterol esterification studies (Wraith, 2010). Filipin is a fluorescent probe that detects unesterified cholesterol. Biliary atresia and congenital viral infection are the chief differential diagnoses.

Management. There is no definitive or consistently effective therapy for NP-C to date. Splenectomy is sometimes necessary if anemia and thrombocytopenia are severe. Liver transplantation corrects the hepatic dysfunction but not the neurodegenerative disease.

Gaucher's Disease

Pathophysiology. Gaucher's disease, the most common of the lysosomal storage diseases, is an inborn error of glycosphingolipid metabolism caused by the deficient activity of the lysosomal

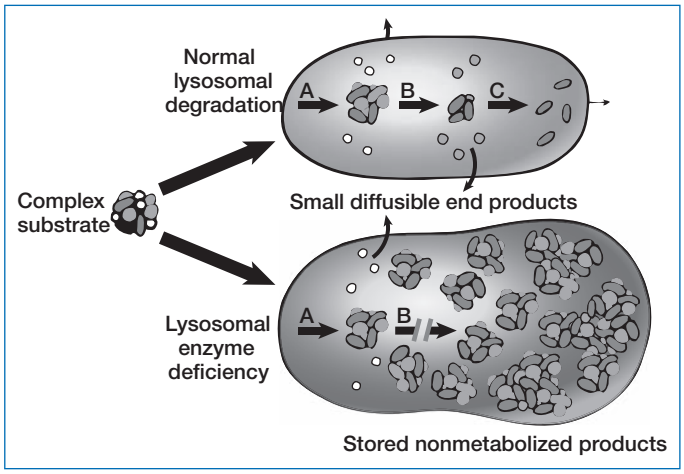

FIGURE 9.4 The pathogenesis of lysosomal storage diseases. A complex substrate is normally degraded by lysosomal enzymes A, B, and C into soluble end products. If these enzymes are deficient, catabolism is incomplete and nonmetabolized products accumulate in the lysosomes.

Source: From Kumar, V., Abbas, A. K., Fausto, N., & Aster, J. (Eds.). (2009). *Robbins and Cotran: Pathologic basis of disease* (8th ed.). Philadelphia, PA: Elsevier.

enzyme acid beta-glucosidase. Widespread accumulation of glucosylceramide-laden macrophages results from the enzyme deficiency. These accumulated compounds are toxic to various tissues in the body. There are three types of Gaucher's disease. Type I is the most common (95%). A subset of type II, a neuronopathic form of Gaucher's disease, is the only one with neonatal onset.

Clinical Manifestations. Neonates with type II Gaucher's disease can present with congenital ichthyosis or a collodion membrane (hyperkeratotic scale), hepatosplenomegaly, and/or nonimmune hydrops fetalis, hypertonicity, seizures, and other evidence of neurologic deterioration.

Diagnosis. Diagnosis is made by analysis of acid beta-glucosidase activity in white blood cells or DNA analysis. Characteristic Gaucher cells (large, lipid-laden macrophages with foamy cytoplasm) can be seen in a bone marrow aspirate.

Management. Enzyme replacement therapy for Gaucher's disease is available, but has not been very effective for patients with type II disease. Splenectomy may be necessary to manage severe anemia and thrombocytopenia. Death from respiratory insufficiency or severe neurologic disease usually occurs shortly after birth or within the first year of life.

GM1 Gangliosidosis

Pathophysiology. Gangliosides are normal components of cell membranes, particularly neurons. GM1 gangliosidosis is a devastating lysosomal storage disease caused by a deficiency of the enzyme acid beta-galactosidase, resulting in a generalized accumulation of GM1 gangliosides, oligosaccharides, and the mucopolysaccharide keratan sulfate in both the brain and viscera.

Clinical Manifestations. Affected infants may have coarse facial features known as a "Hurler phenotype" (frontal bossing, depressed nasal bridge, maxillary hyperplasia, large ears, wide upper lip, macroglossia, and gingival hyperplasia), hirsutism of forehead and neck, macular cherry-red spots, and corneal clouding (Figure 9.5). The dysmorphic features might not be obvious in the neonate (Thomas et al., 2018). Facial edema, pitting edema of the extremities, or ascites may also be apparent, and the neonate may present with hydrops fetalis and placental evidence of vacuolated cells. Neurologic examination reveals hypotonia and hypoactivity. The liver and spleen are both enlarged upon palpation.

FIGURE 9.5 The "Hurler phenotype" seen in some neonates with lysosomal storage disorders.

Source: From Wraith, J. E. (2002). Lysosomal disorders. *Seminars in Neonatology, 7,* 81. doi:10.1053/siny.2001.0088

Diagnosis. Diagnosis is made by demonstrating lack of beta-galactosidase activity in white blood cells. Galactose-containing oligosaccharides can also be measured in the urine.

Management. Currently, there is no effective therapy for infants with GM1 gangliosidosis. Enzyme and gene therapies are being studied as potential treatments for this lethal disorder.

Mucopolysaccharidoses

Pathophysiology. The mucopolysaccharidoses (MPS) are a family of seven disorders caused by deficiency of lysosomal enzymes required for the stepwise degradation of glycosaminoglycans (polysaccharides that make up an important component of connective tissue). The undegraded glycosaminoglycans are stored in lysosomes, causing cell, tissue, and organ dysfunction. MPS VII, the type with the most prominent neonatal presentation, is caused by a deficiency of the enzyme beta-glucuronidase.

Clinical Manifestations. MPS VII (Sly's disease) has a well-recognized neonatal presentation with nonimmune hydrops fetalis, hepatosplenomegaly, ascites, pitting edema, hernias, skeletal abnormalities (dysostosis multiplex), and corneal clouding. In the most severely affected patients, MPS I (Hurler's syndrome) can present in the neonatal period with an umbilical or inguinal hernia or an excess of mongolian spots. Hearing loss is common. Clinical evidence of heart disease is present in most patients with MPS.

Diagnosis. MPS VII is diagnosed by evaluating the activity of beta-glucuronidase in white blood cells. Urine glycosaminoglycans can also be quantitated.

Management. Management is primarily supportive care and treatment of complications. Range-of-motion exercises are important to preserve joint function and prevent joint stiffness. Recurrent pneumonia is a frequent complication of MPS VII. Development of hydrocephalus often necessitates the insertion of a ventriculoperitoneal shunt. An ophthalmologic examination should be performed to evaluate for corneal clouding and the development of glaucoma.

Glycogen Storage Disease Type II (Pompe's Disease)

Pathophysiology. Glycogen storage disease type II (GSD-II), also called acid maltase deficiency or Pompe's disease, is an inherited disorder of glycogen metabolism resulting from defects in activity of the lysosomal hydrolase acid alpha-glucosidase in all tissues of the body. This enzyme is required for the degradation of a portion of the body's glycogen. Without it, excessive glycogen accumulates within the lysosomes, eventually causing cellular injury, and enlarging and hindering the function of the entire organ, such as the heart. Energy production is not affected, and hypoglycemia does not occur. Pompe's disease has a worldwide incidence of about 1 in 40,000 births (Chien et al., 2009).

Clinical Manifestations. Prominent findings in infants are cardiomyopathy, progressive cardiomegaly, and left ventricular thickening that eventually leads to outflow tract obstruction. Characteristic findings on ECG are large QRS complexes coupled with abnormally short PR interval. The QRS complex is the combination of the Q wave, R wave, and S wave and represents ventricular depolarization. The PR interval is the interval between the beginning of the P wave and the beginning of the QRS complex of an electrocardiogram that represents the time between the beginning of the contraction of the atria and the beginning of the contraction of the ventricles. Other manifestations are hepatomegaly, striking hypotonia, macroglossia, feeding difficulties, and respiratory distress complicated by pulmonary infection.

Diagnosis. Definitive diagnosis requires the measurement of acid alpha-glucosidase activity in cultured skin fibroblasts or white blood cells. Serum creatinine kinase (CK) is elevated (up to 10 times normal). Hepatic enzymes may also be elevated. Newborn screening for Pompe's disease is under study with the hope that presymptomatic diagnosis would permit earlier therapeutic intervention (before extensive muscle damage), leading to better outcomes (Chien et al., 2009).

Management. Until recently, no effective treatment was available for Pompe's disease, and these infants usually succumbed to cardiopulmonary failure. A recombinant version of human alpha-glucosidase, a glycoprotein enzyme needed for breakdown of glycogen in cell lysosomes, has now been developed for treatment of Pompe's disease.

DISORDERS OF CHOLESTEROL SYNTHESIS

Smith–Lemli–Opitz Syndrome

Smith–Lemli–Opitz (SLO) syndrome is a multiple congenital anomalies/mental retardation syndrome caused by an inherited defect in cholesterol biosynthesis. SLO syndrome has an estimated incidence of 1 in 10,000 to 60,000 births (Haas, Herman, & Hoffmann, 2017).

Pathophysiology. The underlying biochemical defect in SLO syndrome is a lack of the microsomal enzyme 3 beta-hydroxysterol-delta 7 reductase (DHCR7), the final enzyme in the sterol biosynthetic pathway that converts 7-dehydrocholesterol (7DHC) to cholesterol. In the absence of DHCR7, the precursor 7DHC accumulates to potentially toxic levels, and insufficient cholesterol is produced. Because cholesterol is required for the development of cell membranes and myelin, and the production of steroid hormones and bile acids, a severe deficiency of cholesterol during morphogenesis is believed to contribute to the abnormalities associated with SLO syndrome. SLO syndrome is different from other disorders of intermediary metabolism, from which the fetus is protected until after birth. Without endogenous cholesterol, the growing embryo depends on maternal cholesterol, which may not be transported across the placenta in sufficient amounts. Thus, the fetus with SLO syndrome suffers systemic and cerebral malformations in proportion to the severity of the deficiency of cholesterol biosynthesis (Quélin et al., 2012).

Clinical Manifestations. Common findings at birth are intrauterine growth restriction, microcephaly, and hypotonia. Facial dysmorphism may feature epicanthic folds, ptosis, anteverted nares, broad nasal tip, micrognathia, and low-set ears. Associated anomalies include syndactyly of the second and third toes (>98%), postaxial polydactyly, small abnormally positioned thumbs, Hirschsprung's disease, and cataracts, and in males, hypospadias, cryptorchidism, and a hypoplastic scrotum. Common clinical manifestations in the newborn include severe hypotonia, feeding difficulties with poor suck and vomiting, and excessive sleepiness with poor responsiveness (Haas et al., 2017). A severe, lethal form of SLO syndrome presents with microcephaly, lethal cardiac and brain anomalies, and ambiguous genitalia (Quélin et al., 2012). These infants expire during the first week of life from multisystem organ failure.

Diagnosis. SLO syndrome is often recognized by its distinctive clinical features. Confirmation is made by finding elevated blood levels of its direct precursor, 7DHC. Plasma cholesterol may be normal or low. Some fetuses with SLO syndrome are identified by anomalies detected prior to birth by ultrasonography, and confirmation can be made by amniotic fluid or chorionic villus sample analysis.

Management. Immediate management is directed toward raising body cholesterol and removing toxic precursors. Providing exogenous cholesterol not only restores low cholesterol levels, but also suppresses the infant's endogenous cholesterol synthesis, decreasing the production of 7DHC (Haas et al., 2017).

DISORDERS OF METAL METABOLISM

Errors of metal metabolism are genetic biochemical disorders in the way that metals are processed by the body: their synthesis, transport, absorption, storage, or utilization.

Molybdenum Cofactor Deficiency

Pathophysiology. The molybdenum cofactor is an essential component of a large family of enzymes involved in important transformations in carbon, nitrogen, and sulfur metabolism. Molybdenum cofactor deficiency is an autosomal recessive, fatal neurologic disorder, characterized by the combined deficiency of sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase.

Clinical Manifestations. Affected neonates are usually born after an uneventful pregnancy and normal delivery. Soon after birth, feeding difficulties and neurologic symptoms develop. The neurologic picture includes intractable tonic-clonic seizures, axial hypotonia, and peripheral hypertonicity (Koeller & Kaler, 2017). Typical facial features include puffy cheeks, a long philtrum, and a small nose. The neuropathologic findings are consistent with a toxic insult to the brain that causes severe neuronal loss, demyelination of white matter, reactive astrogliosis, and spongiosis. Ectopia lentis (displacement of the lens) may be noted on ophthalmologic examination.

Diagnosis. Molybdenum cofactor deficiency can be difficult to diagnose because there are no clues on routine laboratory studies. A positive sulfite dipstick of fresh urine is suggestive of the disorder; however, a negative test does not rule it out. Urinary S-sulfocysteine, thiosulfate, urothion, xanthine, and hypoxanthine levels aid in the diagnosis of molybdenum cofactor deficiency (Koeller & Kaler, 2017). Plasma uric acid is typically low.

Management. Substitution therapy with purified cyclic pyranopterin monophosphate (cPMP) has been described in the successful treatment of a 6-day-old infant with molybdenum cofactor deficiency (Veldman et al., 2010). No other therapy is currently available for molybdenum cofactor deficiency. One measure that has proved helpful is to limit the intake of sulfur-containing amino acids (cysteine and methionine). Seizures are often difficult to control.

SUMMARY

The number of known inherited disorders of metabolism has risen steadily in recent years and is likely to continue to do so. Although not all will manifest in the neonatal period, many disorders with neonatal onset are rapidly lethal if not recognized and treated without delay. Expanded newborn screening programs have saved many lives through presymptomatic diagnosis, but these programs currently screen for only a fraction of the hundreds of possible metabolic disorders. Neonatal health professionals must be vigilant and consider the diagnosis of an inborn EM in a neonate presenting with clinical manifestations resembling sepsis, or in an infant becoming ill after one or more days of normal health,

particularly when the laboratory data do not fit the clinical picture. Although many neonatal metabolic disorders are not yet amenable to therapy, an exact diagnosis is important for genetic counseling and prenatal diagnostic procedures that the family may desire for future pregnancies.

CASE STUDY

■ **Identification of the Problem.** A newborn infant, just over 48 hours of age, was rooming with his mother, who noted him to be jaundiced and unusually sleepy. His mother could not awaken him to breastfeed and she notified the nurse, who took him to the nursery to check his bilirubin level. His total serum bilirubin was 10.4. However, the infant made no response to having his heel lanced for the blood draw, and the nurse was unable to awaken him to feed. She placed a call to the infant's pediatrician, and a CBC with differential and a blood culture were ordered. The infant was then transferred to the NICU for further evaluation. An intravenous drip of D10W at 100 mL/kg/day was begun, and ampicillin and gentamicin were given. However, the CBC, differential, and C-reactive protein (CRP) were all within normal limits, and subsequently, the blood culture was negative as well.

■ **Assessment: History and Physical Examination.** The infant, a boy, was born by cesarean section to a 33-year-old G3, P2 group B streptococcus (GBS)–negative, insulin-dependent gestational diabetic mother, in satisfactory glucose control during the last trimester of pregnancy. Family history was significant for a maternal brother who died on the third day of life from unknown causes. Siblings of this infant were two healthy girls. This infant's Apgar scores were 8 and 9. Birth weight was 3,790 g. The infant's blood sugar levels on day 1 were all within normal limits; he appeared healthy and roomed in with his mother, breastfeeding on demand with occasional formula supplementation. He was voiding and stooling normally.

On examination, his color was pale pink with mild jaundice on room air. Respirations were regular and rapid, but there were no retractions, grunting, or flaring. His axillary temperature was 97°F, heart rate 122, respiratory rate 80, blood pressure 60/36 (mean 44). Glucose screen (point of care) was 52. An arterial blood gas was obtained, and the results were pH 7.32, Po_2 71, Pco_2 30, base deficit −2. Capillary refill was 2 to 3 seconds, pulses were equal, and there was no murmur. His abdomen was rounded with mild hepatomegaly. He did not react to stimulation of any type and could not be aroused. His overall tone was decreased, he did not suck, and no Moro reflex was noted. Within 24 hours, he began having seizures requiring treatment with phenobarbital. Severe apnea and respiratory failure led to intubation and mechanical ventilation.

■ **Differential Diagnosis.** The chief differential diagnosis for a full-term infant becoming ill at about 48 hours of age is neonatal sepsis, although this mother was GBS negative and the infant's laboratory data did not support this diagnosis. His serum bilirubin was not high enough to explain his somnolence and lethargy as stemming from bilirubin encephalopathy. Transient tachypnea of the newborn was unlikely, because he did not appear to be in any significant respiratory distress other than his rapid respiratory rate, and the clinical picture was more consistent with a neurologic insult. The history did not suggest an etiology for neonatal encephalopathy. The next most likely diagnostic possibilities would be inborn errors of intermediary metabolism that present with an "intoxication" syndrome and without hypoglycemia, following a symptom-free interval: organic acid disorders, amino acid disorders, and UCDs.

■ **Diagnostic Tests.** To start differentiating between the most likely categories of metabolic disorders, a blood ammonia level is needed. Depending on this result, other important diagnostic tests might include electrolytes, BUN, creatinine, quantitative plasma, and urine amino acids, urine organic acids, and urine orotic acid.

■ **Working Diagnosis.** The infant's blood ammonia level was 1,901 µmol/L. This suggests a working diagnosis of a urea cycle defect. Additional testing revealed the following:

Plasma amino acids: Glutamine 1,632 µmol/L (reference range 376–709 µmol/L)

Citrulline trace (reference range 10–45 µmol/L)

Urine orotic acid: 852 mmol/mol creatinine (reference range 0.12–3.07 mmol/mol creatinine)

Following the algorithm for neonatal hyperammonemia (see Figure 9.2), these findings point to a working diagnosis of OTC deficiency. In support of this diagnosis, the infant's symptoms began after 24 hours of age, and he had no significant acidosis.

■ **Development of Management Plan.** The most urgent priority was reduction of the baby's toxic blood ammonia level. In addition, all protein intake had to be stopped temporarily until the blood ammonia level was normalized; so, the baby was made NPO and no amino acids were added to the intravenous solution. Protein would be reintroduced within 48 hours in small yet sufficient amounts to prevent catabolism. While preparations were being made for hemodialysis, an umbilical venous catheter was inserted for administration of "scavenger drugs," or agents that supply alternatives to urea for elimination of waste nitrogen.

■ **Implementation and Evaluation of Effectiveness.** A loading dose of sodium phenylacetate plus sodium benzoate 2.5 mL/kg was given via central catheter over 90 minutes (Ammonul, Ucyclyd Pharma, Scottsdale, AZ). In addition, a dose of arginine HCl 10% (2.0 mL/kg) was administered. Hemodialysis was initiated, and after about 36 hours, the infant's ammonia level was successfully reduced to less than 70 µmol/L. He showed rapid improvement in neurologic status and was extubated. Amino acids were reintroduced to the intravenous solution after another 24 hours, and feedings were restarted shortly thereafter with citrulline supplementation. Following discharge, he was maintained on this regimen, plus pharmacologic diversion therapy, and he had two metabolic crises requiring hospitalization before receiving a liver transplant. An MRI of his brain at 1 year of age revealed that the neurologic prognosis remains guarded. The family also underwent genetic counseling regarding recurrence risks and prenatal genetic diagnosis for future pregnancies.

EVIDENCE-BASED PRACTICE BOX

Hyperammonemia (plasma ammonium level >150 μmol/L or >260 mcg/dL) is a metabolic disturbance that is a characteristic feature of many different EMs, including disorders of organic acids, fatty acid oxidation, and the urea cycle. Ammonia, a product of protein metabolism, is a neurotoxin that can accumulate in the brain along with glutamine, resulting in osmotic swelling, brain edema, and permanent brain damage.

Many areas of the developing brain are vulnerable to the effects of excess ammonia, and the neurologic sequelae are correlated with the duration and magnitude of hyperammonemia (Braissant, 2010). Therefore, the prevention or reversal of hyperammonemic coma is of prime concern in a suspected metabolic disorder. The initial management of ammonia encephalopathy must often proceed in the absence of a definitive diagnosis (Westrope, Morris, Burford, & Morrison, 2010). The kidneys clear ammonia poorly, so removal of ammonia from the body must be expedited by another method. Two means of accomplishing this are diversion therapy using ammonia-scavenging drugs, and physical removal of ammonia from the circulation with dialysis or hemofiltration.

Although the efficacy of dialysis or hemofiltration in the clearance of serum ammonia has been established, the optimal treatment modality has not. Few published studies have shown associations between specific dialysis modalities and survival rates. Owing to the rarity of the EMs, randomized controlled trials to compare these therapies do not exist. The evidence is largely retrospective and observational, from single case reports and case series.

Expert consensus suggests that first-line treatment of hyperammonemia should involve stopping protein intake, suppressing protein catabolism, and administering agents that combine with ammonia to form compounds with high renal clearance. Many case reports describe successful medical treatment of newborns with various EMs using N-carbamylglutamate (Filippi et al., 2010; Gessler, Buchal, Schwenk, & Wermuth, 2010; Kasapkara et al., 2011), sodium benzoate, and sodium phenylbutyrate. When plasma ammonia levels decline within 4 hours of treatment, the need for dialysis may be averted (Picca et al., 2001). During this 4-hour window, however, preparations should be underway to institute a more aggressive route of ammonia clearance in neonates who do not respond to medical treatment (Picca, Bartuli, & Dionisi-Vici, 2008).

If detoxification with ammonia-scavenging drugs fails to reduce the plasma ammonia level within a few hours, another method of clearance must be initiated without delay. Options include hemodialysis, continuous venovenous hemofiltration (CVVHF), continuous venovenous hemodialysis (CVVHD), and peritoneal dialysis. Methods that provide continuous renal replacement (hemodialysis or hemofiltration) are preferred over peritoneal dialysis, although evidence is scant. Picca et al. (2001) reported their experience using three different extracorporeal methods of clearing ammonia (continuous arteriovenous hemodialysis, CVVHD, and hemodialysis). They found that CVVHD was the most effective method to promptly lower ammonia levels. However, they also found that the most relevant indicator of prognosis was not how quickly the plasma ammonia level was reduced, but the duration of hyperammonemic coma before the initiation of dialysis (Picca et al., 2001). In particular, coma duration longer than 30 hours before dialysis initiation negatively affects the outcome (Picca et al., 2001). Therefore, they recommend that infants with rising ammonia levels should be transferred without delay to a facility capable of providing extracorporeal dialysis if medical therapy fails.

In a 10-year experience with CVVHF to treat hyperammonemia, Westrope et al. (2010) found this method to be safe, effective, and efficient in lowering plasma ammonia levels. However, neither the pretreatment ammonia level nor the speed of ammonia removal was associated with outcome (Westrope et al., 2010). This study suggests that the pretreatment status of the neonate may be the main determinant of outcome, reinforcing the need to initiate medical treatment and to proceed with continuous renal replacement therapy without delay.

In another series of 21 children (15 neonates), investigators retrospectively analyzed outcomes for patients receiving CVVHD or peritoneal dialysis (Arbeiter et al., 2010). A 50% reduction in serum ammonia levels was achieved significantly faster with CVVHD than with peritoneal dialysis. In neonatal patients, survival and survival without mental retardation were both better following CVVHD, although the sample sizes were small and the duration of pretreatment encephalopathy was not known. Of interest, these investigators documented the best outcomes in patients with neonatal-onset citrullinemia.

Although it would be desirable to have randomized, controlled trial evidence of the superiority of one method of treating hyperammonemia over another, the trend toward presymptomatic detection of metabolic disorders could, in the future, lead to preventive treatments that will obviate the need for such aggressive approaches to hyperammonemia. In the meantime, clinicians should continue to collect data on the few patients encountered with these disorders to inform best practice and improve outcomes.

PARENT VOICES

Jimena Guild

The simple act of feeding my child seems ordinary to most parents, but for us whose child suffered from feeding issues, it was huge. My son Kai was born premature at 28 weeks and developed acute oral aversion among other issues during his 4-month stay in the NICU. To ensure he received the necessary nutrition, my son was fed through a tube that from his nose fed right into his stomach called a nasal gastric (NG) tube. In the NICU, he fought the bottle so much I was not even going to try him on the breast. He continued to struggle with drinking from a bottle for the first 6 months of his life. He was labeled "failure to thrive" and needed assistance from nursing services and an O.T. who would come to help him develop the skills he needed to eat orally. Kai was tube-fed for the first 2 years of his life. Most parents whose children have feeding tubes do not know for how long their child will need the tube. We were lucky that he only had it for 2 years; he will never remember the awful nights we would struggle to get the tube put back in when he would pull it out; the screams, the cries, from both of us were not something I wish on any parent; having to hold him down while my husband fished the tube down into his stomach, sometimes having to redo it multiple times if it went down the wrong tube (into his lungs) or came out of his mouth as he coughed. Those are days I will never forget, but it's also important to know that feeding tubes offer hope. Sure, it's an alternative way of eating by mouth, but it is one that gives children—and all people—with no other alternative, a way to thrive. Nowadays, Kai is a healthy little 7-year-old boy who, you wouldn't believe, has an insatiable hunger; he is the most nonpicky child you will meet and is willing to try anything and everything once.

CHAPTER 10

Endocrine System

Susan Kau and Stephanie Hoe

INTRODUCTION

Our understanding of endocrine disorders in the neonate advances to the molecular level in parallel with discoveries in genetics and cell biology. Endocrine processes are fundamental to growth and development of the fetus and newborn. Prompt recognition of endocrine disorders in the neonate is the chief prerequisite in our ability to institute life-saving treatment and minimize long-term morbidity. This chapter provides an overview of the clinical endocrine disorders that may be seen in the neonatal period.

THE ENDOCRINE SYSTEM

The word *endocrine*, from the Greek words *endo* (within) and *krinein* (to separate), describes a diverse group of ductless organs that secrete hormones directly into the bloodstream. The classic endocrine glands are the hypothalamus, pineal, pituitary, thyroid, parathyroid, thymus, pancreatic islet cells, adrenals, ovaries, and testes, although the heart, kidneys, and intestines also secrete and regulate hormones. Among the many functions of the endocrine system are coordination and regulation of metabolism and energy, the internal environment, growth and development, and sexual differentiation and reproduction. Maintenance of homeostasis (the metabolic milieu of the body in a steady state) is considered the most important function of the endocrine system (Bethin & Fuqua, 2014).

The endocrine glands synthesize, store, and secrete hormones, the chemical messengers, or signals, of the endocrine system, that are responsible for tight regulation of diverse physiologic functions. Hormones are peptides, amines, or steroids and are further classified as either regulatory or effector hormones (Bethin & Fuqua, 2014). Secreted into the blood or extracellular fluid, hormones exert their actions on specific cells, either locally or in distant tissues called target cells. Target cells respond to hormones that contain receptors for those precise hormones. Hormones must first bind to these receptor sites before exerting physiologic actions. Some hormones, such as insulin, are fully active on release into the circulatory system, whereas others, such as T_4, require activation to produce their biologic effects. Hormones that must be modified to active hormone after synthesis are known as prepro- or prohormones.

Many hormones are insoluble in water and must be bound to carrier proteins to be transported in the circulatory system. These protein-bound hormones exist in rapid equilibrium with minute quantities of hormone that remain in the aqueous plasma. This "free" fraction of the circulating hormone is taken up by the cell and represents the active hormone concentration that provides feedback to regulate synthesis of the new hormone.

Target hormone levels also serve as powerful negative feedback regulators of their own production via suppression of trophic hormones and hypothalamic releasing hormones. As the target hormone level rises, a message is sent to the anterior pituitary to reduce production of the respective trophic hormone, and also to the hypothalamus to slow production of the respective releasing hormone. Endocrine disease has traditionally been classified as hormone excess, hormone deficiency, or altered tissue responses to hormones (e.g., hormone resistance). Clinical endocrine abnormalities can also be driven by deviations in the feedback systems that control hormone levels. An explosion of new data from molecular genetic studies is redefining "endocrine disease" as a broad array of mutations and alterations in expression of thousands of genes that result in either "loss of function" or "gain of function"; in other words, hyposecretory or hypersecretory disorders (Tenore & Driul, 2009).

Development of the fetal endocrine system is more or less independent of maternal endocrine influences (Divall & Merjaneh, 2018). The placenta blocks the entry of most maternal hormones into the fetal circulation, but the minute quantities that do achieve transplacental passage can have profound effects. Some of these prenatal exposures are essential to fetal growth and development; others may contribute to fetal and neonatal endocrine dysfunction.

FETAL ORIGINS OF ADULT DISEASE

The intrauterine endocrine milieu can have powerful effects on growth and development of the fetal endocrine system. When exposed to a variety of different stressors (maternal undernutrition, uteroplacental insufficiency, or psychological stress), the fetus releases glucocorticoids and catecholamines that, during critical periods of development, affect the development of the fetal hypothalamic–pituitary–adrenal (HPA) axis. Chronic stress can also induce intrauterine growth restriction, or the so-called thrifty phenotype, in the fetus, an adaptation to the limited supply of nutrients (Divall & Merjaneh, 2018). The way in which the fetus adapts, a concept known as programming, is believed to permanently alter physiology and metabolism. Permanent alterations in

fetal metabolic programming contribute to endocrine, metabolic, and cardiovascular disease in adult life (Seki, Williams, Vuguin, & Charron, 2012).

NEONATAL ENDOCRINE DISORDERS

Many neonatal endocrine disorders originate in developmental defects of, or injury to, the endocrine glands (Bethin & Fuqua, 2014). Endocrinopathy in the newborn can be caused by a mutation in a single gene or by genomic imprinting, when the expression of the gene depends on which parent passed on that particular gene (Divall & Merjaneh, 2018). In addition to well-described neonatal endocrine disorders such as hypothyroidism and congenital adrenal hyperplasia (CAH), endocrine dysfunction can affect the preterm infant in a variety of ways as a function of maturation. Exposure to various exogenous agents in the environment, known as *endocrine disruptors,* can have deleterious effects on the development of the endocrine system. Numerous chemicals have known estrogenic or antiandrogenic properties and have been shown to disturb sexual differentiation in animals (Divall & Merjaneh, 2018). The extent to which endocrine disruptors are responsible for increases in hypospadias and testicular dysgenesis syndrome in humans that have been reported in some parts of the world is unknown.

PITUITARY GLAND AND HYPOTHALAMUS

The pituitary gland is the master gland; it produces and secretes hormones, and sends signals to the other glands. The pituitary gland has two distinct structures, the anterior and posterior pituitary, with different embryologic origins. The anterior pituitary develops from oral ectoderm, a diverticulum called Rathke's pouch, and its cells differentiate into specific hormone-secreting cells. The posterior pituitary develops from neuroectoderm evaginating ventrally from the developing brain. The two tissues grow together into a single gland but remain functionally separate.

The hypothalamus, located just above the pituitary gland, secretes the releasing and inhibiting hormones that in turn influence the production of anterior pituitary hormones. Hypothalamic hormones are carried to the anterior pituitary via hypothalamic–hypophyseal portal veins where they bind to receptors on the anterior pituitary cells. The anterior pituitary regulates growth, differentiation, and homeostasis and produces growth hormone, prolactin, adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH). Hormones secreted by the posterior pituitary include oxytocin and hypothalamic-produced vasopressin (antidiuretic hormone, ADH). The hypothalamus is the interface between the endocrine and autonomic nervous systems.

ANTERIOR PITUITARY DISORDERS

Congenital Hypopituitarism

Congenital hypopituitarism, although rare in the newborn, has a number of possible etiologies. Some cases of congenital hypopituitarism are attributed to mutations in genes encoding transcription factors involved in pituitary gland development (Alatzoglou & Dattani, 2009). Congenital hypopituitarism can be an isolated defect, or it can be associated with malformations including holoprosencephaly, septo-optic dysplasia, and other midline cerebral anomalies, the same developmental defects of the embryonic brain that lead to hypothalamic dysfunction. Infection and hypovolemic shock stemming from birth-related complications such as placenta previa and abruptio placentae are additional etiologies.

Pathophysiology. Complete absence of the pituitary gland (pituitary agenesis) and other pituitary lesions can produce deficiencies of one or all pituitary hormones. Panhypopituitarism is a deficiency of all pituitary hormones. In the newborn, the foremost effect of congenital hypopituitarism is hypoglycemia. Owing to the absence of growth hormone, and possibly cortisol as well, insulin is unopposed, placing the neonate at risk for hypoglycemia. Deficiency of growth hormone, and often gonadotropin, combine to stunt penile growth in utero; this is usually referred to as *hypogonadotropic hypogonadism*. Although fetal pituitary growth hormone is not the primary stimulus for fetal growth, growth hormone does make an important contribution to birth size.

Clinical Manifestations. Neonates with congenital hypopituitarism can initially be asymptomatic, with evidence of pituitary hormone deficiencies developing over time (Alatzoglou & Dattani, 2009). Neonates with hypopituitary syndromes can present with midline craniofacial defects such as cleft lip, cleft palate, or bifid uvula. Males may have a micropenis, defined as a normally formed and proportioned penis with a stretched penile length more than two standard deviations below the mean for age. Average penile length for preterm infants 30 weeks of age or older is 2.5 + 0.4 cm and for term infants 3.5 + 0.4 cm. For preterm infants 24 to 26 weeks gestation, the following formula can be used: penile length in centimeters = 2.27 + 0.16 × (gestational age in weeks) (Tuladhar, Davis, Batch, & Doyle, 1998). Hypoglycemia can be mild or severe and persistent. Later in the neonatal period, infants may present with prolonged jaundice and direct hyperbilirubinemia, or evidence of other endocrinopathy, such as diabetes insipidus (DI; high urine output, dehydration, hypernatremia).

Diagnosis. A pediatric endocrinologist usually coordinates the diagnostic testing and interpretation for these infants. The aim of laboratory testing is to determine which hormone deficiencies are present. Measurement of growth hormone, thyroid hormone, and cortisol is essential. MRI of the brain is used to define the anatomy and look for a structural cause of hypopituitarism. For infants with suspected septo-optic dysplasia, an ophthalmologic examination is indicated.

Management. The immediate goals of management are to stabilize the neonate's blood sugar and ensure that the neonate is not at risk for life-threatening cortisol insufficiency. Hypoglycemia might not resolve without growth hormone replacement. Further treatment is geared toward correcting specific hormonal deficiencies. The infant will require follow-up management by the pediatric endocrinologist throughout hospitalization and after discharge.

POSTERIOR PITUITARY DISORDERS

Diabetes Insipidus

DI is a deficiency of ADH (vasopressin). In neonates, central or neurogenic DI can be associated with congenital midline anatomic defects (septo-optic dysplasia, holoprosencephaly), central nervous system (CNS) injury such as intracranial hemorrhage or hypoxia, neoplasms, or it can be idiopathic. As many as 90% of neonates with inherited nephrogenic DI are boys with an X-linked form caused by mutations in the *arginine vasopressin receptor 2* (*AVP2R*) gene, a condition that can be diagnosed prenatally (Richardson & Yonekawa, 2018).

Pathophysiology. Normally, ADH secretion is triggered by changes in osmolality detected by supraoptic and paraventricular osmosensors in the brain. Increased osmolality stimulates the posterior pituitary to release ADH, which in turn increases the permeability of the renal collecting tubules to water, reducing

urinary water loss. Damage to the osmosensors, the posterior pituitary gland, or the hypothalamic–hypophyseal axis results in a deficiency of ADH and increased urinary free water loss.

Clinical Manifestations. Neonates with DI may suck vigorously during feeding but vomit immediately afterward, resulting in poor growth. **Emergency Alert: Urine output is high, in excess of 5 mL/kg/hour, with low specific gravity (<1.010). Irritability and fever may accompany evidence of dehydration (poor skin turgor, depressed anterior fontanel, sunken eyes, mottled skin, weak pulses, low blood pressure, and constipation).**

Diagnosis. Serum electrolytes, osmolality, and plasma ADH levels are the primary laboratory tests used to diagnose DI. Plasma ADH is normally elevated in the newborn following delivery, playing a role in the low urine output that is typical on the first day of life. In neonates with DI, hypernatremia may result in levels as high as 180 mEq/L with elevated serum osmolality. Urinalysis reveals inappropriately dilute urine (low urine osmolality and low specific gravity). MRI is used to visualize the pituitary gland and stalk to delineate the possible cause of DI.

Management. DI in neonates requires very careful fluid management. Severe dehydration and hypernatremia are corrected primarily with intravenous fluids. Insensible water losses should be minimized. **Quality and Safety: Serum electrolytes and osmolality, blood glucose, accurate intake and output, and the evidence of dehydration (weight loss, blood pressure, pulses, skin turgor, etc.) should be closely monitored during treatment.** **Emergency Alert: Infants with severe hypernatremia must be observed for possible seizure activity.** Although it is expected that serum sodium will decline, very rapid shifts in serum sodium should be avoided. During therapy to correct serum sodium, the infant's neurologic status must be monitored closely for signs and symptoms of cerebral edema. **Quality and Safety: Hyperglycemia must be avoided as this may lead to glycosuria and exaggerate the diuresis.** If possible, DI in the neonate should be managed with fluid therapy alone, preferably breast milk or formula with a whey-to-casein ratio of 60 to 40, supplemented with free water if necessary (Srivatsa, Majzoub, & Kappy, 2014). If it is not possible to manage DI with fluids alone, the agent of choice for pharmacologic treatment is desmopressin (DDAVP), a long-acting synthetic analogue of pituitary ADH. Intranasal DDAVP can be diluted with normal saline for administration to the neonate. Subcutaneous and oral formulations of DDAVP are also available, as well as short-acting intravenous aqueous pitressin for emergency treatment of severe dehydration. **Emergency Alert: Caution must be observed when using vasopressin and high fluid intake to manage DI in the neonate because this combination can result in severe hyponatremia** (Srivatsa et al., 2014).

Syndrome of Inappropriate Antidiuretic Hormone

Syndrome of inappropriate antidiuretic hormone (SIADH) is an impairment of free water clearance associated with inappropriately raised secretion of ADH. SIADH is believed to be associated with CNS infection and injury (birth asphyxia, intracranial hemorrhage, meningitis), pain, and maternal substance abuse (Modi, 2012).

Pathophysiology. An uncontrolled release of ADH can occur in sick preterm and term infants, resulting in renal free water retention that is inappropriate to the level of serum osmolality. The infant becomes hyponatremic, not because of true sodium depletion, but because of a dilutional effect from the fluid that is retained. ADH levels can become elevated in infants born after fetal distress, or those with severe pulmonary disease, undergoing surgery, or experiencing pain. Raised ADH levels are common in acutely ill neonates (Modi, 2012).

Clinical Manifestations. Signs and symptoms of SIADH are oliguria, hyponatremia, low serum osmolality (<275 mOsm/L), weight gain, and edema. Patients with SIADH are euvolemic or hypervolemic.

Diagnosis. The diagnosis of SIADH should be made only when hyponatremia exists with normovolemia, normal blood pressure, normal renal and cardiac function, evidence of continuing sodium excretion, and urine that is not maximally dilute (Modi, 2012). True SIADH fulfilling all diagnostic criteria is probably uncommon in the neonate. Apparent SIADH may be due to hypovolemia-induced baroreceptor-driven ADH secretion, a normal response to reduced blood volume in the sick neonate (Modi, 2012).

Collaborative Management. Fluid restriction, with close monitoring of intake, output, serum electrolytes, blood glucose, accurate daily weights, evidence of increasing edema, and measures of hydration, are the essentials of management. It can be difficult to restrict fluids because infants receive all of their nutrition in liquid form. Diuretics are sometimes used to promote free water excretion. Comparison of intake and output is important. **Quality and Safety: A careful neurologic assessment should be performed, noting changes in relation to fluid or sodium balance.**

THYROID GLAND

The thyroid gland is a butterfly-shaped structure made up of two lateral lobes connected by a thin band of tissue called the isthmus. Composed of densely packed follicular cells containing colloid, the thyroid gland also contains parafollicular cells (C-cells) that produce the calcium-lowering hormone calcitonin.

The thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) are produced from the amino acid tyrosine. Essential to this process is the trapping and storage of iodide, a trace element required for thyroid hormone synthesis. Thyroglobulin (Tg), a thyroid hormone precursor, is synthesized in the follicular cell. Iodine is taken up by the Tg molecule, incorporated into its tyrosine residues, and returned to the colloid, where a coupling reaction takes place. This step, called organification, is catalyzed by the enzyme thyroid peroxidase (TPO). The coupling of two tyrosine residues produces T_4, whereas the coupling of diiodotyrosine (DIT) with monoiodotyrosine (MIT) produces T_3. These are stored in the follicular lumens until TSH stimulates their release into the circulation.

The thyroid gland produces mostly T_4, which serves as a storage pool for T_3. T_3 is the most biologically active thyroid hormone, with greater affinity for the thyroid receptor. Circulating T_4 is metabolized by outer ring 5' monodeiodination to T_3 in the peripheral tissues. Inner ring 5' monodeiodination of T_4 produces reverse T_3 (rT_3), an inactive metabolite. T_4 and T_3 circulate in plasma bound to thyroid-binding globulin (TBG), leaving just a small fraction in equilibrium as free hormone. It is possible for TBG, which is synthesized in the liver, to be deficient even though the free hormone levels are normal. It is the free hormone that is available to the tissues, with the bound hormone acting as a circulating reservoir. The concentration of free hormone determines the individual's metabolic state.

The hypothalamic–pituitary–thyroid (HPT) axis controls thyroid hormone secretion (Figure 10.1). The hypothalamus synthesizes thyrotropin, stimulating release of TSH from the anterior pituitary. In turn, TSH stimulates uptake of iodine by the thyroid, thyroid hormone synthesis and release, and increased size and

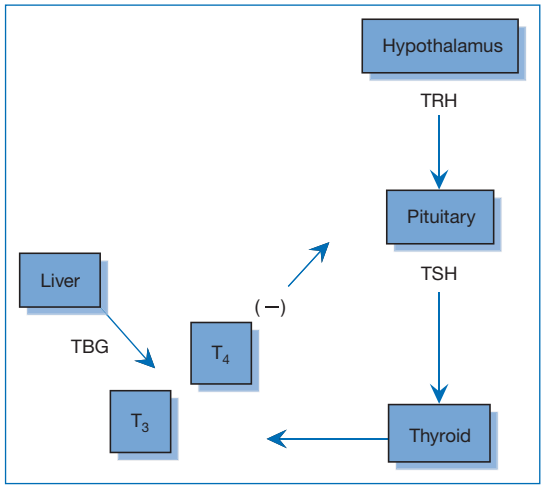

FIGURE 10.1 The hypothalamic–pituitary–thyroid (HPT) axis. Thyroid hormone levels are regulated by a system of feedback inhibition operating along the HPT axis. The hypothalamus secretes thyrotropin-releasing hormone (TRH), which stimulates the pituitary to secrete thyroid-stimulating hormone (TSH). TSH, in turn, stimulates the thyroid gland to produce and secrete thyroid hormones (T_4 and T_3) into the circulation, which circulate bound to thyroid-binding globulin (TBG) synthesized by the liver. Once levels of T_4 and T_3 are adequate, further production of TSH is suppressed.

vascularity of the thyroid gland itself. The feedback loop is responsive to changes in free hormone concentration, and TSH secretion adjusts accordingly.

FETAL AND NEONATAL THYROID DEVELOPMENT

The thyroid gland is the first endocrine organ to develop in the human embryo. Concurrent with development of the fetal thyroid are growth and maturation of the hypothalamus and pituitary glands, which are required for thyroid function. At about 10 to 12 weeks gestation, the hypothalamus begins synthesizing thyrotropin-releasing hormone (TRH), the pituitary gland begins secreting TSH, and thyroid-binding globulin (TBG) is detectable in fetal serum. Maternal thyroxine is measurable in amniotic fluid before the onset of fetal thyroid function. Before 20 weeks gestation, transplacental passage of maternal T_4 largely provides for fetal thyroidal needs and is critical for normal development. Maternal hypothyroidism during early gestation can impair CNS development in the fetus. By the start of the second trimester, however, the fetal contribution to circulating thyroid hormones is significant. The capacity of the fetal thyroid gland to trap and store iodide and synthesize thyroid hormones begins at about 11 weeks gestation, but hormone production is limited until 18 to 20 weeks, when iodine uptake increases markedly. The only source of iodide for the fetus is transplacental passage from the maternal circulation and placenta.

As pregnancy progresses, the placenta becomes less permeable to maternal thyroid hormone. Permeability is likely to be highest during the first trimester because thyroid hormone is critical to fetal neurodevelopment, and no other source is available to the fetus during this period. The fetal HPT axis develops from mid-gestation through 4 weeks post birth. In infants born before term, maturation of the HPT axis is disrupted (Simpser & Rapaport, 2010). In the last trimester, the fetus is less dependent on maternally derived thyroid hormone. Although thyroid hormone is required for CNS maturation, it is not needed for metabolism, growth, or generation of heat. An excess of bioactive T_3 could be harmful to fetal development. For this reason, the concentration of T_3 is tightly controlled in the tissues (van Wassenaer & Kok, 2004). This is accomplished by preferential conversion of excess fetal T_4 to the bioinactive reverse T_3 by type III deiodinase. In the event of T_4 deficiency, as in fetal hypothyroidism, T_4 is shunted to the brain where it is deiodinated to T_3 to provide a critical source of intracellular T_3 to the developing brain.

Birth represents a temporary state of hyperthyroidism for the newborn. In response to sudden exposure to a cold environment, the pituitary releases a surge of TSH that peaks at 70 to 100 mU/mL at 30 minutes after birth. This cold-stimulated TSH surge provokes rises in serum T_4, T_3, and free T_4, all of which peak at about 48 hours. T_4 increases in most infants to a level of 6.5 mcg/dL or higher. The rise in T_4 causes the TSH to decline to 20 mU/mL or less (the cutoff used in most screening programs for congenital hypothyroidism [CH]) because of feedback inhibition. Free and total T_4 and T_3 gradually decrease over the next 1 to 2 months.

CONGENITAL HYPOTHYROIDISM

CH is a deficiency of thyroid function present at the time of birth. With an incidence of 1 in 2,000 to 4,000 births (Rastogi & LaFranchi, 2010), it is the most common congenital endocrine disorder (Polak, Refetoff, Szinnai, & Van Vliet, 2017). CH is classified as either permanent or transient, depending on the underlying etiology. Early diagnosis and appropriate treatment are essential to prevent permanent neurologic damage. Because most affected infants are asymptomatic at birth, neonatal screening for hypothyroidism is now mandated so infants with CH are promptly identified and treated.

Causes of Congenital Hypothyroidism

Thyroid Dysgenesis. The most common cause (85%) of permanent CH is thyroid dysgenesis, which includes thyroidal ectopy, hypoplasia, and complete thyroid agenesis. The severity of thyroid dysfunction is variable, depending on the amount of functional thyroid tissue present. Thyroidal ectopy accounts for two-thirds of neonates with thyroid dysgenesis. Ectopic thyroid tissue (lingual, sublingual, subhyoid) provides adequate amounts of thyroid hormone in some infants. Occasionally, ectopias are associated with thyroglossal duct cysts. Most of these infants have a thyroid remnant, usually found midline at the base of the tongue, as a result of failure of the gland to descend normally during embryologic development.

Thyroid dysgenesis occurs in 1 in 4,000 live births; however, the incidence in Black infants is 1 in 32,000 live births and in Hispanic infants, 1 in 2,000. The disorder has a female to male ratio of 2 to 1. Only 3% of thyroid dysgenesis is due to mutations in the homeobox genes that control thyroid differentiation *(TTF-2*, *NKX2.1*, *NKX2.5*, or *PAX-8*; Tenore & Driul, 2009). Trisomy 21 or Down syndrome is associated with an increased prevalence of thyroid dysgenesis, and extrathyroidal abnormalities (cardiac, gastrointestinal, CNS, and eyes) are also more common. No serum Tg is measurable in thyroid agenesis, distinguishing it from functional thyroid tissue, which is associated with measurable serum Tg concentrations.

Thyroid Dyshormonogenesis. About 10% to 20% of infants with CH have inborn defects of thyroid hormone metabolism. Mutations in genes coding for proteins involved in thyroid hormone synthesis, secretion, or transport result in failure of one of the steps in this process, leading to thyroid insufficiency. These biochemical defects are usually inherited as autosomal recessive

traits and include TSH hormone resistance, iodide organification defects, iodide transport defects, iodotyrosine deiodinase defects, and thyroglobulin deficiency. Deficient activity of the enzyme TPO is one of the most common disorders of thyroid synthesis caused by mutations of *THOX1* or *THOX2* (Kim, Nandi-Munshi, & DiBlasi, 2018). Although dyshormonogenesis eventually results in a compensatory goiter, it is not typically apparent during the neonatal period.

Thyroid-Binding Globulin Deficiency. Infants born with congenital thyroid-binding globulin (TBG) deficiency have low TBG and total T_4 but normal TSH concentrations and are normal with respect to thyroid function. Familial congenital TBG deficiency, transmitted as an X-linked trait, occurs in 1 in 9,000 newborns (Simpser & Rapaport, 2010). The defect can be complete or partial and is frequently an incidental finding on neonatal screening. A TBG level can be measured to confirm the diagnosis for the purpose of parental counseling, but no treatment is recommended.

Hypothalamic–Pituitary Hypothyroidism. Between 5% and 10% of infants with CH can be accounted for by what is called secondary–tertiary or central hypothyroidism. A deficiency of hypothalamic TRH or pituitary TSH can occur as a consequence of a developmental defect of the pituitary or hypothalamus. Central hypothyroidism is generally associated with other anomalies of the midbrain (such as absence of the septum pellucidum or other midline defects), hypopituitarism, pituitary stalk interruption, or empty sella syndrome, all of which lead to typical laboratory findings of low serum T_4 and low or inappropriately normal serum TSH.

Thyroid Hormone Resistance. Increasing numbers of patients are being found with resistance to the actions of endogenous and exogenous T_4 and triiodothyronine (T_3), a form of "peripheral hypothyroidism." At least 90% of these cases are caused by a mutation in the genes encoding for thyroid hormone receptor-beta (Rastogi & LaFranchi, 2010). Most patients have goiter, and levels of T_4, T_3, free T_4, and free T_3 are elevated. These findings have often led to the erroneous diagnosis of Graves' disease, although most affected patients are clinically euthyroid. The unresponsiveness to thyroid hormone may vary among tissues.

Clinical Manifestations of Congenital Hypothyroidism

Few neonates are diagnosed with CH solely on clinical grounds. Signs and symptoms of CH can be slow to develop owing to persistence of maternal thyroid hormone. When present, signs and symptoms of CH in the neonate are subtle and nonspecific; thus, they are not immediately linked with hypothyroidism. **Quality and Safety: Early diagnosis is critical, however, to ensure prompt treatment that will reduce the risk for mental retardation.** The signs and symptoms of hypothyroidism in the neonate reflect the wide-ranging actions of thyroid hormones on metabolism, intestinal motility, cardiac function, temperature regulation, neurologic function, and skeletal maturation (Box 10.1). The possibility of CH must be considered in infants presenting with birth weight in excess of the 90th percentile, prolonged jaundice, hypothermia, and cold mottled skin, an enlarged (>1 cm) posterior fontanel, umbilical hernia, and failure to feed well (Rastogi & LaFranchi, 2010).

Other features traditionally associated with hypothyroidism (macroglossia, dry skin, lethargy, hypotonia, hoarse cry, coarse hair, and constipation) evolve over the first weeks of life. A palpable, enlarged thyroid gland (also called a goiter) can be associated with impaired thyroid hormone synthesis and hypothyroidism. Hyperplasia of the thyroid gland results from hypersecretion of TSH in response to low T_3 and T_4 levels. Infants with suspected central hypothyroidism may present with midline or cranial defects or other signs of pituitary deficiency. Central hypothyroidism should be suspected in infants presenting with septo-optic dysplasia, hypoglycemia, micropenis, or cleft lip/palate.

Box 10.1

SIGNS AND SYMPTOMS OF HYPOTHYROIDISM IN THE NEONATE

- Birth weight >4 kg, gestation longer than 42 weeks
- Large, open posterior fontanel (>1 cm)
- Umbilical hernia
- Abdominal distension
- Poor feeding
- Hypothermia, cool extremities
- Prolonged jaundice
- Bradycardia
- Poor muscle tone
- Mottled skin
- Delayed skeletal maturation

Diagnosis of Congenital Hypothyroidism

Neonatal Screening. Because even severe CH can be clinically silent, universal newborn screening for CH is widely practiced. Routine screening of all newborn infants for CH has greatly improved early detection and treatment of the disorder, preventing much of the mental retardation that was previously associated with CH. Newborn screening was first introduced as a public health program in the United States in the early 1960s, and has expanded to other countries around the world, with different testing menus in each country. The conditions included in the newborn screening programs around the world vary greatly, based on the legal requirements for screening programs, prevalence of certain diseases within a population, political pressure, and availability of resources for both testing and follow-up of identified patients.

The incidence of CH, as detected through newborn screening, is approximately 1 per 3,000 to 4,000. Screening all newborns for CH is mandated in all U.S. states and throughout Canada. Recent increases in the incidence of CH reported by some screening programs could be the result of increased detection of mild hypothyroidism and preterm infants with delayed TSH rise (Mitchell, Hsu, Sahai, & Massachusetts Pediatric Endocrine Workgroup, 2011).

Some screening programs in North America measure the TSH directly from blood samples collected on filter paper. Other programs initially measure T_4 on all specimens, followed by TSH measurement only if T_4 is low. Owing to the physiologic surge in TSH in the first hours of life as the newborn adapts to the extrauterine environment, the screening specimen must be collected when the infant is at least 24 hours of age, and preferably between 2 and 4 days of age. If blood is collected earlier, particularly in the first 3 hours of life, a false positive result can occur. In those instances, a repeat specimen must be collected within the first 7 days of life, regardless of prior test results. Protein intake is not required prior to screening for CH.

False negatives can also occur with screening. When only T_4 testing is done, as many as 8% of infants with central CH can be missed (Kim et al., 2018). Their initial T_4 levels are in the normal

range (Kim et al., 2018). A similar problem can occur with infants who have hypothyroxinemia with delayed TSH elevation and those with residual thyroid tissue (such as an ectopic thyroid gland), because their initial T_4 levels are also in the normal range. All of these infants would be detected by repeat screening at 2 to 6 weeks of age.

Certain infants are at risk for a missed or delayed diagnosis, including those born at home, those who are extremely ill in the neonatal period, and those who are transferred between hospitals at an early age. Screening errors, including incorrect specimen collection, or improper storage and transport can result in a false negative test. Thyroid medications taken by the mother during pregnancy can also produce false negative results. Blood transfusions can alter test results. Preservatives (EDTA or citrate) in blood-collection containers can result in false negative or false positive screening results.

When a low T_4 and elevated TSH level (>40 mU/L) are encountered, the neonate should be presumed to have primary hypothyroidism until proven otherwise. A thorough examination for signs and symptoms of CH is indicated, along with confirmatory serum testing. Treatment with L-thyroxine should be initiated while awaiting the results of further testing.

Laboratory Testing. Low serum total and free T_4 and T_3, along with elevated TSH levels, confirm CH in the neonate. Permanent congenital CH is highly likely in a full-term neonate with a serum T_4 less than 6 mcg/dL and a serum TSH greater than 50 mU/L. A normal T_4 (e.g., >10 mcg/dL) in combination with elevated TSH suggests that the infant has enough functional thyroid tissue to respond to excess TSH stimulation, the pattern seen in a subgroup of infants with compensated or subclinical hypothyroidism. Age-related reference norms, for both gestational age and hours of age, should be used when interpreting all thyroid test results. If maternal antibody-mediated hypothyroidism is suspected, maternal antithyroid (TSH receptor–blocking, TRBAb) antibody testing should be done. Other thyroid autoantibodies that can produce hypothyroidism include thyroglobulin (TGAb) and thyroid peroxidase antibodies (TPOAb). TBG levels can be measured to rule out TBG deficiency. Thyroglobulin levels in infants with possible CH can help to differentiate between thyroid agenesis and dyshormonogenesis, as an adjunct to thyroid imaging. Genetic studies have already helped to identify the etiology of CH in some infants.

Imaging Studies. Infants with biochemical evidence of CH usually undergo scintigraphy with iodine-123 (^{123}I) or pertechnetate ($^{99m}TcO_4$), which is trapped by the thyroid gland and like iodine (Polak et al., 2017) aids in detection of an ectopic (lingual or sublingual) or missing gland. A normal or enlarged gland suggests a defect in thyroxine synthesis as the source of CH. Thyroid ultrasound can also be useful initially to demonstrate presence or absence of a gland. Lateral radiographs of the knee and foot reveal bone age, indicating the degree of intrauterine hypothyroidism experienced by the fetus. Ossification of the distal femoral epiphysis usually appears at 36 weeks gestation; its absence in a term or post term infant suggests delayed bone maturation from long-standing hypothyroidism.

Management of Hypothyroidism

Early, adequate treatment of permanent CH is critical for optimal neurologic development. The goal of hormone replacement therapy is to rapidly normalize the infant's serum T_4 level and maintain it in the upper half of the normal range, which should result in a TSH of 0.5 to 4 mU/L (Kim et al., 2018). The agent of choice is sodium-L-thyroxine (NaT_4) because it is substantially converted to T_3 within the brain. Tablets are crushed and given in a small amount of liquid. One method is to instruct parents to crush the tablet and place it on the baby's tongue just before feeding (Polak et al., 2017). The tablet should not be diluted in the entire volume of the baby's bottle because if the bottle is not finished, the baby will not receive the full dose needed. Parents should be counseled about the importance of consistent administration of the medication, and instructed on actions to take if a dose is missed or the infant vomits after a dose is given.

Infants receiving thyroid replacement therapy must be monitored closely for adequacy of treatment and evidence of thyrotoxicosis (irritability, tachycardia, poor weight gain). Serum T_4 should normalize in 1 to 2 weeks; serum TSH can take longer to normalize.

TRANSIENT DISORDERS OF THYROID FUNCTION

Transient Hypothyroxinemia of Prematurity

Preterm infants have the same incidence of permanent CH as full-term infants (Srinivasan, Harigopal, Turner, & Cheetham, 2012). In addition, about 50% of infants born at less than 30 weeks gestation exhibit transiently low thyroxine levels when compared with their full-term counterparts. This relative hypothyroxinemia is primarily a function of HPT axis immaturity, a physiologically normal stage of thyroid system development. However, many other factors influence thyroid function, particularly in the extremely preterm infant (Hyman, Novoa, & Holzman, 2011). The abrupt cessation of maternal T_4 supply, occurring at the time of birth when demand for thyroid hormone is high, contributes to low thyroid hormone levels. Other factors include immature ability to concentrate iodine and to synthesize and iodinate thyroglobulin. Preterm infants may also suffer from insufficient iodine intake during the early weeks after birth before full enteral feeding is established. In addition, iodine excess related to the use of iodine-containing antiseptics and radiopaque agents can interfere with thyroid function by blocking thyroid hormone release from the thyroid gland.

Pathophysiology. The postnatal TSH surge of the preterm infant is similar, yet quantitatively lower, than that of the more mature infant. Likewise, the corresponding rise in T_4 that occurs in preterm infants is blunted in comparison to term infants. It takes approximately 4 to 8 weeks, depending on the gestational age at birth, for normal term hormone levels to be reached. The more premature the infant, the more severe the hypothyroxinemia is. Infants with transiently low thyroxine need follow-up testing to ensure that the low T_4 levels rise into the normal range over time.

Extremely preterm infants (24–27 weeks gestation) are at an even greater disadvantage, having a distinct and more ineffective pattern of postnatal thyroid function. The TSH surge of these very immature infants is significantly attenuated, and TSH levels continue to fall after birth to less than cord blood values by 7 hours of age. Such very low TSH levels fail to stimulate a postnatal rise in T_4 at all. T_4 levels in extremely immature infants remain quite low after birth and are even slightly lower than cord blood values at 24 hours of age.

Clinical Manifestations. Hypothyroxinemia of prematurity is a subtle condition with no overt signs or symptoms of hypothyroidism. Many classic signs and symptoms of hypothyroidism are common clinical findings in the preterm infant (slow intestinal motility, distension, prolonged jaundice, low muscle tone, mottled skin, etc.). **Quality and Safety: Thyroid hormones are critical to brain development, so a prolonged low thyroxine level while the brain is still undeveloped could be a factor in poor neurocognitive outcomes in these infants.**

Diagnosis. Hypothyroxinemia of prematurity is identified by routine newborn screening. T_4 and free T_4 are low, but TSH is not elevated above the cutoff of 20 mU/L. This is the critical difference between transient hypothyroxinemia of prematurity and CH. A repeat test is conducted after several weeks to recheck T_4 and monitor for a possible delayed rise in TSH.

Management. The bothersome fact about hypothyroxinemia of prematurity is that it is associated with higher mortality and neurodevelopmental deficits, yet cumulative evidence to date has not been able to demonstrate clear benefits of routinely supplementing these infants with thyroxine during early life. It has been suggested that using a continuous dose of 4 mcg/kg/day, rather than a single daily supplement, would be a more physiologic way to raise thyroxine levels and maintain biologic euthyroidism in very low gestational age infants (La Gamma et al., 2009). However, long-term studies to show the neurocognitive benefit of this approach are lacking. A recent *Cochrane Database of Systematic Reviews* did not support the use of prophylactic thyroid hormones in preterm infants to reduce neonatal mortality and neonatal morbidity or improve neurodevelopmental outcomes (Osborn & Hunt, 2007). The exception is the infant with an elevated TSH level; these infants require treatment. Thyroid function tests should be followed carefully in preterm infants at risk for hypothyroxinemia, and treatment should be instituted promptly if indicated by elevated TSH. It is a good idea to flag or highlight the low thyroid results from the initial newborn screen to ensure that repeat thyroid testing is not overlooked.

However, we should not assume that just because studies to date have not been able to demonstrate the benefits of treating hypothyroxinemia of prematurity this condition is not significant. The persisting neurodevelopmental deficits in extremely low gestational age neonates could be, in part, related to their thyroid status during critical periods of CNS development (La Gamma & Paneth, 2012).

Nonthyroidal Illness

In some ill preterm infants, T_4 is preferentially converted to rT_3 instead of T_3, possibly as an adaptive response to lower the metabolic rate during times of severe illness. The outcome is low serum concentrations of both T_4 and T_3. Reverse T_3 is elevated and TSH is normal. This condition, also known as "low T_3 syndrome" or "euthyroid sick syndrome," occurs in infants who have immature lungs or infections, because the cytokines produced in response to illness or inflammation are believed to inhibit thyroid function, metabolism, or action (van Wassenaer & Kok, 2004). The low T_4 from nonthyroidal illness reverses spontaneously when the infant's condition improves. No treatment is required. Similar effects are seen in infants who are receiving dopamine or glucocorticoids, both of which can lower serum T_4 concentrations.

Transient Primary Hypothyroidism

Hypothyroidism is defined as transient when a low T_4 and elevated TSH in apparently healthy full-term infants revert to normal spontaneously or after several months of thyroxine supplementation. About 5% to 10% of the infants identified by newborn screening programs as having CH eventually are recognized as having a transient condition. Initial management is the same as for CH.

Transplacental Passage of Drugs or Antibodies

Transient hypothyroidism in the newborn can be precipitated by transplacental passage of antithyroid agents taken during pregnancy for the treatment of maternal Graves' disease. Medications such as propylthiouracil (PTU), methimazole, radioiodine, and amiodarone can inhibit fetal thyroid production. A similar inhibitory effect can occur if the fetus is exposed to excess iodine in utero. If the mother has a history of autoimmune thyroid disease, maternal TSH receptor–blocking antibodies (TRBAb, also termed thyrotropin binding inhibitor immunoglobulin, or TBII) readily cross the placenta and block the fetal thyroid, producing hypothyroidism. These TRBAbs can persist in the infant's circulation for 2 to 3 months after birth before they are completely metabolized and disappear. However, it can be difficult to predict the effects of these antibodies because some mothers will simultaneously produce TSH-receptor stimulating antibodies that will offset the effects of the TRBAbs.

Clinical Manifestations. Like CH, transient hypothyroidism is usually asymptomatic in the newborn. If present, the signs and symptoms are the same as for CH. Transient hypothyroidism caused by antithyroid drugs (goitrogens) can cause a goiter in the neonate. Iodine deficiency or excess has a similar effect.

Diagnosis. Transient hypothyroidism is typically detected by routine neonatal screening or is based on maternal history. The neonate displays the thyroid profile of low T_4 and elevated TSH that is characteristic of hypothyroidism. When the maternal history is positive for autoimmune thyroid disease, thyroid stimulating hormone antibodies (TRSAb) and TRSAb levels (as indicated) are also obtained for baseline purposes. Thyroid imaging tests may also be conducted.

Management. Transient hypothyroidism caused by maternal antithyroid medication will resolve spontaneously when the medication is cleared from the infant's circulation, usually within a day or two after birth. The infant's serum T_4 and TSH should be monitored to ensure that they return to normal. Supplementation with L-thyroxine is not usually necessary. Transplacentally acquired TSH receptor–blocking antibodies can be slow to degrade completely; therefore, most infants will require supplementation for several months. TRBAb levels in the infant can be monitored to determine when to discontinue therapy. Breastfeeding is not contraindicated in neonates whose mothers continue their antithyroid medication in the postpartum period, as very little passes into the breast milk.

Hyperthyroidism (Neonatal Graves' Disease)

Pathophysiology. The transient condition neonatal Graves' disease occurs in infants born to mothers with active or inactive Graves' disease, to those who have undergone thyroidectomy or radioiodine ablation of the thyroid gland, and to women taking antithyroid drugs. Maternal TRSAbs cross the placenta readily and stimulate the fetal thyroid gland, causing an overproduction of thyroid hormone and, in some cases, development of a goiter. Usually the higher the TRSAb level in the mother, the more severely affected the infant will be. Hyperthyroidism in the neonate is typically transient, lasting approximately 3 to 12 weeks. The clinical course varies depending on characteristics of the mother's disease and treatment. The onset of hyperthyroidism may be delayed for a week or longer in neonates whose mothers produce not only TRSAb but TSH receptor–blocking antibodies as well. Similarly, if the mother took antithyroid medication during pregnancy, the neonate might not exhibit evidence of hyperthyroidism for several days until the drugs are metabolized (and, in fact, some infants are hypothyroid during that time). Occasionally, the hyperthyroidism persists beyond the expected recovery period and becomes true, permanent Graves' disease.

Clinical Manifestations. Neonates may be born preterm, often with evidence of intrauterine growth restriction. Common clinical signs of thyrotoxicosis include tachycardia, arrhythmias, hypertension,

FIGURE 10.2 Newborn infant presenting at birth with goiter.

tachypnea, poor feeding, vomiting, sweating, hyperthermia, flushing, diarrhea, restlessness, tremors, irritability, and hyperalertness. In severe cases of untreated maternal Graves' disease, advanced bone age, craniosynostosis, and microcephaly are evident in both the fetus and newborn. The infant should be examined for a goiter, which can be very small or large enough to compress the trachea and cause respiratory distress in the newborn. A goiter is a symmetrical, smooth enlargement of the gland and can be recognized as a swelling in the anterior neck of the neonate (Figure 10.2). To examine the neonate for goiter, place the infant supine and elevate the trunk while allowing the head to fall back gently (Escobar, Viswanathan, & Witchel, 2018). It is important to appreciate that a goiter can increase in size during the early neonatal period.

Diagnosis. Serum T_4, free T_4, and T_3 are elevated, and serum TSH is low, all relative to age-appropriate norms. A TRSAb titer in the neonate will give an indication of the expected severity of the disease course. **Emergency Alert: Infants at risk (e.g., high maternal titer of TRSAb) for severe thyrotoxicosis require frequent monitoring of free T_4 and TSH.** A good maternal history is essential (e.g., history of radioablation therapy, antithyroid drugs taken during pregnancy and when they were taken, and maternal symptoms, if any).

Management. The mainstays of treatment of hyperthyroidism in the neonate are iodine, antithyroid medication, sedation, and beta-adrenergic blockers, if needed. Treatment is tailored to the severity of the infant's symptoms. Lugol's iodine solution (potassium iodide), given in a single drop three times daily, acutely inhibits the release of thyroxine from the thyroid gland. Other preparations include iodine-based contrast agents (ipodate), PTU, and methimazole. Propranolol can be used to manage cardiovascular symptoms. The infant's serum T_4 must be followed closely during treatment for possible iatrogenic hypothyroidism. TRSAb levels are also followed to monitor the infant's recovery and aid in determining the appropriate time for weaning antithyroid medication.

ADRENAL GLAND

The highly vascular adrenal glands are located at the superior poles of the kidneys. Each gland is composed of two distinct, independently functioning organs: the outer cortex, which produces steroid hormones (mineralocorticoids, glucocorticoids, and androgens), and the inner medulla, which produces catecholamines. Adrenal steroid production and regulation require a functional HPA axis. Cortisol is also released in response to stress, hypoglycemia, surgery, extreme heat or cold, hypoxia, infection, or injury.

Aldosterone, the most important mineralocorticoid, regulates renal sodium and water retention and potassium excretion. Aldosterone influences not only electrolyte balance but blood pressure and intravascular volume as well. Aldosterone is regulated by the plasma renin-angiotensin system.

Adrenal androgens include dehydroepiandrosterone (DHEA), DHEA sulfate, and androstenedione and are regulated by ACTH. These steroids have minimal androgenic activity but are converted in the peripheral tissues to two more potent androgens, testosterone and dihydrotestosterone (DHT), required for normal sexual differentiation.

FETAL ADRENAL GLAND

The fetal adrenal gland is evident from 6 to 8 weeks gestation and rapidly increases in size. Fetal cortisol is secreted at 8 weeks gestation. Early in gestation, the fetal adrenal cortex differentiates into three regions: an inner prominent fetal zone, an outer definitive zone, and a transitional zone. After birth, the fetal zone involutes and the definitive zone is transformed into the mature gland. Cortisol maintains intrauterine homeostasis and influences the development of a wide variety of fetal tissues. Cortisol is essential for prenatal maturation of organ systems, including lungs, GI tract, liver, and the CNS, which are vital for neonatal survival.

The fetal adrenal gland and the placenta are an integrated endocrine system known as the fetoplacental unit. The fetal zone of the developing adrenal gland produces DHEA and DHEA sulfate, precursors for placental estrogen, which is critical to maintenance of the pregnancy and fetal well-being. In turn, the placenta regulates fetal exposure to maternal cortisol by oxidizing cortisol to the biologically inactive cortisone, protecting the fetus from excessive cortisol levels. The placenta also releases corticotropin-releasing hormone (CRH), which heightens activity of the fetal HPA axis and stimulates fetal cortisol production. All of this contributes to the prenatal cortisol surge that prepares the fetus for the stress of birth and adaptation to the extrauterine environment.

NEONATAL ADRENOCORTICAL FUNCTION

Plasma cortisol levels are elevated at the time of birth but decline in the first few days of life. In term infants, a nadir is seen on day 4 of life. Likewise, levels of cortisol precursors such as 17-hydroxyprogesterone (17-OHP) are high at birth but decrease to normal neonatal levels by 12 to 24 hours of age. Cortisol is regulated by pituitary ACTH, which in turn is controlled by hypothalamic CRH via a negative feedback loop. Cortisol in the newborn plays a key role in response to stress and illness, and is important in the maintenance of blood pressure (Ng, 2011).

Aldosterone and plasma renin activity (PRA) are elevated in neonates compared with values for older infants, allowing for positive sodium balance until the kidneys fully mature. The hyponatremia and urinary sodium losses often seen in preterm infants during the early postnatal weeks are due to a relative mineralocorticoid deficiency as a consequence of immaturity of both the kidneys and the adrenal glands.

ADRENAL DISORDERS IN THE NEONATE

Transient Adrenocortical Insufficiency of Prematurity

A limited ability of the adrenal glands to maintain cortisol homeostasis in the early days of life has been observed in some preterm newborns. Manifestations are a low serum cortisol,

normal or exaggerated pituitary response, and good recovery of adrenal function by day 14 of life (Ng, 2011). A proportion of very-low-birth-weight infants with inotrope and volume-resistant hypotension show an inadequate adrenal response to stress in the immediate postnatal period (Ng, 2011). Whether a relative adrenal insufficiency contributes to hemodynamic instability and hypotension in critically ill infants is still under debate (Fechner, 2018).

Adrenal Hemorrhage

Adrenal hemorrhage in the neonate can be precipitated by traumatic delivery, breech presentation, macrosomia, or disseminated intravascular coagulation. The large size and vascularity of the fetal adrenal gland predisposes the gland to injury and rupture during the birth process. Although it is often asymptomatic, classic findings include jaundice, pallor, or a flank mass on either side (although hemorrhage is more common on the right), with discoloration and purpura of the overlying skin and discoloration of the scrotum (Mutlu, Karagüzel, Aslan, Cansu, & Ökten, 2011). In severe cases, the infant may exhibit signs of adrenal insufficiency. Small hemorrhages can be initially undetected, but eventually manifest in anemia and persistent jaundice (Askenazi, Selewski, Willig, & Warady, 2018). Adrenal hemorrhage can be visualized on ultrasound and usually resolves in 4 to 16 weeks (Mutlu et al., 2011).

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is a spectrum of autosomal recessive disorders resulting from a deficiency of one of the five enzymes required to synthesize cortisol from cholesterol in the adrenal cortex. Each enzyme is encoded by its own gene, and mutations in the 21-hydroxylase (21-OHD) gene, *CYP21A2*, are the most frequent. To date, 127 different mutations of *CYP2A12* have been described, ranging from complete loss of enzyme function to partial enzyme activity (Witchell & Azziz, 2011). The severity of the disease correlates with *CYP21A2* allelic variation (Speiser et al., 2010). 21-OHD deficiency accounts for 95% of CAH and is the most common cause of ambiguous genitalia of the neonate.

Pathophysiology. A lack of 21-OHD prevents conversion of progesterone to its two end products: cortisol and aldosterone (Figure 10.3). By reduced negative feedback regulation, the absence of cortisol causes oversecretion of ACTH, which chronically stimulates the adrenal cortex, resulting in hyperplasia of the gland. The precursor steroids proximal to the blocked step accumulate and are shunted into other metabolic pathways such as androgen biosynthesis. In a female fetus, these superfluous yet potent systemic androgens cause virilization of the developing external genitalia. Also, the effects of this androgen exposure on the developing CNS may be important. Internal reproductive organs (ovaries, fallopian tubes, and uterus) are not affected by androgen exposure and develop normally.

Classic 21-OHD has a worldwide incidence of about 1 in 5,000 to 1 in 15,000 live births (Witchell & Azziz, 2011). Two-thirds of those have a severe form known as salt-wasting or salt-losing in which there is a concurrent inability to produce aldosterone. High sodium excretion leads to profound hyponatremia, dehydration, and hyperkalemia. Glucocorticoid deficiency impairs carbohydrate metabolism, resulting in hypoglycemia and leading to hypotension, shock, and cardiovascular collapse from adrenal insufficiency. The remaining one-third has a simple virilizing form. These infants have an incomplete enzymatic block, with enough aldosterone biosynthesis to maintain fluid and electrolyte homeostasis.

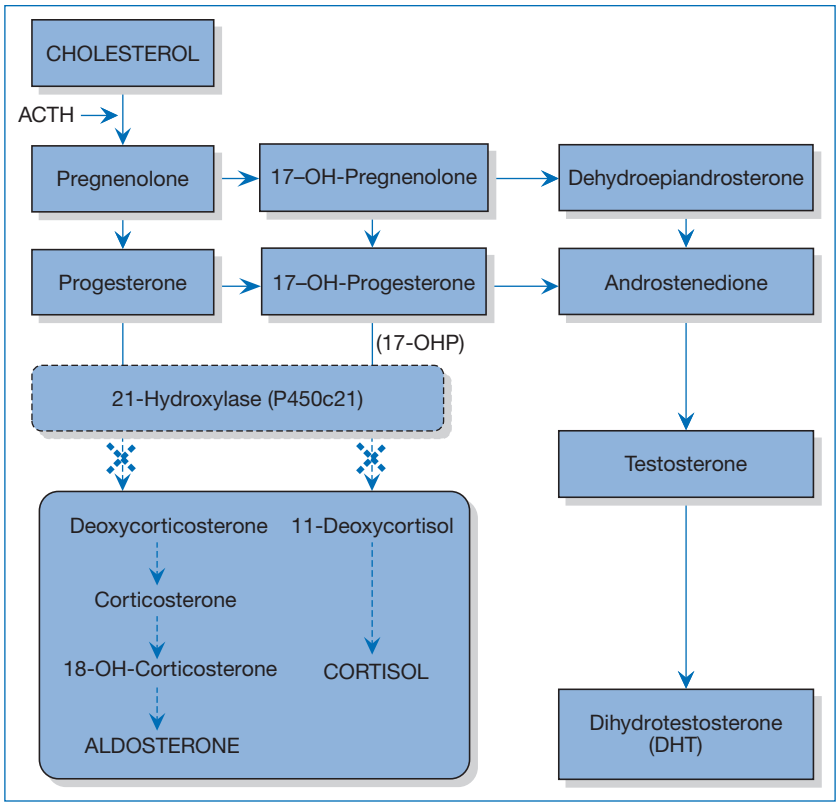

FIGURE 10.3 Pathophysiology of congenital adrenal hyperplasia caused by 21-hydroxylase (21-OHD) deficiency. A deficiency of the enzyme 21-OHD prevents the normal conversion of cholesterol to aldosterone and cortisol. Precursor steroids including 17-hydroxyprogesterone (17-OHP) proximal to the blocked step are shunted into the androgen synthesis pathway, resulting in an excess production of androgens.

ACTH, adrenocorticotropic hormone.

Clinical Manifestations. Affected female infants are usually recognized at birth by their nontypical genitals, a cardinal feature of CAH. A range of findings is possible, including clitoromegaly, posterior fusion of the labia majora with rugae, and a single perineal orifice instead of separate urethral and vaginal openings (Witchel & Azziz, 2011). In the last instance, the vagina joins the urethra above the perineum, forming a single urogenital. In severe cases, clitoral hypertrophy is so marked that it resembles a penile urethra (Figure 10.4). These infants can be mistaken for boys with bilateral cryptorchidism and hypospadias. There may also be hyperpigmentation of the genital skin resulting from excessive pituitary ACTH secretion. Male infants with 21-OHD are phenotypically normal and may not be identified in the immediate neonatal period, because the onset of adrenal symptoms is delayed until 7 to 14 days of life. Undetected infants may present to the emergency room with signs and symptoms of impending adrenal collapse: vomiting, weight loss, lethargy, dehydration, hyponatremia, hyperkalemia, hypoglycemia, hypovolemia, and shock. Infants of either sex who are untreated will undergo rapid postnatal growth and sexual precocity; those with severe enzyme deficiencies can develop salt loss and die (Speiser et al., 2010).

Diagnosis. A markedly elevated 17-OHP level is diagnostic for classic 21-OHD deficiency. Random 17-OHP levels in affected infants can reach 10,000 ng/dL (normal is <100 ng/dL). However, such high 17-OHP levels may not be reached until the second or third day of life, so a specimen drawn too early could lead to false reassurance that the infant does not have CAH. Prenatal or postnatal steroids can suppress the 17-OHP level and produce a false negative result as well. Biochemical support for the diagnosis of CAH also includes elevated serum DHEA and androstenedione levels in males and females, and elevated serum testosterone in females. Molecular genetic analysis is not usually essential for the diagnosis but may be helpful to confirm the exact type of defect and to aid in genetic counseling.

Part of the evaluation of every newborn with ambiguous genitalia is a karyotype or FISH test for sex chromosome material, and this is also true when the suspected diagnosis is CAH. Imaging studies, including pelvic and abdominal ultrasound, will determine the presence or absence of a uterus, evaluate adrenal size, and more rapidly identify the gender of the infant.

The increased serum 17-OHP levels in affected infants permit screening for the disorder using blood filter specimens on routine newborn screening panels. **Quality and Safety: The major objectives of newborn screening for CAH are the presymptomatic identification of infants at risk for the development of life-threatening adrenal crises and prevention of incorrect sex assignment of affected female infants with ambiguous genitalia.** The former is particularly important for affected boys whose initial manifestation may be adrenal crisis. All 50 states now screen newborns for CAH. False positives occur in about 1% of all tests, and can also occur in preterm infants or sick infants, both of whom have higher levels of 17-OHP (Speiser et al., 2010). The higher 17-OHP concentrations of preterm infants, sick infants, and heterozygotic carriers can overlap the levels typical of babies with nonclassic CAH (Witchel & Azziz, 2011).

Management. The newborn with CAH requires urgent expert medical attention. When the diagnosis of CAH is confirmed, physiologic replacement dosing of cortisol is initiated to overcome cortisol deficiency and to suppress ACTH and androgen overproduction, without completely suppressing the HPA axis (Pass & Neto, 2011). Aldosterone replacement maintains fluid and electrolyte homeostasis. Agents of choice in the newborn are hydrocortisone, a glucocorticoid, plus fludrocortisone, a mineralocorticoid. Further clinical management is guided by daily

checking weight, adrenal steroid concentration, PRA, electrolytes, blood glucose, and other data. PRA should be compared against age-specific norms, because basal PRA is higher in the newborn than in older infants. Dietary sodium chloride supplementation is often necessary.

Most 46XX individuals with CAH develop a female gender identity, regardless of the degree of genital virilization present at birth, according to currently available evidence (Houk & Lee, 2012). Therefore, even in cases where babies are initially "misassigned" as boys, it is still generally recommended that these genetic females with CAH be raised as females (Brown & Warne, 2005), although some experts maintain that in extensively virilized infants, a male sex assignment should be considered (Houk & Lee, 2012). Hypertrophy of the clitoris will gradually abate with medical therapy; however, severe virilization will not be reversed. Parents of virilized female infants may have many questions about possible genital surgery. Although such surgery is not usually performed until the infant is 2 to 6 months of age, it is helpful for the parents to meet with the pediatric endocrinologist and pediatric urologic surgeon during the initial hospitalization or shortly afterward to discuss available options, one of which is to delay surgery performed for cosmetic purposes until the child is old enough to participate in the decision (Auchus et al., 2010; Intersex Society of North America [ISNA], 2006). The goals of genital surgery for virilized girls with CAH are to achieve genital appearance compatible with gender, unobstructed urinary emptying without incontinence or infections, and good adult sexual and reproductive function. After discharge, infants with CAH must be closely followed by a pediatric endocrinologist for assessments of hormone levels, blood sugar, blood pressure, growth, skeletal maturation, and other parameters necessary to guard against over- or undertreatment.

Some authorities now use the term *disorder of sex development* or *DSD related to physical changes in genitalia,* or the older term, *ambiguous genitalia,* discussed in the next section (Houk, Baskin, & Levitsky, 2019). Whether to force a specific sexual identification early is still hotly debated and often results in ethical considerations—especially the wishes of the family.

GENITALIA

Sexual Development in the Fetus

Sexual differentiation is a sequential process with three stages: (a) fertilization (determination of chromosomal sex), (b) gonadal differentiation, and (c) differentiation of phenotypic sex (internal ductal system and external genitalia; Shnorhavorian & Fechner, 2018).

At the time of conception, the sex chromosome complement of the fertilizing sperm determines the chromosomal sex.

The following events are directed by genes. During the early weeks of development, all embryos have bipotential gonads and structures for both male and female internal and external genitalia. Male-specific development requires the expression of the testis-determining gene (*SRY*) located on the short arm of the Y chromosome. This directs the gonad to differentiate to a testis, the key event in sex determination, by downstream regulation of sex-determining factors (Öçal, 2011).

Numerous other genes are required for normal gonadal development, and mutations in many of these genes (such as *SRY, WT1, SOX9, DAX-1, DMRT1,* and *SF1*) are the source of identified syndromes of gonadal dysgenesis, such as Swyer syndrome, Denys–Drash syndrome, campomelic dysplasia, dosage-sensitive sex reversal, and gonadal dysgenesis. It was formerly believed that the ovary developed as a "default" gonad (in the absence of genes for testis development), but we now know that specific genes are necessary for normal ovarian differentiation (Shnorhavorian & Fechner, 2018).

Internal Genitalia

The next events in sexual development are hormonally mediated, predicated on the established gonadal sex (Shnorhavorian & Fechner, 2018). By 7 weeks gestation, the fetus has two sets of primitive ducts that will become the internal reproductive tracts: the Müllerian (female) and Wolffian (male). In the XY fetus, the testis differentiates by the end of week 7. The embryonic testis develops two types of hormone-producing cells: the Sertoli and the Leydig cells. The Sertoli cells begin secreting Müllerian-inhibiting factor (MIF), causing the Müllerian ducts to regress. By the ninth week, testicular Leydig cells are secreting the androgens necessary for further virilization of the male fetus.

Testosterone, the major androgen produced by the testes, acts locally in high concentrations to induce development of the Wolffian ducts into the epididymis, vas deferens, and seminal vesicles. In the absence of testosterone, the Wolffian ducts regress at 11 weeks gestation. Müllerian ducts require no ovarian hormonal inducement to develop into fallopian tubes, uterus, and upper vagina. This occurs in fetuses with a normal ovary or on any side lacking a gonad.

External Genitalia

The primitive external genital structures are identical in both sexes (Figure 10.5). In this indifferent stage, a genital tubercle forms and elongates to form a phallus and urogenital sinus, surrounded by inner urogenital folds and labioscrotal swellings. Between the 8th and 14th weeks of gestation, male differentiation of the external genitalia takes place. Central to this development is availability of

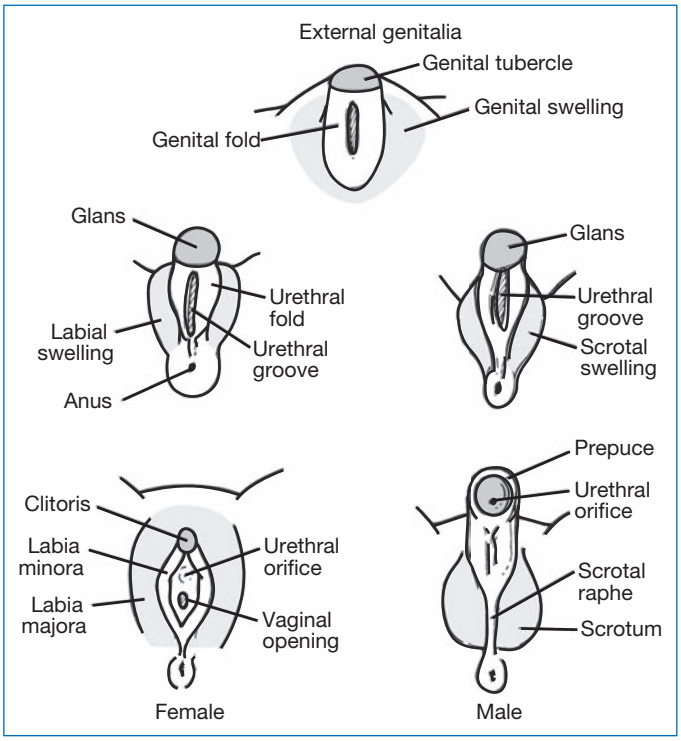

FIGURE 10.5 Development of the external genitalia.

DHT, a potent metabolite produced from testosterone by the enzyme 5 alpha-reductase-2 (5-ARD-2). With ten times the binding affinity of testosterone, DHT binds to androgen receptors in the genital tissues, stimulating fusion of the urethral folds to form the penile shaft, and the labioscrotal swellings to form the scrotum. The urogenital sinus becomes the urethra. Penile growth continues throughout gestation, and migration of the testes from the abdominal cavity to the scrotum is a late event, at 25 to 35 weeks gestation. Androgen exposure after about 14 weeks contributes to further phallic enlargement (Shnorhavorian & Fechner, 2018).

In the absence of DHT, feminization of the external genitalia occurs. The phallus becomes a clitoris, and the labioscrotal swellings remain unfused to form the labia majora and minora. The urogenital sinus develops into the lower vagina and urethra. Feminine external genital development is complete by 11 weeks of gestation. Androgen exposure after this critical period can promote growth of the clitoris but does not cause labial fusion or the development of a penile urethra (Shnorhavorian & Fechner, 2018).

GENERAL PRINCIPLES OF MANAGEMENT OF DISORDERS OF SEXUAL DEVELOPMENT

The fact that doctors and nurses are not quite sure if one's long-awaited newborn baby is a boy or a girl must surely be one of the most incomprehensible things that parents can hear in the delivery room. This situation requires a high degree of sensitivity and tact. Many infants are identified prenatally following ultrasound recognition of genital ambiguity or a karyotype/phenotype discordance, and these families will be prepared, to some degree, for the experience of having a baby of uncertain sex. Others will be taken completely by surprise. In spite of the family's desire for a quick answer, no attempt should be made by medical professionals at the time of birth to guess the sex of the baby (Ogilvy-Stuart & Brain, 2004). The extreme phenotypic heterogeneity seen in DSDs makes it impossible to accurately predict either the diagnosis or the karyotype from a brief genital examination (Houk & Lee, 2005). Neonates who do not have health concerns requiring intensive care monitoring or treatment should not be transferred to the NICU. Admission to the NICU heightens the parents' anxiety unnecessarily and impairs parent–infant bonding (ISNA, 2006).

The Lawson Wilkins Pediatric Society and the European Society for Paediatric Endocrinology recently established an International Consensus Conference on Intersex. The result was a consensus statement on management of DSDs (Lee, Houk, Ahmed, & Hughes, 2006). That document represents the first agreed-on set of guiding principles for approaching and managing the newborn with a DSD.

Clinical Manifestations. Essential to the evaluation of the neonate with genital ambiguity is obtaining a detailed family history. Any of the following might suggest a congenital or inherited DSD: maternal virilization or ingestion of hormones or oral contraceptives during pregnancy; consanguinity; history of urologic abnormalities, infertility, or genital ambiguity in other family members; or previous neonatal deaths that might suggest an undiagnosed adrenal crisis. Dysmorphic features suggest the possibility of a syndrome.

A detailed assessment of the genitalia should be conducted. This and all subsequent examinations should respect the privacy of the infant and the family as much as possible, avoiding overexposure of the infant even for educational purposes (Auchus et al., 2010). Because of considerable overlap in the genital anatomy among DSDs, the physical assessment alone does not permit a firm diagnosis (Shnorhavorian & Fechner, 2018). However, some assessment findings can provide clues to the underlying pathophysiology and guide the diagnostic process in one direction or another. A precise description of the anatomy is more useful than simply staging classifications. If preferred, however, the degree of virilization can be documented by Prader staging from a phenotypic female with mild clitoromegaly (Prader stage II) to phenotypic male with glandular hypospadias (Prader stage V; Figure 10.6). Look for symmetry or asymmetry of the genitalia, which provides an important clue. The presence of a uterus can be determined by digital rectal examination as an anterior midline cordlike structure.

Gonads. Determine whether gonads are palpable. The presence or absence of palpable gonads helps to differentiate the major categories of DSDs. An apparent male infant with bilateral or a single impalpable testis with hypospadias should be considered as having a potential DSD until proven otherwise. A palpable gonad excludes the diagnosis of virilized genetic female (46XX) with CAH. A gonad palpated below the external inguinal ring is presumed to contain testicular tissue. Because ovaries are rarely palpable, a unilateral gonad is usually a testis or occasionally an ovotestis. To palpate testes, place fingers flat from the internal ring and milk down into the labioscrotal folds. Gonads may be situated high in the inguinal canal, requiring a careful examination. Sweep the fingers down along the line of the inguinal canal on each side, beginning well above the site of the internal inguinal ring. A gonad milked down by this maneuver is gently grasped by the other hand and its size and consistency are noted. Ovotestes are softer and

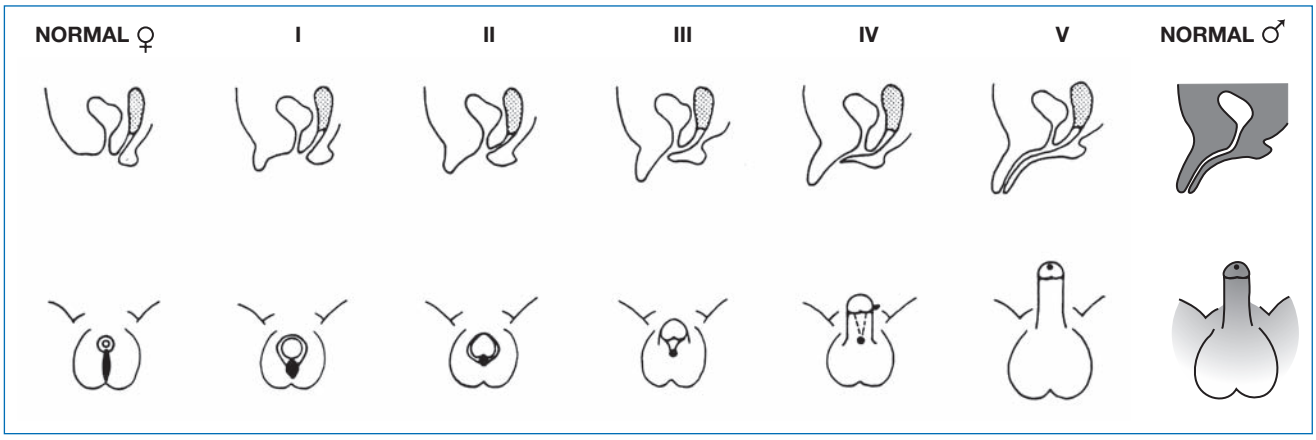

FIGURE 10.6 Degrees of genital virilization according to the stages of Prader. The upper panel shows sagittal view and the lower panel shows perineal view.

less homogeneous than testes (Brown & Warne, 2005). Bilateral absence of the testes is known as cryptorchidism.

Phallus. Phallic size should be measured with a straight-edge ruler, depressing the fat pad and measuring the stretched length from pubic tubercle to tip of penis, not including the foreskin. Both length and mid-shaft diameter of the penis should be noted. Chordee, ventral curvature of the penis caused by residual urethral tissue that tethers the phallus to the perineum, should be noted because it can reduce the apparent length of the penis (Shnorhavorian & Fechner, 2018). The actual position of the urethral meatus and the severity of hypospadias, if present, should be determined.

Clitoral size should also be measured when clitoromegaly is present. Clitoral length greater than 9 mm in term infants is considered excessive. Clitoral size often appears large in preterm infants because breadth remains constant from 27 weeks onward. A prominent, but not truly enlarged, clitoris, or a normally sized penis concealed by an abundance of prepubic fat are two normal assessment findings that sometimes prompt referrals for genital ambiguity (Houk & Lee, 2005).

Labioscrotal Folds. Labial fullness, a benign finding, is another feature occasionally mistaken for genital ambiguity. The labioscrotal folds are examined for fusion, which starts posteriorly and moves anteriorly, increasing the anogenital distance. The perineum is inspected by gently separating the labia and using an exam light to confirm the presence of separate urethral and vaginal openings or a single urogenital orifice (an opening connected to both urinary and genital systems). Visualization of voiding is helpful. If skin tags with slightly bluish hue are seen, a hymen and vagina are present. Note rugosity or hyperpigmentation of the labioscrotal fold, signifying hypersecretion of ACTH associated with CAH. Other variations include a bifid scrotum (a deep midline cleft) or a shawl scrotum (scrotum surrounds the penis like a shawl).

Diagnostic Studies. DSDs are diagnosed with a combination of biochemical, hormonal, imaging, and molecular testing. Many diagnostic algorithms have been published, but no single algorithm is perfect for all circumstances (Lee et al., 2006). The principal aim of an initial investigation is to rule out a life-threatening illness such as CAH, which can precipitate an adrenal crisis. Such testing includes serum 17-OHP level (after 24–48 hours of age), electrolytes, glucose, baseline levels of testosterone, DHT, and other steroid precursors (progesterone, DHEA, delta 4-androstenedione, and 17 alpha-hydroxypregnenolone). A karyotype with X- and Y-specific probe detection is obtained from all infants, even if a prenatal karyotype is available (Allen, 2009).

A urinary steroid profile is helpful in the diagnosis of disorders of steroid biosynthesis. Other investigations that may be warranted include ACTH stimulation test, PRA, and serum MIF, LH, and FSH. An hCG stimulation test is undertaken to delineate a block in testosterone biosynthesis from androstenedione (17 beta-hydroxysteroid dehydrogenase deficiency) or conversion of testosterone to DHT (5 alpha-reductase deficiency). An hCG test involves measuring baseline levels of testosterone and its precursors DHEA or DHEA sulfate and androstenedione and its metabolite DHT. One to three intramuscular injections of high-dose hCG are given at 24-hour intervals, and repeat testosterone levels are drawn at 72 or 24 hours after the last injection (Ogilvy-Stuart & Brain, 2004).

Imaging studies include abdominopelvic ultrasound (to determine the presence or absence of a uterus, to visualize the presence or absence of gonads in the inguinal region, and to assess the Müllerian anatomy), genitourethrogram (to delineate the anatomy of the vagina and urethra, and where the vagina opens into the urogenital sinus), and pelvic MRI. Laparoscopic exploration with gonadal biopsy may be necessary to evaluate gonadal histology. Finally, molecular analysis may be required to arrive at a definitive diagnosis for some disorders, although molecular diagnosis continues to be limited by cost, accessibility, and quality control (Lee et al., 2006).

Interpretation of Findings. The most common cause of genital ambiguity in the newborn is 21-OHD deficiency. This form of CAH, responsible for over 90% of cases of ambiguous genitalia, presents with a virilized XX (female) infant and should be suspected in the presence of a virilized infant with a uterus and no palpable gonads (Öçal, 2011).

Among the remainder of cases of ambiguous genitalia, the most common diagnoses are gonadal dysgenesis, followed by partial androgen insensitivity syndrome (PAIS) and testosterone biosynthetic disorders. Symmetrical external genitalia, with or without palpable gonads, and no uterus, suggests an undervirilized male (Öçal, 2011). A micropenis should prompt investigation for hypopituitarism or growth hormone deficiency, particularly in the presence of hypoglycemia (Shnorhavorian & Fechner, 2018).

It is not always possible to reach a diagnosis in the undervirilized male infant. In a study of 67 XY infants with external sexual ambiguity, testicular tissue, and/or an XY karyotype, in 52% of cases, no diagnosis could be reached, despite an exhaustive clinical and laboratory workup, including sequencing of the androgen receptor (Morel et al., 2002). Provisional diagnostic groupings can be determined based on the presence or absence of a uterus, symmetry of the external genitalia, and presence of gonads (Table 10.1), providing a basis for more focused additional investigations (Brown & Warne, 2005).

Talking With Families. Optimal care of the infant with a DSD involves a well-coordinated team approach. The team comprises at minimum the attending neonatologist, neonatal nurse, endocrinologist, pediatric surgeon/pediatric urologic surgeon, social worker, counselor or other mental health professional, and, in some instances, geneticist. The initial contact with parents of

TABLE 10.1

DIAGNOSTIC GROUPING SUGGESTED BY ASSESSMENT FINDINGS

Diagnostic Grouping	Assessment Finding		
	Uterus	Gonads	External Genitalia
CAH (21-OHD) virilized female	Present	Not palpable	Symmetrical hyperpigmented
Undervirilized male (PAIS or testosterone biosynthetic defect)	Absent	Palpable	Symmetrical
Gonadal dysgenesis (with Y chromosome) ovotesticular DSD	Present	Palpable	Asymmetrical

21-OHD, 21-hydroxylase; CAH, congenital adrenal hyperplasia; DSD, disorder of sex development; PAIS, partial androgen insensitivity syndrome.

a newborn with a DSD is extremely important. This interaction should emphasize that a DSD is not a shameful condition and does not preclude the child from becoming a well-adjusted, functional adult, who can be expected to lead a fulfilling life (Houk & Lee, 2012). A single person should be identified to communicate diagnostic findings and plans with the family. When discussing possible diagnoses with the family, language must be carefully chosen. The terms *hermaphrodite* and *pseudohermaphrodite* are outdated, confusing, and perceived as distasteful by many (Lee et al., 2006). These words should not be used, and instead, accurate, informative terms that describe the infant's diagnosis should be used. A clear explanation of sexual development in the fetus will help parents understand how an infant can be born with atypical genitalia, an important component of parental coping (Houk & Lee, 2005). It is helpful to explain that the appearance of the external genitalia is determined by prenatal androgen exposure, and not the molecular sex (Witchel & Azziz, 2011).

It is the parents who have the responsibility to make or defer decisions about care for their infant with a DSD, including gender-of-rearing (Houk & Lee, 2005). The role of the healthcare team is to provide information, to share and explain all diagnostic findings, to inform parents of all available options, and to support the parents in the decision-making process. The approach should be family-centered as well as culturally sensitive (Thyen, Richter-Appelt, Wiesemann, Holterhus, & Hiort, 2005). Family concerns must be respected and addressed in strict confidence (Auchus et al., 2010). A relationship of trust is paramount, and this requires open and honest communication and full disclosure of available information (Shnorhavorian & Fechner, 2018), including candid discussion of the controversies and dilemmas concerning gender assignment and early genital surgery. Parental acceptance of the child with a DSD and condition are key determinants of a favorable outcome (Houk & Lee, 2012). Healthcare professionals must also recognize and respect the cultural and psychosocial influences on parents' decisions about care for their infant (Shnorhavorian & Fechner, 2018).

Gender Assignment. Parents are naturally anxious to find out their baby's gender so that they can name the baby and announce the birth to family and friends. Nevertheless, it must be sensitively communicated that although their distress is acknowledged, when gender is in doubt, a gender-of-rearing decision is one with lifelong implications and cannot be made in haste. Gender assignment must be deferred until expert evaluation of the newborn takes place and sufficient data are available for a fully informed decision (Lee et al., 2006; Shnorhavorian & Fechner, 2018).

Unfortunately, some tests required for evaluation of a DSD must be sent out to referral laboratories, and the long wait for results can be frustrating for the parents. It is helpful if an experienced mental health professional can meet very early with the parents to help them formulate what to tell family and friends in the interim (Ogilvy-Stuart & Brain, 2004). All infants should receive a gender assignment as soon as the best course is reasonably determined (Lee et al., 2006). Questions about the infant's future management and treatment needs, gender identity/gender role development, and potential long-term outcomes should be addressed by clinicians who have extensive experience with DSDs.

DISORDERS OF SEXUAL DEVELOPMENT

A DSD is a misalignment, and therefore leads to incongruence between molecular, gonadal, and phenotypic sex (Houk & Lee, 2012). Most DSDs result from one of two events: either a failure in one of the steps of the male sexual developmental pathway, or the exposure of an XX fetus to androgens during a sensitive period of development. Less frequent are DSDs resulting from gonadal differentiation, chromosomal disorders, and syndromes associated with ambiguous genitalia (Shnorhavorian & Fechner, 2018). The genes and multigenic factors responsible for DSDs are just beginning to be understood, but this information has yet to prove beneficial in terms of clinical management.

46XX DSD Trimester

The most frequently encountered DSD in the neonate is the virilized female, or the 46XX infant with ambiguous external genitalia but normal female internal structures. The most common etiology is CAH, caused by 21-OHD deficiency. This enzyme deficiency results in an overproduction of androgens at a critical stage of development, causing masculinization of the external, but not the internal (ovaries, uterus, fallopian tubes), genitalia. In the most severe cases, the excess androgens also prevent the vagina from fully descending into the perineum, leaving a common urogenital canal (see section, Adrenal Disorders in the Neonate).

Other possible, yet rare, causes of virilization of external genitalia in the 46XX infant are placental aromatase deficiency, maternal androgen-producing or adrenal tumors, and maternal medications with androgenic action taken during pregnancy.

46XY DSD

The combination of a 46XY karyotype with ambiguous genitalia results from a failure in one of the steps involved in the synthesis or response to testosterone during sexual differentiation and penile growth. These infants have bilateral testicular development, but incomplete virilization of the internal or external genitalia. This results in an external phenotype ranging from completely female to isolated hypospadias or cryptorchidism. Another condition associated with incomplete virilization in the XY male is cloacal exstrophy, a defect of embryogenesis involving exstrophy of the bladder. Although not a DSD, significant ambiguity of external genitalia may be present. In most cases of 46 XY DSD, it has not been possible to determine the causative genetic mutation (Houk & Lee, 2012).

Androgen Insensitivity Syndrome

Pathophysiology. Androgen insensitivity syndrome (AIS) is caused by a loss-of-function mutation in the androgen receptor gene located on the long arm of the X chromosome. More than 300 different mutations have been identified (Shnorhavorian & Fechner, 2018). Both testosterone and its target tissue metabolite, DHT, must bind to androgen receptors to masculinize the genital tissues. When androgen receptor activity is impaired, androgen binding is insufficient. One variant of AIS is receptor negative: Cytosol receptors are incapable of binding DHT. Another variant is receptor positive: Receptors are able to bind DHT, but this does not result in normal differentiation. Both internal Wolffian structures and external genitalia fail to respond to high levels of testosterone and DHT. There are partial and complete forms of the disorder, resulting in different degrees of undervirilization. In PAIS, the clinical phenotype varies considerably and often parallels the severity of androgen resistance, but genotype-phenotype correlations have not been found.

Clinical Manifestations. Infants with PAIS have undervirilization ranging from simple hypospadias to microphallus with a labia majora–like bifid scrotum, undescended testes, and a urogenital sinus. No visible features distinguish PAIS from other causes of incomplete masculinization. Infants with complete androgen insensitivity (CAIS) are born with apparently female genitalia.

However, these neonates may have palpable inguinal or labial masses, which further testing will reveal to be testes. Some may also have a short, blind-ending vagina.

Diagnosis. The diagnosis of CAIS is missed in the newborn period unless the infant presents with bilateral masses in the labia or inguinal canals or a boy was expected based on a prenatal karyotype. CAIS might also be discovered at the time of inguinal hernia repair, or there may be a history of similarly affected family members. Important investigations include a karyotype, levels of testosterone, DHT, and LH. In PAIS, the ratio of androstenedione to testosterone is normal. Testosterone, estradiol, and LH are normal or high: FSH is usually normal.

Androgen receptor (AR) binding assays are not always helpful, because normal ligand binding does not rule out androgen insensitivity caused by mutations in other domains of the androgen receptor (Shnorhavorian & Fechner, 2018). Less than half of the infants with suspected PAIS have abnormal androgen binding; those with normal binding may have a defect in DNA binding or transcriptional activation (Misra & Lee, 2005). A test for direct sequencing of the AR for mutational analysis is commercially available, but AR mutations are not always found in PAIS (Shnorhavorian & Fechner, 2018). Imaging studies reveal the absence of female internal reproductive structures (uterus, fallopian tubes). Two normal testes are present.

Management. Infants with CAIS have unambiguously female external anatomy and are raised in the female gender. Testes are removed (usually after puberty) to prevent later malignancy. The gender assignment of infants with PAIS can be more complex and is often based on the severity of the phenotype (Misra & Lee, 2005). When the phenotype is predominantly male, a male sex rearing is recommended. However, no consensus exists for the management of infants with severe perineoscrotal hypospadias and microphallus. The detection of somatic mutations in AIS is of importance for correct sex assignment because the presence of a functional wild-type AR receptor can induce virilization at puberty (Köhler et al., 2005). When it is contemplated to rear as male sex, a therapeutic trial with pharmacologic doses of androgen, especially in those with an identified AR mutation, is often used to predict potential androgen responsiveness at puberty. If the phallus does not grow in response to testosterone, some experts would recommend consideration of a female gender assignment. However, many experts now believe that, given the putative influence of prenatal androgen exposure on the developing CNS, and the possibility that the child will develop a male gender identity, it is more prudent to raise these infants as boys.

Testosterone Biosynthetic Defects

Pathophysiology. Defects in the chain of steroidogenic enzymes involved in the testosterone biosynthesis pathway result in insufficient androgen concentrations during fetal development. Disorders include congenital lipoid adrenal hyperplasia (CLAH), 3 beta-HDD, 17 alpha-hydroxylase/17,20 lyase deficiency, and 17 beta-hydroxysteroid dehydrogenase deficiency (17 beta-HSD). CLAH is caused by a defect in the steroidogenic acute regulatory (StAR) protein, responsible for transporting cholesterol to the inner membrane of the mitochondria. Insufficient testosterone in affected males leads to underdeveloped Wolffian duct structures and external male anatomy. Müllerian structures are absent because there is normal testicular MIF production.

Clinical Manifestations. Male infants with CLAH present with complete adrenal insufficiency: vomiting, weight loss, and hypotension. Genital appearance is primarily female. Infants with 3 beta-HDD can present with varying degrees of genital ambiguity and evidence of salt-losing crisis (see 21-OHD). Infants with 17 alpha-hydroxylase/17,20 lyase deficiency have genital ambiguity, whereas patients with primary 17 alpha-hydroxylase deficiency also have hypertension. Male infants with 17 beta-HSD present with what appear to be external female genitalia that may include mild clitoral enlargement. An inguinal hernia may be present, possibly the only finding that will bring the infant to medical attention.

Diagnosis. General laboratory investigations in suspected testosterone biosynthetic defects include chromosomes, baseline levels of testosterone, androgen precursors and DHT, and levels of steroids and steroid precursors. An hCG stimulation test can be performed to measure the ratio of androstenedione to testosterone; an elevated ratio suggests 17 beta-HSD deficiency. In CLAH, ultrasound, CT, or MRI may show enlarged, lipid-laden adrenal glands (Shnorhavorian & Fechner, 2018).

Management. Acute management of these disorders requires full steroid replacement with both glucocorticoids and mineralocorticoids. In CLAH and 3 beta-HDD, general supportive measures may be necessary, as severe adrenal insufficiency can cause rapid metabolic decompensation if the disorder is not recognized at birth (Misra & Lee, 2005). Genetic XY infants with CLAH are raised in the female gender. Children with 17 beta-HSD often virilize significantly at puberty owing to increased peripheral conversion of androstenedione to testosterone by 17 beta-HSD isoenzymes, making gender assignment of those diagnosed as neonates a less straightforward decision.

5-Alpha-Reductase-2 Deficiency

Pathophysiology. 5-ARD-2 deficiency is an autosomal recessive disorder caused by more than 20 different mutations of the *5-ARD* gene. 5-ARD-2 is an enzyme found in the genital skin and fibroblasts of the developing fetus, without which testosterone is not converted to DHT, and fetal external genitalia do not virilize. Development of the internal structures is unaffected because DHT is not required, so the Wolffian ducts differentiate normally in response to testosterone and the Müllerian ducts regress. At puberty, the external genitalia become virilized and fertility is possible (Misra & Lee, 2005).

Clinical Manifestations. The spectrum of findings ranges from mild (isolated micropenis or hypospadias) to severe (a female phenotype with clitoromegaly, mild rugation, or pigmentation) undervirilization (Figure 10.7). Testes are intact and are found in the inguinal canals or labioscrotal folds, or are retained in the abdomen. The uterus and fallopian tubes regress because of normal secretion of MIS. Wolffian duct differentiation is not affected because DHT is not required. Male internal ducts terminate either in a blind pseudovaginal pouch or on the perineum.

Diagnosis. Diagnosis is made by assessing the ratio of testosterone to DHT following an hCG stimulation test. A normal T/DHT ratio is less than 4 to 1. In 5-ARD-2 deficiency, this ratio is elevated to higher than 14 to 1 (Shnorhavorian & Fechner, 2018). The hCG stimulation test also rules out other causes of undervirilization, such as Leydig cell hypoplasia and testosterone biosynthetic defects. Analysis of 5-ARD-2 activity in genital skin fibroblasts provides a definitive diagnosis.

Management. Boys with 5-ARD-2 respond to endogenous testosterone and undergo virilization and penile growth at puberty. The mechanism behind this late virilization may be extraglandular DHT formation due to peripheral conversion of increased testicular testosterone by unaffected isoenzymes. For this reason, it is recommended that when the diagnosis is made in the newborn period, a male sex assignment is usually made.

FIGURE 10.7 External genitalia of 46XY neonate with 5 alpha-reductase deficiency. Undervirilization is so severe in this infant that the phenotype is almost completely female, with labia majora–like bifid scrotum and severe microphallus.

Gonadal Dysgenesis

This group of disorders is usually associated with chromosomal anomalies or mutations or deletions of genes responsible for sexual differentiation. Karyotypes producing gonadal dysgenesis include 46XY, 46XX, 46XY/46X, and mosaic forms including the Y chromosome. Gonadal dysgenesis can occur as an isolated condition or as part of a complex syndrome such as Fraser, Denys–Drash, or campomelic dysplasia (Brown & Warne, 2005).

Pathophysiology. Dysgenetic gonads are characterized by variable degrees of immaturity or dysfunction, which can manifest in a wide range of genital ambiguity. Gonadal dysgenesis is considered partial or incomplete when the testes are dysgenic or incompletely formed, and complete when the gonads are streaks containing only stromal tissue. Mixed gonadal dysgenesis occurs when one gonad is a streak and the other is a well-formed testis. The internal ducts correlate with the ipsilateral gonad. On the side of a streak gonad, a fallopian tube and a hemiuterus will develop, and on the side of a normal testis, the vas deferens and epididymis will form.

Clinical Manifestations. The external genitalia are highly variable depending on how much testosterone is produced. In mixed gonadal dysgenesis, the external genitalia are asymmetric, appearing male on one side and female on the other. A vagina and uterine cavity may be present. Complete (or pure) gonadal dysgenesis is a form of sex reversal that results in unambiguously female genitalia with features of Turner's syndrome. These infants might not be identified in the newborn period unless a discrepancy is noted between a prenatal karyotype (46XY) and appearance of the genitals.

Diagnosis. Determining the sex chromosome complement by FISH testing is the most important diagnostic test. Imaging studies, genitography, or laparoscopy is used to define the internal anatomy. Gonadal histologic analysis is necessary to differentiate gonadal dysgenesis from ovotesticular DSD, a condition wherein elements of both testes and ovaries are present in the same individual (see Ovotesticular DSD).

Management. Determining the sex of rearing for the infant with partial or mixed gonadal dysgenesis can be a difficult decision, one that is typically based on the degree of virilization and details of the internal anatomy. When a uterus is present, the female sex assignment may be preferred. Most infants with complete gonadal dysgenesis are raised as females.

Ovotesticular DSD

In ovotesticular DSDs, both ovarian and testicular components are present in the same individual. Possible combinations include an ovary on one side and a testis on the other, an ovary or testis with an ovotestis, or two ovotestes. More than half the affected babies will have an XX karyotype. This condition was formerly known as true hermaphroditism, a label that is considered outdated.

Pathophysiology. The amount of testosterone produced by the testicular tissue that is present determines the degree of differentiation of Wolffian ducts, regression of Müllerian ducts, and virilization of external genitalia. The internal ducts usually parallel the ipsilateral gonadal histology. Ovarian tissue can be normal.

Clinical Manifestations. Asymmetry of the external genitalia is a hallmark of ovotesticular DSD. Genital ambiguity ranges from a female phenotype with slight clitoromegaly to a mildly undervirilized male phenotype. The most common presentation is marked genital ambiguity: microphallus with penoscrotal or perineoscrotal hypospadias, fusion of labioscrotal folds, and cryptorchidism (Misra & Lee, 2005).

Diagnosis. FISH testing is used to determine the sex chromosome complement. Imaging studies are used to define the internal anatomy. To diagnose ovotesticular dysgenesis, the presence of functional ovarian tissue containing follicles and testicular tissue with distinct seminiferous tubules must be established (Misra & Lee, 2005). Laparoscopy with gonadal biopsy is necessary at some point to confirm the diagnosis.

Management. Principles of management for infants with true ovotesticular DSD are similar to those of gonadal dysgenesis.

PANCREAS

The pancreas is both an exocrine and endocrine gland. The endocrine pancreas is responsible for hormonal regulation of blood glucose levels. The endocrine functions are performed by clusters of cells called islets of Langerhans that include alpha, beta, and delta cells. Hormones secreted by the endocrine pancreas include glucagon, insulin, amylin, and somatostatin.

Fetal insulin, present by 8 to 10 weeks gestation, is secreted in response to both glucose and amino acids. The fetus is critically dependent for growth on its own supply of insulin, which does not cross the placenta. Insulin stimulates uptake of glucose by muscle and adipose tissue. The fetal pancreas becomes progressively more responsive to glucose late in gestation and beta-cell mass increases markedly. At birth, when maternal glucose supply ceases, the neonate's blood glucose level declines, along with plasma insulin. A concomitant surge in the counter-regulatory hormones epinephrine and glucagon sets in motion the production of glucose that will sustain the neonate until milk feeding is established.

The exocrine portion of the pancreas constitutes 80% of the total gland. Acinar cells secrete digestive enzymes including trypsin, lipase, and amylase into the duodenum. Epithelial cells along the pancreatic ducts secrete bicarbonate and water that neutralize gastric acid.

DISORDERS OF PANCREAS

Rare pancreatic disorders in the newborn include congenital anomalies such as pancreatic agenesis, pancreatic hypoplasia, and annular pancreas. Disorders of the endocrine pancreas include neonatal diabetes mellitus (NDM) and hyperinsulinism, as well as the developmental disorder of the pancreas seen in the infant of the diabetic mother (IDM). The most common newborn disorder of the exocrine pancreas is cystic fibrosis (CF).

Infant of a Diabetic Mother

Diabetes in pregnancy is on the rise, paralleling the marked increase in people with type 2 diabetes and prediabetes (Homko, 2010). More newborns will be at risk for the problems associated with glucose intolerance and abnormal glucose regulation during pregnancy if this epidemic does not abate.

Pathophysiology. If maternal glycemic control is poor in the third trimester, high circulating maternal glucose levels chronically stimulate the fetal pancreas to release insulin, leading to fetal fat deposition. Maternal glucose homeostasis is a key determinant of fetal size (Walsh, Mahony, Byrne, Foley, & McAuliffe, 2011). Fetal macrosomia is more likely to occur in women whose hyperglycemia occurs episodically, particularly after a meal, and from the transfer of lipids from mother to fetus (Hay, 2012). At birth, the neonatal beta-cells take time to adjust to the lower circulating glucose level, and continue to secrete insulin, preventing the mobilization of glycogen and fat as sources of glucose. This failure of normal metabolic adaptation places the baby at risk of hypoglycemia. Hyperinsulinemia, regardless of whether the mother had type 1 or type 2 diabetes, can result in increased glucose utilization, decreased glucose production, and reduced availability of alternate substrates in the newborn (Hay, 2012).

Excess fetal insulin may also be the cause of delayed maturation of type II alveolar cells and pulmonary surfactant deficiency seen in some IDMs. Transient functional anomalies of the heart, including cardiomyopathy and intraventricular septal hypertrophy, begin in utero with glycogen loading of the septum. A delayed adaptation in parathyroid regulation after birth is the source of hypocalcemia and hypomagnesemia of the IDM. An increase in fetal erythropoiesis leading to polycythemia in the IDM is common, but its etiology is unknown. Hyperbilirubinemia results from the presence of excess hemoglobin, in turn, resulting in a larger than normal bilirubin load.

The higher rate of congenital anomalies associated with diabetic pregnancy is related to maternal glycemic control at the time of conception and during early gestation, when organogenesis is taking place. Congenital malformations associated with maternal diabetes include those of the CNS (anencephaly, meningomyelocele, encephalocele, caudal dysplasia), the heart (transposition of the great vessels, coarctation of the aorta, ventricular septal defects, atrial septal defects), the kidneys (hydronephrosis, renal agenesis), and the gastrointestinal tract (duodenal atresia, small left colon syndrome).

Clinical Manifestations. As a result of fat accumulation in late gestation, affected fetuses can develop macrosomia, with birth weights that are not in proportion with their length and head circumference measurements. Intrauterine growth restriction is a less common presentation, seen in advanced maternal diabetic vascular disease. Skin tones may be ruddy with sluggish capillary refill. The neonate may present in respiratory distress. If there is a history of difficult vaginal delivery with shoulder dystocia, the infant may present with musculoskeletal or peripheral nerve findings, suggesting fractured clavicle or humerus or brachial plexus palsy. With the latter condition, the affected arm is held limply at the side, and movements, including Moro responses, are asymmetric. Deep tendon reflexes are absent. Crepitus may be palpated along the clavicle if a fracture is present.

Diagnosis. Macrosomia at birth is a good marker for detecting the infant at risk for neonatal morbidities related to maternal diabetes. In spite of the IDM's size, it is also important to determine gestational age to assess the risk of problems related to prematurity. **Quality and Safety: The IDM must be monitored for hypoglycemia, which usually occurs within an hour or two of birth. Objective measurements of blood and plasma glucose should be used rather than relying on symptoms of hypoglycemia, because the latter are nonspecific and unreliable.** Point-of-care blood glucose test results indicating hypoglycemia (<40 mg/dL in the newborn) should be verified with a serum laboratory glucose; however, treatment should not be delayed while awaiting the results of the laboratory test. If no treatment is initiated and the serum glucose confirms hypoglycemia, valuable time is wasted, but if treatment is begun and the serum glucose is actually higher than the point-of-care glucose, the treatment is relatively benign.

Additional testing required for the IDM is a serum calcium concentration and, if this is low, a serum magnesium is done. Hemoglobin level should be measured with a venous, rather than a capillary, blood sample. Additional diagnostic tests will depend on findings of the initial physical examination.

Management. Close consultation between maternal and infant caregivers, particularly at the time of labor and delivery, is a necessary ingredient for successful management of the IDM (Hawdon, 2011). Unless life-threatening complications, such as perinatal asphyxia, are present, prevention of hypoglycemia is typically the primary concern in the early management of the IDM. Early, frequent milk feedings in stable infants are ideal, if tolerated. Infants born preterm may display immature feeding skills, despite their large size, and require gavage feedings. **Quality and Safety: Severe or persistent hypoglycemia is managed with intravenous glucose boluses, followed by continuous glucose infusion starting at 6 to 8 mg/kg/minute.** Glucose infusions must be weaned slowly, with close monitoring of blood glucose levels, as the neonate acquires the ability to sustain a normal blood sugar level between feedings.

Neonatal Diabetes Mellitus

NDM is a rare disorder manifested by persistent, insulin-sensitive hyperglycemia occurring as early as the first week of life and lasting more than 2 weeks. About half of all cases of NDM are of the transient form (TNDM), and half the permanent form (PNDM). Recent data suggest that the frequency of NDM is 1 in 100,000 live births (Grulich-Henn et al., 2010).

Pathophysiology. The fundamental problem in NDM is a failure of the pancreas to release sufficient insulin in response to high blood glucose levels. NDM is unrelated to the presence of anti-insulin or anti-islet cell antibodies. In TNDM, diabetes develops within days of birth and resolves again within weeks or months before recurring, in a milder form, in late childhood. PNDM develops within days to months after birth and persists throughout life. Most cases of PNDM are caused by transcription factors involved in beta-cell development and in insulin secretion, the glucose-sensing enzyme glucokinase, and a gene-regulating immune response. About half of the affected neonates have activating mutations of the KATP channel—KCNJ11 and ABCC8

(Edghill, Flanagan, & Ellard, 2010). Most cases of TNDM are caused by one of three genetic mechanisms: a paternal uniparental isodisomy of chromosome 6, a paternally inherited duplication of 6q24, or a maternal methylation defect within the same region (Sperling, 2006).

Clinical Manifestations. A common feature of NDM is intrauterine growth restriction, a result of insufficient insulin secretion and subsequent failure to thrive in utero. Intrauterine growth restriction in infants with deficient insulin secretion in utero highlights the importance of insulin as a growth hormone. In addition to being small for gestational age, infants with NDM exhibit hyperglycemia, glycosuria, osmotic polyuria, dehydration, and minimal ketoacidosis.

Diagnosis. The diagnosis is made by demonstrating hyperglycemia with low levels of insulin, insulin-like growth factor-1, and C-peptide. The hyperglycemia responds to insulin infusion. Antibodies to insulin or islet cells are absent. If there are signs and symptoms of malabsorption, pancreatic agenesis should be ruled out by abdominal ultrasound. TNDM and PNDM cannot be differentiated, based on clinical course, in the neonatal period; genetic testing for chromosome 6 anomalies is required. A genetic diagnosis is worth the expense in infants with NDM (Greeley et al., 2011). If the neonate is shown to have a mutation of the KATP channel, treatment with oral sulfonylureas, rather than insulin, is possible, which is tremendously beneficial to the child's glucose control and quality of life.

Management. Insulin therapy is necessary in some affected infants to manage hyperglycemia and achieve adequate growth, initially by continuous drip and transitioning to subcutaneous injection of an intermediate-acting insulin preparation when condition permits. A high caloric intake can be difficult to maintain. In some infants, insulin therapy can be withdrawn after a period of time when it is observed that exogenous insulin induces hypoglycemia. The course of disease in NDM is highly variable. Some infants with TNDM will have spontaneous recovery with no further disease recurrence, whereas others will have apparent remission with recurrence of permanent disease in late childhood. Infants with PNDM have no remission of their disease.

The opportunity for parents to speak with the pediatric endocrinologist and geneticist should be provided, if possible, for information and guidance about both the cause of NDM and the plans for continuing care for their infant. Close follow-up is essential even if the diabetes has resolved because of the high rate of recurrence later in childhood.

Congenital Hyperinsulinism

Congenital hyperinsulinism is not a single disorder, but a group of disorders with the common feature of hyperinsulinemic hypoglycemia, secondary to inappropriate secretion of insulin (Arnoux et al., 2011). It is the most frequent cause of severe, persistent hypoglycemia in the newborn, with an incidence of 1 in 30,000 to 50,000 live births (Werny, Taplin, Bennett, & Pihoker, 2018). Several different genetic forms have been described. Between 10% and 15% of congenital hyperinsulinism is transient and will spontaneously resolve at 1 month of age. Beckwith–Wiedemann syndrome is a congenital overgrowth syndrome, with hyperinsulinism caused by beta-cell hyperplasia.

Pathophysiology. Hyperinsulinism is due to unregulated insulin release from either the entire pancreas (diffuse beta-cell hyperfunction) or confined areas of the pancreas (focal adenomatous islet-cell hyperplasia). Insulin lowers circulating glucose, suppressing lipolysis and ketogenesis and decreasing the availability of free fatty acids and ketone bodies. Since these are alternative energy substrates for the brain during hypoglycemia, hyperinsulinemia places the infant at risk of severe neurologic dysfunction and seizures as consequences of neuroglycopenia.

Clinical Manifestations. Most infants with congenital hyperinsulinism present within the first postnatal days. Generally, they are born at term and are normal or large for gestational age. Many are macrosomic with a characteristic facial appearance. Neonates with Beckwith–Wiedemann syndrome present with a constellation of findings including macroglossia, abdominal wall defects, Wilms' tumors, renal abnormalities, and facial nevus.

Diagnosis. Congenital hyperinsulinism is recognized by severe hypoglycemia with an insulin level that is inappropriate to the level of blood glucose that is present (e.g., insulin level >5 U/mL with a plasma glucose level <50 mg/dL).

Diagnostic criteria are a high glucose requirement (>6–8 mg/kg/minute) needed to maintain normoglycemia, low serum blood glucose by laboratory analysis, measurable insulin, raised C-peptide, low free fatty acids, and low ketone body concentrations. Blood sampling must take place during hypoglycemia to be of diagnostic value (Werny et al., 2018). The administration of glucagon during hypoglycemia results in a glycemic response.

Management. The cornerstones of management are a high caloric intake and pharmacologic therapy to inhibit insulin secretion by the pancreas. A central venous catheter is required for reliable and safe administration of high glucose infusates during the acute phase. **Quality and Safety: Glucose infusion rates of 10 to 15 mg/kg/minute or higher may be required, and the rate of glucose necessary to maintain normoglycemia (fasting blood glucose >70 mg/dL)** is an indicator of the severity of the disease (Arnoux et al., 2011). Drugs include diazoxide, which inhibits insulin secretion by blocking the sulfonylurea receptor of the beta-cell, and octreotide, which is a somatostatin analogue. Diazoxide must be used with caution in the presence of hyperbilirubinemia because it is highly protein bound and will displace bilirubin from albumin binding sites. Glucagon to mobilize hepatic glucose can be added if needed as a short-term adjunct to therapy (Arnoux et al., 2011).

Unfortunately, the responsiveness of infants with hyperinsulinism to these agents is inconsistent and variable. Babies who do not show an adequate and immediate response may require pancreatectomy to prevent recurrent neuroglycopenia. Preoperative localization procedures and intraoperative biopsies will determine the exact nature of the lesion and how much of the pancreas must be removed. Focal disease may require only a partial pancreatectomy, but a near-total (>95%) removal of the pancreas is indicated for diffuse congenital hyperinsulinism. Loss of the pancreas can pose additional risks such as pancreatic insufficiency and diabetes mellitus.

Cystic Fibrosis

CF is an autosomal recessive disorder caused by mutations in the gene encoding for the CF transmembrane conductance regulator (CFTR) protein, of which more than 1,500 have been identified (O'Sullivan & Freedman, 2009). Data from newborn screening programs in the United States reveal that CF occurs in 1 in 3,000 White and 1 in 15,000 to 20,000 Blacks (Walters & Mehta, 2007).

Pathophysiology. Mutations in the *CFTR* gene affect the cyclic adenosine-5'-monophosphate (AMP)-mediated signals that stimulate chloride conductance in the epithelial cells of the exocrine ducts. Deficient chloride transport and the associated water transport abnormalities result in the production of abnormally viscid mucus. Nearly all organs and systems of the

body are affected, including the lungs and upper respiratory tract, gastrointestinal tract, pancreas, liver, sweat glands, and genitourinary tract. In the neonate, hyperviscous secretions in the intestines and a deficiency of pancreatic enzymes can combine to create a sticky plug of meconium, a condition known as *meconium ileus*. The meconium has a higher protein and lower carbohydrate concentration, making it more viscid than normal meconium.

Clinical Manifestations. Without a family history or prenatal screening, CF is not recognized at the time of birth in most affected neonates unless a meconium ileus is present. A simple meconium ileus is usually identified at 24 to 48 hours of age (occasionally earlier) when there are signs of intestinal obstruction: abdominal distension, bilious vomiting, and either failure to pass meconium or passage of gray-colored stools. On examination, the dilated loops of bowel have a doughy character that indent on palpation. A complicated meconium ileus has a more dramatic presentation with severe abdominal distension, signs of peritonitis such as tenderness, erythema, and clinical evidence of sepsis. The neonate may be acutely ill and require urgent surgical attention. Although not always present in the neonatal period, most patients with CF have pancreatic enzyme insufficiency and present with digestive symptoms or failure to thrive early in life. Other neonatal signs and symptoms include intestinal atresia, prolonged jaundice, and abdominal or scrotal calcifications (O'Sullivan & Freedman, 2009).

Diagnosis. The possibility of CF is raised in the neonate with meconium ileus, and the diagnosis can be confirmed with DNA testing. A sweat test can also be performed after the first 48 hours of life, if the infant is not edematous. A sweat test uses electrical-chemical stimulation of the skin to induce sweat, which is collected and analyzed for chloride content. Newborn screening for CF can be accomplished by measuring immunoreactive trypsinogen in dried blood samples. Screening for CF is now universally conducted in all 50 states and the District of Columbia (Wagener, Zemanick, & Sontag, 2012). Sometimes a meconium ileus is identified on prenatal ultrasound as a hyperechoic mass in the terminal ileum, representing thickened or dried meconium, and dilated bowel loops. Postnatal abdominal radiographs show unevenly dilated bowel and, occasionally, a characteristic "soap bubble" pattern, or small bubbles of gas that are caused by air mixing with the tenacious meconium.

Management. A meconium ileus requires prompt attention to prevent complications such as volvulus, bowel necrosis, or intestinal perforation. Treatment for simple meconium ileus is a therapeutic Gastrografin (Diatrizoate Meglumine) enema performed under fluoroscopy. Gastrografin is a hyperosmolar, radiopaque solution that evacuates the dried or thickened meconium from the intestine. Gastrografin is not used in infants with evidence of volvulus, gangrene, perforation, peritonitis, or atresia of the small bowel. The risks of the procedure are ischemia, hypovolemic shock, and perforation. It is essential to provide adequate hydration to compensate for the rapid fluid losses that can occur with the Gastrografin enema. It usually takes 24 to 48 hours to evacuate the softened meconium, and serial radiographs are usually ordered to monitor the evacuation. Feedings are started when signs of obstruction have subsided. **Quality and Safety: An infant who has undergone a Gastrografin enema should be observed closely for at least 48 hours for signs and symptoms of perforation of the bowel; late perforation is a rare but possible complication as long as 48 hours after the procedure.**

CF is also managed with a diet high in energy and fat to compensate for malabsorption and the increased energy demand of chronic inflammation. In addition to vitamin and mineral supplementation, a hydrolyzed protein formula containing medium-chain triglycerides is used. Medium-chain triglycerides do not require digestion by pancreatic enzymes for absorption. Pancreatic enzyme supplements are also needed to improve fat absorption. Meticulous care of the perianal area must be taken because these enzymes can cause severe perianal dermatitis. Breastfeeding has been shown to have significant benefits for infants with CF, although growth might be slightly slower, and should be encouraged (Wagener et al., 2012).

Infants can also develop early pulmonary infections with *Staphylococcus aureus* followed often by *Pseudomonas aeruginosa* (Wagener et al., 2012). Newer, promising therapies for the pulmonary complications of CF are currently under study. One of these is inhaled hypertonic saline, which draws water into the airways, rehydrating the periciliary layer and improving mucociliary clearance (O'Sullivan & Freedman, 2009).

Finally, of utmost importance, the care of the neonate with CF requires a team approach, in order to provide the family with the necessary resources and anticipatory guidance to manage this disorder and prevent complications for the best possible outcome (Box 10.2).

Box 10.2

NURSING IMPLICATIONS OF INFANTS WITH ENDOCRINE DISORDERS

Nurses should support the families of these infants in the following ways:

1. Assuring that the programs are implemented safely and effectively
2. Facilitating education of the nursing workforce and developing and contributing to programs of research focused on endocrine disorders
3. Educating parents with appropriately timed discussion of results
4. Parental teaching that includes materials that provide descriptions and results that will be communicated to the family and what they should expect if further testing is needed (Arnold et al., 2006; Davis et al., 2006)

SUMMARY

Some neonatal endocrine disorders are quite rare, and recognizing them requires a high index of suspicion. In recent years, neonatal screening programs have permitted the presymptomatic diagnosis of some of these disorders. This has led to earlier treatment and reduced morbidity, although most endocrine disorders still imply lifelong therapy for the affected infant.

CASE STUDY

■ **Identification of the Problem.** A 34-week gestation, 1.33-kg male infant was admitted to the NICU for small size and prematurity. Admission vital signs were HR 128, RR 72, BP 42/23 (mean 30), and axillary temperature 97.4°F. Blood glucose screen (point of care) was 104.

A peripheral IV was started with D10W at 80 mL/kg/day (GIR 5.5 mg/kg/minute), and the infant was made NPO. A repeat blood glucose screen on D10W was 545. In the belief that this was an error, it was repeated, and the result was 550. A serum glucose level

was drawn, and the IV fluids were changed to D5W. The serum glucose was 535. The initial D10W fluid bag was sent to the lab for analysis.

A repeat blood glucose screen on D5W was 550 (serum 632). IV fluids were changed to normal saline, and the repeat blood glucose was 443 (serum 635). An insulin drip was started at 0.05 U/kg/hour and titrated to maintain blood glucose level less than 250.

■ **Assessment: History and Physical Examination.** The infant was born by cesarean section to a 25-year-old G1 P0 mother following a pregnancy complicated by oligohydramnios. Apgar scores were 7 and 9 and the arterial cord pH was 7.27. Length was 38.5 cm, and head circumference 28 cm, placing him below the 10th percentile for all growth parameters.

Arterial blood gas taken in room air: pH 7.30, P_{CO_2} 35, P_{O_2} 128, base excess −7.7

Following this, 10 mL/kg of normal saline was given for metabolic acidosis.

Examination revealed a small but healthy-appearing male infant, without evidence of respiratory distress.

■ **Differential Diagnosis.** The initial suspected "diagnosis" for the extremely elevated blood glucose in this case was operator error; when the same result was obtained with a repeat specimen and confirmed by serum glucose, it was still viewed with a high degree of suspicion and the intravenous fluids were sent to the laboratory for analysis. The differential diagnosis of hyperglycemia in neonates includes iatrogenic causes, poor insulin sensitivity of the very-low-birth-weight or growth-restricted infant, sepsis, pancreatic agenesis, insulin resistance, TNDM or PNDM, and side effects of medications such as glucocorticoids and theophylline. Several of these were ruled out as they did not apply (the infant was not extremely premature, nor had he received any medications known to cause blood glucose elevation). Furthermore, the problem persisted after changing the IV fluids, ruling out an iatrogenic cause. Insulin resistance was ruled out because the infant responded promptly to an infusion of insulin. He did show evidence of intrauterine growth restriction but it was believed more likely that this was a consequence, rather than a cause, of his primary problem.

■ **Diagnostic Tests.** The following tests were ordered to further hone in on the cause of hyperglycemia:

- CBC: Hct 42%; WBC 4.4; Segs 20; Bands 8; platelets 274,000
- Blood cultures were negative at 24 and 48 hours
- Abdominal ultrasound (to rule out pancreatic agenesis): the organ appeared normal
- Insulin autoantibodies were negative; the insulin drip was stopped for 2 hours and insulin and C-peptide levels were drawn
- RESULTS: insulin level less than 2 mIU/mL
- C-peptide less than 0.5 ng/mL (reference range 0.8–3.1 ng/mL)
- Concurrent plasma glucose was 412

■ **Working Diagnosis.** The infant's presentation at birth and clinical course were most consistent with a diagnosis of NDM. He was intrauterine growth restricted, indicating a prenatal onset of the condition, and he had a mild metabolic acidosis. He had no evidence of autoimmune or structural pancreatic disease. He did not have septicemia or evidence of other infection. Furthermore, his laboratory studies revealed severe insulinopenia. The low level of C-peptide, a single-chain amino acid normally released with insulin in equal amounts, supports this diagnosis. It was not known whether his NDM was transient or permanent; this would require molecular genetic analysis, a test that was not done during the initial hospitalization.

■ **Development of Management Plan.** The management plan was to reintroduce glucose while continuing the insulin infusion, advancing to total parental nutrition as tolerated. Glucose levels would be monitored at least every 2 hours, with the goal of keeping the blood glucose less than 250. The plan included the introduction of feedings as early as feasible to improve control of blood glucose. Continuous insulin would be weaned as tolerated. If his diabetes showed no signs of resolution, subcutaneous insulin would be started for long-term management. The infant would continue to be followed by the pediatric endocrinologist.

■ **Implementation and Evaluation of Effectiveness.** Over the first few days, stabilization of the blood glucose level proved difficult. On total parenteral nutrition (TPN), the infant fluctuated between hyperglycemia and hypoglycemia. Feedings were introduced and this provided a measure of stability, although weight gain remained slow. The infant was eventually successfully managed with and discharged on subcutaneous insulin.

EVIDENCE-BASED PRACTICE BOX

Upon newborn screening, at least one of two extremely low gestational age neonates (24–28 weeks gestation) is found to have low serum thyroxine (T_4) levels. This condition is known as hypothyroxinemia of prematurity and is believed to be a transient maladaptation of physiology that reflects both immaturity and the effects of illness and treatments for other neonatal problems (La Gamma & Paneth, 2012). Both researchers and clinicians, however, have been uncertain about whether to treat hypothyroxinemia in these infants, or adopt a "watchful waiting" approach.

The concern about not treating these low T_4 levels is that thyroid hormones are known to be critical to normal brain development. With the loss of maternal sources of thyroid hormone, low T_4 levels exist at a vulnerable period of brain development. Evidence suggests that hypothyroxinemia of prematurity is associated with both cognitive and neurological delays (La Gamma, 2008). Therefore, studies have attempted to determine whether thyroid hormone supplementation would improve neurodevelopmental outcomes in low gestational age neonates. One such study, the largest interventional trial to date, tested the effects of a daily dose of 8 mg/kg of T_4 for 42 days, compared with placebo (van Wassenaer et al., 1997). On follow-up testing, an 18-point improvement in IQ scores was found in mental development at 2 years of age, and there

(*continued*)

EVIDENCE-BASED PRACTICE BOX (*continued*)

was an improvement in neurological outcomes in a subgroup of the most immature infants, less than 27 weeks gestation. At 5.5 and 10 years of follow-up, the benefits of T_4 supplementation continued for this subgroup, but for more mature infants, the reverse was true (Briët et al., 2001; van Wassenaer, Westera, Houtzager, & Kok, 2005).

Against a backdrop of this evidence, researchers undertook a study of four different thyroid regimens for neonates less than 28 weeks gestation diagnosed with hypothyroxinemia of prematurity (La Gamma et al., 2009). The key difference between this and previous trials was that this study aimed to maintain "biochemical euthyroidism" by reducing suppression of TSH. In previous trials, thyroid supplementation had resulted in a suppression of TSH levels. La Gamma et al. found evidence of clinical benefit (shorter duration of mechanical ventilation, lower rates of retinopathy of prematurity, and less necrotizing enterocolitis) with a *continuous* regimen of 4 mcg/kg/day for 42 days rather than a single daily supplement. This regimen raised total T_4 levels with only modest suppression of TSH.

As a result of this trial, study authors recommend T_4 replacement of 4 mcg/kg/day for 42 days, to achieve "biochemical euthyroidism," defined as a minimum free T_4 level of 1.5 ng/dL, a minimum total T_4 level of 6 mg/dL, a minimum total T_3 level of 52 ng/dL, and minimal suppression of TSH level (<0.4 mIU/L; La Gamma et al., 2009). Continuous infusion of T_4 is believed to more closely approximate normal physiology by achieving a sustained elevation in total T_4. Iodide supplementation (30 mg/kg/day orally) is also essential. Only a randomized, placebo-controlled clinical trial can provide evidence of long-term neurodevelopmental improvement associated with this regimen. In the absence of such evidence, clinicians may remain reluctant to adopt a new standard of care.

CHAPTER 11

Immune System

Mary Beth Bodin and Jacqueline Hoffman

INTRODUCTION

Despite all the lessons we have learned, neonatal sepsis continues to be a leading cause of neonatal and infant morbidity and mortality. The intact uterine environment helps to protect the fetus from a variety of pathogens including bacteria, viruses, fungi, protozoa, and parasites. Although there is protection, breaches do occur and this protection is not absolute. The birth canal may not be a sterile environment as once thought. New evidence has shown the presence of microbiota in the placenta and amniotic fluid in asymptomatic term pregnancies (Chu et al., 2016). The newborn is exposed to a wide variety of microorganisms during labor and delivery and in the event of ruptured membranes. The extrauterine environment exposes the infant to even more potential pathogens.

To understand and appreciate the challenges infants face in the first few days and weeks of life, it is necessary to review the basics of innate and adaptive immunity and potential alterations to the neonatal immune system. This chapter will discuss development of the immune system and will describe assessment parameters for evaluating the infant with suspected and culture-proven infection as well as diagnostic measures and treatment for the most common causes of newborn infection. Due to the importance of a broader approach to combating mortality from neonatal sepsis, a global perspective will be presented. The emergence of resistant organisms and the possible detrimental effects of prolonged antibiotic usage are becoming more influential in the treatment choices in individual units; therefore, the importance of antibiotic stewardship will be introduced. Detailed discussions on antibiotic stewardship and antibiotic resistance will be covered in another chapter in this text.

DEVELOPMENT OF THE IMMUNE SYSTEM

The overall goal of the immune system is to recognize foreign substances and activate systems to inactivate, destroy, and eliminate this material from the body. Immaturity of the immune system, seen especially in preterm infants, contributes to increased susceptibility to bacterial, viral, and fungal infections. The immune system consists of two separate defense mechanisms, the innate and adaptive subsystems. The innate system consists of external barriers such as the skin and mucous membranes, leukocytes and other defense cells, enzymes, and proteins in the blood. Natural killer cells are an important part of the innate immune system. These cells destroy invasive cells with cytotoxins. It is easy to see why this system is considered to be the first line of defense. The adaptive system takes over when the innate system fails. It may be delayed but is more accurate and efficient. This system produces memory cells; therefore, it is responsible for immunological memory. The adaptive immune system is composed of T lymphocytes, B lymphocytes, and antibodies (Simon, Hollander, & McMichael, 2015).

Innate Immune System

The innate or natural immune system is the first line of defense acting within minutes of initial exposure. This system does not require prior exposure to the pathogen to mount a response. This system consists of granulocytes (mainly neutrophils), antigen-presenting cells (monocytes), and natural killer cells. Neutrophils are the first phagocytic cell to reach the site of infection; sensing the foreign pathogen, neutrophils adhere to the vascular endothelium and migrate toward the site of infection to engulf and kill the pathogen. The response to the infectious process is to release more neutrophils from the storage pool, resulting in the release of more immature neutrophils as well as resulting in what is known as a left shift (a preponderance of immature to mature cells). The innate immune system utilizes toll-like receptors (expressed on monocytes), NOD (nucleotide-binding oligomerization domain)-like receptors, and RIG (retinoic acid-inducible gene)-like receptors to identify and respond to pathogen-associated molecular patterns resulting in the production of cytokines and proinflammatory responses, which activate the adaptive immune system (Camacho-Gonzalez, Spearman, & Stoll, 2013). In neonates, they have a decreased ability to produce proinflammatory cytokines, in particular tumor necrosis factor and interleukin (IL)-6. Neonates also have decreased neutrophil and dendritic cell functions, decreased adhesion ability, and decreased response to chemotactic factors affecting the ability to deform and penetrate the vascular endothelial lining (Basha, Surendran, & Pichichero, 2014; Camacho-Gonzalez et al., 2013). Finally, there is reduced cytokine production resulting in decreased activation of natural killer cells. All of these factors in the neonate place them at increased susceptibility to bacterial and viral infections (Camacho-Gonzalez et al., 2013).

Adaptive Immune System

The adaptive or acquired immune system relies on memory; this antigen-specific response is guided by recognition of prior exposure to pathogens. The adaptive immune system relies on T lymphocytes

and B lymphocytes. T lymphocytes provide cell-mediated immunity. They develop in the thymus and then circulate to the periphery. There are two different types of T lymphocytes: CD4 T cells and CD8 T cells. The CD4 T cells are "helper" cells that stimulate antibody production, whereas CD8 T cells act as cytotoxic killer cells. B lymphocytes provide humoral immunity. They develop in the bone marrow and circulate to the peripheral lymphatic system where they differentiate into plasma cells that secrete five types of immunoglobulins: immunoglobulin A (IgA), immunoglobulin D (IgD), immunoglobulin E (IgE), immunoglobulin G (IgG), and immunoglobulin M (IgM). The only immunoglobulin transplacentally transferred is IgG. The presence of IgM in the neonate at birth reflects a response to intrauterine infection exposure.

To minimize the overwhelming inflammatory response that would occur at the time of delivery from a relatively sterile environment, the adaptive immune system function increases slowly in the newborn. Skin and mucosal barriers in the preterm infant do not provide as effective barrier function as in the term and older neonate (Collins, Weitkamp, & Wynn, 2018). The neonate has decreased cytotoxic function as well as decreased memory, impacting the ability to respond effectively to infections (Camacho-Gonzalez et al., 2013).

The development of the immune system in the fetus and newborn cannot be studied in isolation from maternal influences. The ability of the mother's body to tolerate the fetus during pregnancy, rather than rejecting it as a foreign body, is not thoroughly understood. It is well documented that maternal blood with immunocompetent T lymphocytes circulates in contact with fetal cells, that both fetal and maternal cells are exchanged through the placenta, and that humoral and cellular immunity to fetal antigens develops in the mother. Recent studies have focused on maternal antibody transfer as it protects the newborn against infection prior to childhood immunizations and natural responses of the infant to infection. Secretory IgA in breast milk may also interfere with successful immunization, particularly with live poliovirus, by neutralization of virus by antibody in the gastrointestinal (GI) tract (Jennewein, Abu-Raya, Jiang, Alter, & Marchant, 2017; Maldonado, Nizet, Klein, Remington, & Wilson, 2016). Maternal placental transfer of IgG is inversely related to gestational age with minimal transfer in the first trimester and increases occur predominantly during the third trimester, leaving premature infants with a relative deficit (only 50% transfer by 32 weeks' gestation). Such immunity is transient; nevertheless, it may provide protection during a vulnerable time of life (Camacho-Gonzalez et al., 2013; Hong & Lewis, 2016). After birth, levels of IgG fall to their lowest levels between 2 and 4 months of age, which is referred to as physiologic or transient hypogammaglobulinemia. Infants do not begin producing their own IgG in response to exposure to pathogens until around 6 months of age. New and exciting evidence is available concerning the impact of the maternal microbiota on neonatal immune development. It is now recognized that maternal diet, including micronutrients, and the maternal microbiome significantly influence the neonatal innate and adaptive immune systems. It is known that the maternal gut and genital microbiota are transferred to the infant at birth and through the placental pathway (Jennewein et al., 2017).

Global Perspective on Neonatal Infection

The incidence of infection varies according to the level of perinatal care available, economic standards, and other perinatal risk factors in newborns, such as prematurity. Because the world is becoming smaller in terms of travel and involvement, it is no longer sufficient to concern ourselves with what is relevant to the North American continent. Our greatest concern is the challenge to eliminate the gaps in healthcare access and, therefore, to improve health outcomes worldwide. One of the barriers to understanding the overall burden of global neonatal infection is the general paucity of data from low- and middle-income countries (Fleischmann-Struzek et al., 2018). Although child and infant mortality appears to be declining globally, infant morbidity is not. Neonatal sepsis resulting in death accounts for 26% of all deaths in infants and children under 5 years of age worldwide with mortality the highest in sub-Saharan Africa (Ranjeva, Warf, & Schiff, 2018). A recent meta-analysis of population-based neonatal and pediatric data estimated neonatal mortality from sepsis at 11% to 19%. The authors identified that data from low-income countries were lacking due to not meeting inclusion criteria (Shane, Sanchez, & Stoll, 2017). In the United States, the incidence of culture-proven early-onset sepsis (EOS) is estimated to be 0.77 to 2 per 1,000 live births. The incidence and mortality in very low birthweight (VLBW) infants is even higher. In the United States, there is a large disparity in rates of infection and mortality with black infants, preterm especially, having the highest rates of sepsis and mortality at 5.14 per 1,000 live births (Anderson-Berry, Bellig, & Ohning, 2015; Simonsen, Anderson-Berry, Delair, & Daves, 2014). In those settings with the highest mortality (developing countries), neonatal infections may account for up to 50% of all neonatal deaths (Zaidi, Darmstadt, & Stoll, 2016). Improved knowledge and technology to care for less mature and smaller newborns have led to an increased population of newborns at higher risk for bacterial infection. Major complications of infection include respiratory distress, shock, acidosis, disseminated intravascular coagulation (DIC), and meningitis. Long-term morbidity remains a concerning consequence of neonatal infections.

ASSESSMENT AND MANAGEMENT OF THE INFANT WITH SUSPECTED OR PROVEN INFECTION

Host defense mechanisms begin to develop early in gestation; however, they remain immature and often do not function efficiently even in the term newborn. Although the neonate's immune system is not fully developed, the newborn is able to respond to the environment, resulting in certain markers that can be detected in lab studies such as the complete blood count (CBC) and the C-reactive protein (CRP). Even so, the infant's immature immune system is easily overwhelmed. The immaturity of the immune system is responsible for the relatively high prevalence of infectious disease during the neonatal period, as well as the occurrence of neonatal infection from microorganisms that do not generally cause infection in older individuals. The susceptibility to infectious processes and the associated high morbidity and mortality make early identification and treatment of infection in a newborn a critical component of care (Anderson-Berry et al., 2015).

Clinical Signs of Infection

Identifying and caring for a newborn with an infection can be one of the greatest challenges in nursing. Nurses are often the first to recognize that there is something "wrong" with an infant, and this often leads to investigation of the signs. Generally, treatment is begun once a presumptive diagnosis of infection is made because the benefits of early treatment most often outweigh the risks of unnecessary treatment. Signs and symptoms of neonatal sepsis are nonspecific and are often related to the specific organism responsible and may be attributable to other diseases or conditions such as respiratory distress syndrome, metabolic disorders, or stress from a difficult delivery. These other diagnoses must be ruled out while maintaining a high index of suspicion for sepsis. The most commonly recognized signs and symptoms of infection are listed

in Box 11.1. Temperature instability, hypothermia in particular, the inability of the neonate to maintain temperature in the normal range with rectal temperature less than or equal to 35°C (95°F) is a strong predictor for infection. Newborns traditionally do not have well-developed febrile mechanisms; therefore, the absence of fever does not indicate the absence of infection. Premature infants more often present with a low body temperature. Hyperthermia may occur in both bacterial and viral infections in term newborns, with rectal temperatures of greater than 100.4°F, but this is relatively rare in preterm infants. An infected infant may present with lethargy, poor feeding, decreased reflexes, abdominal distention, delayed gastric emptying time, and perhaps diarrhea or loose green or brown stools. Hypoglycemia or hyperglycemia, as well as glycosuria, may result from the inability to maintain normal metabolic processes and impaired glucose metabolism (Nizet & Klein, 2016).

Vascular perfusion is typically decreased; the infected neonate may appear gray, mottled, or ashen in color with poor perfusion, prolonged capillary filling time, and hypotension. Skin changes may also include cyanosis and petechiae. Thrombocytopenia is often present. Infections can cause DIC, resulting in altered prothrombin time, partial thromboplastin time, and split fibrin product laboratory values. Hemolytic anemia may occur as a part of the inflammatory process and this can significantly decrease oxygen-carrying capacity, especially in the preterm infant. Cardiovascular shock can be a sudden clinical sign of fulminant infection that requires immediate and aggressive intervention to restore adequate circulation. Unexplained bradycardia, sclerema, and sudden purpura, rash, or petechiae are other signs of systemic infection (Weinberg & D'Angio, 2016).

Apnea in a term (nonsedated) newborn in the first few hours of life should be considered a serious sign of inability to regulate the brain's respiratory center. Apnea in the first 24 hours of life in a preterm newborn is a common sign of infection. Respiratory distress can be an early sign of pneumonia and must be considered carefully. Jaundice, hepatosplenomegaly, and irritability may also be found in infants with infection. The wide variability of signs of infection warrants inclusion of infection as part of the differential diagnosis in any ill infant.

Risk Factors

Prematurity is the most prevalent risk factor for infection, as premature infants are far more susceptible to the invasion of foreign microorganisms. Preterm infants have decreased maternal antibodies (passive immunity). The maternal antibodies, developed by exposure to antigens and subsequent creation of an antibody defense system, provide temporary protection to the newborn, but preterm newborns are born before the majority of maternal antibodies are transferred from the maternal circulation. Also, the cellular immune system is not well developed in the preterm newborn; thus, there is decreased phagocytic cellular defenses.

Box 11.1

SIGNS AND SYMPTOMS OF NEONATAL INFECTION

Clinical

- General
- Poor feeding
- Irritability
- Lethargy
- Temperature instability

Skin

- Petechiae
- Pustulosis
- Sclerema
- Edema
- Jaundice

Respiratory

- Grunting
- Nasal flaring
- Intercostal retractions
- Tachypnea/apnea

Gastrointestinal

- Diarrhea
- Hematochezia
- Abdominal distention
- Emesis
- Aspirates

Central Nervous System

- Hypotonia
- Seizures
- Poor spontaneous movement

Circulatory

- Bradycardia/tachycardia
- Hypotension
- Cyanosis
- Decreased perfusion

Laboratory Values

White blood cell count

- Neutrophils
  <5,000 cells/mm^3, neutropenia
  >25,000 cells/mm^3, neutrophilia
- Absolute neutrophil count (neutrophil and bands)
  <1,800 cells/mm^3 (during first week)
- Immature: total neutrophil ratio
  >0:2
- Platelet count
  <100,000, thrombocytopenia

Cerebrospinal fluid (Results outside the normal ranges below suggest central nervous system infection.)

- Protein (normal values)
  150 to 200 mg/L (term)
  300 mg/L (preterm)
- Glucose (normal values)
  50% to 60% or more of blood glucose level

Note: Symptoms and values are based on over 30 years of practice and observation by the authors. Individual practices must rely on current literature for diagnosis and treatment plans.

Prolonged rupture of the fetal membranes (PROM) is a well-known risk factor for the development of infection. The fetus is at increased risk because the break in the amniotic sac provides a pathway for the migration of microorganisms up the vaginal vault to the fetus. Delaying delivery in a pregnancy in a mother with PROM and a preterm fetus until pulmonary maturity is achieved creates the potential environment for bacterial proliferation and subsequent newborn infection. The benefit in promoting maturity of the immature lungs is weighed against the risk of overwhelming infection in the baby. Development of pulmonary hypoplasia is another serious concern when delivery is delayed after premature prolonged rupture of membranes (ROM; Adams Waldorf, Gibbs, & Gravett, 2016). PROM, generally considered as ROM lasting longer than 18 hours, is considered a risk factor in the evaluation of infants for potential for infection (Jefferies, 2017; Leonard & Dobbs, 2015; Shah & Padbury, 2014).

Although the most common cause of maternal fever in labor is dehydration, a fever may indicate maternal infection. A mother with an infection before or during delivery may transmit it to the infant. If maternal temperature is greater than or equal to 100.4°F during labor, evaluation for infection in the newborn is warranted (Adams Waldorf et al., 2016). Maternal cervical or amniotic fluid cultures may identify the causative microorganism. If the maternal illness suggests viral infection, newborn viral cultures should be obtained. Early identification of causative agents in the mother may help in the management of the newborn by allowing faster identification of the microorganism and initiation of appropriate antimicrobial therapy.

Foul-smelling amniotic fluid is an indication for newborn antimicrobial therapy in symptomatic infants. Routine blood cultures and a CBC with differential are indicated as a screen for newborn infection. Under these circumstances, the placenta should be sent for pathologic evaluation. Other risk factors associated with newborn infection are antenatal or intrapartal asphyxia, iatrogenic complications of treatment, and invasive procedures.

Stress inhibits the ability to fight infection by increasing the metabolic rate, which requires more oxygen and energy. A severely compromised hypoxemic newborn may have regional tissue damage. Ischemic or necrotic areas in the lungs, heart, brain, or GI system promote colonization and overgrowth of normal bacterial flora. This overgrowth of bacteria is one of the most common sources of newborn infection. Tissue damage can be prevented or repaired only if the infectious process is reversed and adequate tissue perfusion is restored.

Several known maternal factors are associated with newborn infection: low socioeconomic status, malnutrition, inadequate prenatal care, substance abuse, premature or prolonged ROM, presence of a urinary tract infection at delivery, peripartum infection, clinical amnionitis, and general bacterial colonization. Newborn risk factors include antenatal stress, intrapartal stress (perinatal asphyxia), congenital anomalies, male sex, multiple gestations, concurrent neonatal disease processes, prematurity, immaturity of the immune system, invasive admission procedures, and antimicrobial therapies.

Diagnostic Workup

A high index of suspicion of infection, early identification of the microorganism, and institution of appropriate therapy provide the best outcome. The index of suspicion is directly proportional to the maternal history and risk factors. Early and accurate diagnosis of infection in the newborn is a difficult task and is often complicated by the nonspecificity of the signs associated with sepsis exhibited by the newborn. The evaluation for infection in the newborn often depends on whether EOS or late-onset sepsis (LOS) is suspected. EOS is most often defined as sepsis that presents within the first 72 hours of life; however, many infections include sepsis that occurs within the first 6 days of life. LOS is, therefore, sepsis that presents after the first week of life. Very LOS may occur up to 3 months of age, usually from group B streptococcus (GBS; Nizet & Klein, 2016).

The perfect screen for neonatal sepsis has not been determined, although some laboratory aids have been found to be very helpful in diagnosing neonatal sepsis. A CBC is often the first step in evaluating for infection. The CBC of an infected infant may reveal leukopenia (white blood cell [WBC] count $<5{,}000$ cells/mm^3), leukophilia (WBC count $>25{,}000$ cells/mm^3), or a preponderance of immature neutrophils with the immature-to-mature cell ratio (I:T) greater than 0.2. The I:T ratio is the most studied of ratios of neutrophil counts and adds a level of confidence not appreciated with Band count alone. More important may be the negative predictive value of the I:T ratio. If I:T ratios are normal, it is unlikely that the infant is septic. Keep in mind that if the CBC is obtained early in the infectious process, it may not reflect abnormalities. A follow-up CBC in 12 to 24 hours for the infant with an initially normal CBC, but who is symptomatic for sepsis, should be considered and may reflect abnormalities at that time. Use of the CRP has added another level of confidence in excluding serious infection and in evaluating the infant's response to treatment and in determining length of therapy. Serial CRPs have been found to be more reliable than a single level. In the presence of sepsis, CRP levels may be normal at the onset of symptoms but are typically elevated by 24 hours of age and remain elevated during the acute phase of infection or inflammation.

If signs of central nervous system (CNS) involvement are present, a lumbar puncture (LP) for cerebrospinal fluid (CSF) cultures is indicated, whether EOS or LOS is suspected. Since urinary tract infections are extremely uncommon during the first few days of life, a urine culture is not indicated for EOS (Shane et al., 2017). Gram stain of the CSF or urine can give an early indication of the type of microorganism responsible for the infection. Cell count and protein and glucose levels of the CSF may also indicate the presence of infection. A chest radiograph can identify the presence of pneumonia. Other tests that may be useful include latex agglutination (LA) or counter-immunoelectrophoresis (CIE) of urine or CSF or other body cavity fluids, and erythrocyte sedimentation rate (ESR). Serum procalcitonin (PCT) is a test that is gaining favor in the diagnostic evaluation of possible bacterial sepsis in older infants and adults but is not commonly used in the diagnosis of bacterial infection in the newborn. The known fluctuations seen in the newborn during the first 48 hours complicate its usefulness. Traditionally, culture-positive sepsis from blood, CSF, urine, and other body fluids is the most valid diagnostic sign.

Differential Diagnosis

The microorganisms responsible for newborn infection have changed over the past 60 years, and there are marked regional variations. Organisms responsible for EOS differ from those responsible for LOS; therefore, the antimicrobial agents of choice differ based on the timing of symptoms. Even with the implementation of prophylactic use of intrapartum antibiotics, GBS remains the leading cause of EOS followed by *Escherichia coli*. Some microorganisms, including *E. coli*, groups A and B streptococci, and *Listeria monocytogenes*, are often implicated in EOS and LOS. Other organisms, including *Staphylococcus aureus*, coagulase-negative staphylococci (CoNS), and *Pseudomonas aeruginosa*, are typically associated with LOS (Nizet & Klein, 2016).

After day 7, nosocomial microorganisms should be considered. CoNS is the most frequently identified organism in newborn infants with nosocomial infection, particularly when invasive medical devices have been used, with gram-negative organisms and fungi following. Hospitalized preterm newborns are often affected by repeated episodes of infection. Many of these episodes are termed presumed, suspected, or clinical infection because no microorganism is recovered and cultured, despite clinical evidence of infection that responds to antimicrobial agent therapy (Shane et al., 2017).

Prognosis

The introduction of broad-spectrum antimicrobial agents dramatically improved the prognosis for infection, and there has been a decline in infection-associated neonatal and infant deaths in the United States. However, infection still accounts for significant morbidity and mortality in the neonatal period. Consequences of bacterial infection include prolonged hospitalization, increased hospital costs, and increased mortality. Term infants who are promptly and adequately treated for sepsis rarely have long-term sepsis-associated health problems; however, neurologic sequelae are seen in 15% to 30% of infants with septic meningitis. Preterm infants with sepsis are more likely to experience long-term neurologic damage, especially if shock is present (Anderson-Berry et al., 2015).

Management

Management of a newborn with an infection is aimed at the traditional "ABCs": airway (including oxygen, ventilation, correction of acidosis), breathing, circulation, volume expansion, antimicrobial agents, and consideration of immune therapy. The exact management plan is based on an assessment of clinical signs, careful history, and appropriate laboratory findings with consideration of the most likely microorganisms. Treatment should begin as soon as sepsis is suspected due to the newborn's state of immunosuppression. Antimicrobial agents should be started as soon as relevant diagnostic tests have been completed (Anderson-Berry et al., 2015).

Antimicrobial Agents

The selection of antimicrobial agents is based on identification of the microorganism and the infant's response to therapy. Treatment decisions are divided into empirical (suspected sepsis) or definitive (known pathogen). The prudent use of empiric therapy is necessary in this age of increasing resistant organisms in our hospitals and communities. Infectious microorganisms are divided into two broad classes, based on Gram-stain results: gram-positive and gram-negative (Shane et al., 2017). The shape of the microorganism categorizes it as either a coccus or a rod. Generally, the gram-positive organisms respond to broad-spectrum antibiotics, such as penicillin analogues and first-generation cephalosporins (beta-lactamases), and the beta-lactamase penicillins. The gram-negative microorganisms are most often susceptible to aminoglycosides and cephalosporins. Tests must be run to determine the specific sensitivity of a microorganism to the antimicrobial agent selected to ensure that the appropriate agent is prescribed (Shane et al., 2017). In the United States and Canada, empiric therapy for EOS sepsis is generally treated with a combined approach such as intravenous (IV) ampicillin and an aminoglycoside (usually gentamicin); a third-generation cephalosporin should be considered if there is concern for meningitis (Anderson-Berry et al., 2015). This approach provides coverage for the most likely organisms, which include gram-positive organisms such as GBS and gram-negative bacteria such as *E. coli*. If LOS is suspected, antibiotic choices should be based on site of infection and those that are effective against known hospital-acquired infections such as *S. aureus, S. epidermidis,* and *Pseudomonas* species (Simonsen et al., 2014).

Generally speaking, antimicrobial choices are based on organisms known to be present in the local nursery. Gram-positive cocci generally respond to penicillin, unless the microorganism produces beta-lactamase (or penicillinase). The beta-lactamase destroys the penicillin. *Staphylococcus aureus* is a beta-lactamase–producing microorganism and is therefore not responsive to penicillin. A group of semisynthetic penicillins with added side chains are used for treatment of *S. aureus* infection. Of this group, nafcillin and oxacillin are most often used. Other similar drugs are methicillin, dicloxacillin, and cloxacillin. First-generation cephalosporins, such as cefazolin, cephalexin, and cephalothin, are also resistant to beta-lactamase. *Staphylococcus epidermidis* and *S. aureus* strains may be resistant to penicillin, semisynthetic penicillins, and cephalosporins. Methicillin-resistant *S. aureus* (MRSA) is unresponsive to the semisynthetic penicillins. In this case, vancomycin is the drug of choice (Simonsen et al., 2014). It may also be used for *S. epidermidis* and infection related to foreign bodies or invasive procedures. The emergence of resistant strains to available antimicrobial agents is an increasing problem, due to the lack of other safe and effective antimicrobial agents to treat the infection (Shane et al., 2017).

Third-generation cephalosporins are used to treat gram-negative cocci that are penicillin and methicillin resistant. Carbapenems, such as meropenem, may also be considered for extended-spectrum beta-lactamase–producing gram-negative bacilli infections. *Listeria monocytogenes*, a gram-positive rod, generally responds to ampicillin therapy. Aminoglycosides or third-generation cephalosporins are the drugs of choice for gram-negative enteric rods (Shane et al., 2017). Some gram-negative rods are classified according to their lactose fermentation ability. The lactose fermenters, *E. coli* and *Klebsiella*, are sensitive to aminoglycosides and third-generation cephalosporins. *Shigella* and *Salmonella* are nonlactose fermenters, which respond well to ampicillin and third-generation cephalosporins. *Haemophilus influenzae* is usually sensitive to ampicillin and third-generation cephalosporins, although some strains are ampicillin resistant. *Pseudomonas* requires the following combination therapy: aminoglycoside and an antipseudomonal penicillin such as azlocillin, carbenicillin, imipenem, mezlocillin, piperacillin, or ticarcillin (Simonsen et al., 2014).

Two anaerobic microorganisms, *Bacteroides fragilis* (gram-negative) and *Clostridium* (gram-positive), are sometimes the cause of newborn infections. *Bacteroides fragilis* is susceptible to metronidazole (Flagyl), clindamycin, chloramphenicol, and some of the newer beta-lactamases, such as imipenem and ampicillin with sulbactam. Clostridium is usually susceptible to penicillin. A combination of ampicillin or penicillin and gentamicin is useful for antibacterial action against *Streptococcus*, *L. monocytogenes*, and gram-negative enteric rods. This combination of antimicrobial agents has a synergistic effect (in vitro), increasing the efficacy of either drug therapy used alone. Additional therapy or selection of other agents is necessary if staphylococcal infection is suspected, if *Pseudomonas* or *Bacteroides* (most often iatrogenically acquired) is present, if there is an outbreak of resistant organisms, or if prolonged ampicillin and gentamicin therapy has been used (Simonsen et al., 2014). Antimicrobial agents must be reevaluated after completion of cultures and sensitivity testing. Tables 11.1 and 11.2 show generally recommended antimicrobial choices for infections caused by gram-positive and gram-negative microorganisms.

TABLE 11.1

GENERAL ANTIMICROBIAL SELECTION GUIDELINES FOR GRAM-POSITIVE MICROORGANISMS

Microorganism	Antimicrobial
Streptococcus	Penicillin or ampicillin
Staphylococcus aureus	Semisynthetic penicillins, such as methicillin (or methicillin-type), nafcillin, oxacillin, dicloxacillin, cephalin, cephalothin
Methicillin-resistant *Staphylococcus aureus* (MRSA)	Vancomycin
Staphylococcus epidermidis	Vancomycin
Listeria monocytogenes	Ampicillin
Clostridium difficile	Penicillin

TABLE 11.2

GENERAL ANTIMICROBIAL SELECTION GUIDELINES FOR GRAM-NEGATIVE MICROORGANISMS

Microorganism	Antimicrobial
Escherichia coli	Aminoglycosides or third-generation cephalosporins
Klebsiella	Aminoglycosides or third-generation cephalosporins
Shigella	Ampicillin and third-generation cephalosporins
Salmonella	Ampicillin and third-generation cephalosporins
Haemophilus influenzae	Ampicillin and third-generation cephalosporins; some strains are ampicillin resistant
Pseudomonas	Aminoglycoside plus an antipseudomonas penicillin
Serratia	Aminoglycoside plus an antipseudomonas penicillin
Bacteroides fragilis	Metronidazole, clindamycin, some beta-lactamases such as imipenum and ampicillin with sulbactam; and chloramphenicol

TYPES OF NEONATAL INFECTION

This section briefly describes the types of microorganisms that typically cause neonatal infection and their clinical manifestations, diagnosis, and collaborative management. The discussion includes both congenitally acquired and nosocomially acquired infections caused by bacterial, viral, fungal, and protozoal organisms.

Bacterial Infections

Group B *Streptococcus*. Group B beta-hemolytic streptococci were unknown to the perinatal scene until the early 1970s when they replaced *E. coli* as the single most common agent associated with bacterial meningitis during the first 2 months of life. Since the implementation of intrapartum antibiotic prophylaxis (IAP) for prevention of neonatal GBS disease, rates of EOS with GBS have declined; however, GBS sepsis continues to be the most common pathogen in term infants.

Epidemiology. The number of newborn deaths associated with either early-onset or late-onset GBS continues to be high, particularly in high-risk urban centers. Potential for permanent neurologic sequelae for infant survivors of meningeal infections is approximately 15%. The mortality rate of infected newborns varies according to time of onset. Early-onset infection (within the first week of life) has a mortality rate of 8%, which is decreased from 50% in the 1970s; late-onset (after first week of life) mortality is approximately 3% (Nizet & Klein, 2016). Although the incidence of GBS EOS has declined, universal screening and intrapartum antibiotic prophylaxis (IAP) has not resulted in a decline in the incidence or morbidity of LOS. More research is needed related to disparity and the burden of prenatal GBS (Kimberlin, Long, Brady, & Jackson, 2018; Verani, McGee, & Schrag, 2010).

GBS is a gram-positive diplococcus with an ultrastructure similar to that of other gram-positive cocci. It was classified as hemolytic because of its double zone of hemolysis surrounding colonies on blood agar plates. Culture of body fluids, such as blood, urine, CSF, and other secretions, is the most common method of identifying group B streptococci. More rapid techniques, DNA probe assays, LA assays, and nucleic acid amplification assays, such as polymerase chain reaction (PCR), enable a presumptive diagnosis before cultures are returned. Rapid identification of the GBS organism is important in treating colonized pregnant women and in the early diagnosis and treatment of infection in the sick, unstable septic infant. To accurately predict maternal colonization with group B streptococci, both vaginal and rectal areas should be cultured on more than one occasion (Kimberlin et al., 2018; Veranit et al., 2010).

Clinical Manifestations. GBS has been identified as a relatively common cause of mid-gestational fetal loss in women who experience vaginal hemorrhage, PROM, fetal membrane infection, and spontaneous abortion. The rate of stillbirth is reported to be as high as 61% in association with these bacteria. Early-onset neonatal infections with GBS can be asymptomatic or can manifest with severe symptoms of respiratory distress and shock, which can rapidly progress to death (Nizet & Klein, 2016).

Early-Onset Group B *Streptococcus*. Early-onset GBS infection usually appears within the first 24 hours of life and is most common in premature infants. Congenital pneumonia is a more common presentation sign in infants who weigh 1,000 g or less. The most common presentations are pneumonia and meningitis. Signs of respiratory distress, apnea, grunting, tachypnea, and cyanosis are common. Hypotension is found in 25% of newborns with GBS infection; these infants are at risk for cardiopulmonary collapse. Nonspecific signs of infection include lethargy, poor feeding,

temperature instability, abdominal distention, pallor, tachycardia, and jaundice. Experienced nurses may observe that the neonate "just doesn't look right," which is sometimes a critical point for early detection and implementation of therapy. Overwhelming GBS septicemia is often compounded by meningitis. LP and examination of the CSF are the only way to exclude meningeal involvement and therefore represent an important part of the workup. Seizures may occur in infants with GBS meningitis. Low birth weight (LBW) infants have been identified as particularly vulnerable, but a study in Texas revealed a high incidence of infection in term newborns. These infants had no risk factors for infection; therefore, there was a delay in identification and treatment. The mortality rate in these term newborns was 14% (Nizet & Klein, 2016).

Late-Onset GBS Infection. Late-onset infection with GBS usually occurs in term newborns 7 days to 12 weeks of age. The fatality rate is less than that with early-onset infection, but meningitis may lead to permanent neurologic damage, varying in severity from mild handicaps to severe impairment. Complications include global or profound intellectual disability, spastic quadriplegia, cortical blindness, deafness, uncontrolled seizures, hydrocephalus, and diabetes insipidus. Thus, early treatment is an important part of the prevention of long-term serious sequelae. An infant with a positive blood culture can often be asymptomatic initially. The diagnosis of GBS infection is complicated because signs and symptoms of neonatal infection are not specific and symptoms may represent other conditions of the neonate. For example, apnea may be a symptom of CNS immaturity in the preterm neonate, but it is also associated with infection. The caregiver must have a high index of suspicion for infection in all conditions involving the neonate. Infection should be considered in the differential diagnosis of most newborn illnesses. Screening tests, such as CBC with differential, are often used to identify the need for further evaluation for infection. Abnormal results indicate the necessity for definitive testing and implementation of antimicrobial therapy.

Treatment. Regional and hospital differences in infectious agents must be considered in the selection of antimicrobial therapy. Before culture results are returned, administration of a broad-spectrum penicillin and an aminoglycoside provides coverage for the most prevalent microorganisms. Generally, ampicillin and gentamicin are selected until culture results and sensitivities are available. Although most strains of GBS are resistant to aminoglycosides, there is a synergistic effect observed when gentamicin and ampicillin are used in combination until these results are known. GBS is generally very sensitive to penicillin G, and, in many institutions, penicillin G is substituted for ampicillin once the diagnosis is made. It is acceptable practice to discontinue gentamicin when cultures confirm GBS infection. Therapy is maintained for 7 to 10 days for uncomplicated bacteremia or pneumonia and 14 to 21 days for meningitis (Edwards, Nizet, & Baker, 2016; Simonsen et al., 2014). The LP may be repeated midway or at the end of therapy to ensure that there are no microorganisms remaining in the CSF. Fluid management, volume expansion, and appropriate antimicrobial therapy are the key components of nursing care. Infants with GBS infection are often very labile and do not tolerate frequent interventions. Minimal handling is sometimes required for their care.

Prevention. The most potentially lasting method for prevention of early- and late-onset infections, as well as maternal morbidity associated with GBS, appears to be active immunization of all women of childbearing age, either before pregnancy or late in pregnancy (at ~7 months gestation). Passive transmission of antibodies to the newborn occurs via the placenta; however, women often deliver infants prematurely, before the successful transmission of appropriate protective antibodies. Because 65% to 85% of all infants with GBS disease are born at term, vaccines given to women early in the third trimester could prevent up to 95% of these infections. The cost of developing a suitable vaccine would probably be less than the cost of the care required by the critically ill newborn and the chronically ill, debilitated, severely handicapped newborn. To date, there are no licensed maternal vaccines for neonatal GBS prevention, although much research has been done and development is progressing (Edwards et al., 2016).

Staphylococcus. *Staphylococcus* is another gram-positive bacteria. From the 1950s to the 1970s, coagulase-positive *S. aureus* was the main organism identified as a pathogen in hospitals. In the 1980s, coagulase-negative organisms, in particular *S. epidermidis*, were discovered to be equally important.

Epidemiology. These organisms have caused many serious and even fatal infections in newborns. Critically ill and preterm newborns are already immunocompromised and therefore are especially vulnerable to infections. Open skin lesions, surgical incisions, or puncture wounds caused by diagnostic tests or procedures are conducive to bacterial growth, especially *S. aureus* or *S. epidermidis*. Nosocomial infections may also be transmitted to the neonate through contaminated articles or from the hands of healthcare providers. Overgrowth of *S. epidermidis* may occur in nurseries where an attempt has been made to reduce colonization of *S. aureus*. Development of resistant organisms is a risk for critically ill or preterm infants who require extensive invasive treatments. CoNS or MRSA have a potential for causing a wide variety of significant clinical syndromes including those with high mortality. Staphylococci release endotoxins that have systemic effects, including alterations in the skin's protective layer. Scalded skin syndrome is one of the most common examples of this effect (Bradley & Nizet, 2016).

Treatment. Management and supportive therapy for staphylococcal infection are initially the same as for infection with group B streptococci. Antimicrobial therapy begins with ampicillin and gentamicin. Once definitive cultures and sensitivities are available and if the organism is ampicillin resistant, the drug of choice is one of the synthetic penicillins: oxacillin, methicillin, cloxacillin, dicloxacillin, or nafcillin. If the organism is methicillin resistant, the best available drug is vancomycin. It is essential that the choice of antimicrobial agent be carefully made and reconsidered when culture results are available.

Escherichia coli. *E. coli* is second to GBS as the most common cause of EOS and is the most common cause of gram-negative infection in the newborn.

Epidemiology. *E. coli* is associated with preterm delivery, LBW, prolonged ROM, intrapartum fever, and maternal chorioamnionitis (Mendoza-Palomar et al., 2017). As with other maternal organisms that are associated with the GI tract, coliform organisms are common in the maternal birth canal, causing a high incidence of colonization in the lower GI or respiratory tract of newborns during labor or at delivery (Nizet & Klein, 2016).

Treatment. Uncomplicated bacteremia due to susceptible organisms should be treated for 14 days following the first negative culture while meningitis should be treated for a minimum of 21 days. Although there appears to be increasing resistance to ampicillin and gentamicin in the United States, this combination remains the best choice for empiric therapy (Simonsen et al., 2014). Use of third-generation cephalosporins for empiric therapy is not recommended due to increasing resistance unless gram-negative meningitis is highly suspected (Leonard & Dobbs, 2015). **Emergency Alert: Due to increasing ampicillin resistance patterns, it is important to follow blood culture sensitivities when treating organisms with ampicillin.**

Listeria monocytogenes

Epidemiology. *L. monocytogenes*, a gram-positive rod, has been recognized as a cause of perinatal complications since the early 1900s. In the United States during 2009 to 2011, 1,651 cases were reported to surveillance systems with a case-fatality rate of 21%. Those at greatest risk are older adults, pregnant women, and immunocompromised individuals. *Listeria* is found in birds and mammals, including domestic and farm animals, and in unpasteurized milk, soil, and fecal material (Kollmann, Mailman, & Bortolussi, 2016; Leonard & Dobbs, 2015).

Clinical Manifestations. A mother infected with *Listeria* commonly has flulike symptoms, including malaise, fever, chills, diarrhea, and back pain. It is also possible to contract the infection and remain asymptomatic or have only minor symptoms. If contracted between 17 and 28 weeks' gestation, *Listeria* can cause fetal death or premature birth of an acutely ill newborn who may develop EOS or LOS or meningitis. However, early maternal treatment with IV ampicillin and gentamicin has been associated with a normal newborn outcome. Infection late in pregnancy may cause the infant to be born with a congenital infection, usually pneumonia. Mortality rates are high but are usually related to the degree of prematurity. Late-onset listeriosis, which can occur up to 4 weeks after delivery, can easily result in meningitis. A term newborn with listeriosis has less chance of dying but often suffers complications of hydrocephalus and intellectual disability. However, in either preterm or term neonates in whom meningitis develops, there is a 70% mortality rate if treatment is delayed. Newborns infected with *Listeria* may be meconium-stained (or have brown-colored amniotic fluid), exhibit apnea and flaccidity, have a papular erythematous skin rash and hepatosplenomegaly, and be poor feeders. Preterm birth associated with the appearance of meconium staining of amniotic fluid should always be considered suspicious for listeriosis (Kimberlin et al., 2018; Kollmann et al., 2016).

Treatment. Intrapartum administration of antibiotics may decrease fetal morbidity and mortality rates. Ampicillin in combination with an aminoglycoside is the most common treatment. Investigators have shown that newborn survival rates are significantly different if the mother as well as the infant receives treatment (71% vs. 29%; Kollmann et al., 2016). Treatment for bacteremia is typically 14 days, whereas meningitis is treated for 21 days. It is suggested to perform diagnostic imaging of the brain near the end of the anticipated treatment course to evaluate if prolonged therapy is needed for parenchymal involvement of the brain. Careful handwashing is a very important aspect of caring for the infant infected with *Listeria*. Institutional policy may require that the infant be isolated for the first 24 hours of life, until the antibiotics are on board. The mother's urine, stool, and lochia should be cultured, and if positive, she should be given ampicillin. Listeriosis often presents suddenly in the last trimester of pregnancy, precipitating an unexpected preterm delivery. Extensive emotional support may be necessary for the mother and family. In the United States, listeriosis is a nationally reportable disease for state or local health departments (Kimberlin et al., 2018).

Neonatal Meningitis

Epidemiology. Meningitis is commonly associated with newborn infection. The single most important factor in the enhanced risk for sepsis or meningitis in the newborn is LBW (Nizet & Klein, 2016). Mortality rates have decreased over the past decades but remain estimated at 10% to 20%. Meningitis can be associated with both early- and late-onset infection but is more common as a complication of late-onset infection (Leonard & Dobbs, 2015). In most cases, meningitis results from bacteremia. Thus, an inoculation of organisms may pass the blood–brain barrier and infect the CSF.

Although the overall incidence of neonatal bacterial meningitis in developed countries is less than 1%, the incidence is much higher in preterm and VLBW infants. Male infants are more vulnerable to infection and, consequently, meningitis. Female infants have lower rates of respiratory distress syndrome and lower rates of most congenital infections. Geography and socioeconomic factors are influential in patterns of neonatal disease. These differences probably reflect populations served, including unique cultural activities and sexual practices, as well as local customs. It probably also reflects different treatment patterns in local nurseries and variations of antimicrobial selections (Gupta, Roa, Al-Mufti, & Roychowdhury, 2018).

Clinical Manifestations and Diagnosis. Initially, the infant with meningitis presents with signs and symptoms of generalized infection. In addition, the meningeal irritation results in increased irritability, alterations in consciousness, lethargy, tremors or twitching, seizure activity, and diminished muscle tone. Focal signs include hemiparesis, horizontal deviation of the eyes, and some cranial nerve involvement. Bulging fontanelles may or may not be a presenting finding due to the flexibility of the cranial sutures (Nizet & Klein, 2016). The most common organisms responsible for bacterial meningitis are GBS (50%), *E. coli* (20%), and *L. monocytogenes* (5%–10%). Herpes simplex virus (HSV) is a major cause of neonatal viral meningitis and carries a 50% risk for neurologic sequela (Gupta et al., 2018). Cytologic tests on the CSF can identify the presence of an inflammatory response. A Gram stain of the CSF fluid should be prepared and other appropriate cultures obtained. High CSF protein and low glucose levels are also indicators of meningitis, although parameters may overlap between those with and without meningitis. As with all procedures in the neonate, the LP presents risks, which must be weighed against the benefit of having a CSF culture. Often the preterm infant may be considered so critically unstable that the LP is deferred (Leonard & Dobbs, 2015).

Treatment. The selection of antimicrobial therapy for meningitis is based on the causative microorganism. Supportive therapy is necessary for the newborn with meningitis. Acute observation and monitoring of vital signs and activity level are crucial. Infants who become critically ill with meningitis may deteriorate quickly and need rapid, acute interventions. Infants often require long-term antibiotic therapy, and often, venous access is a problem. Placement of a percutaneous line for parenteral nutrition may be necessary. Families need educational and emotional support during long-term hospitalizations, particularly if complications develop. Because signs and symptoms of neonatal infection are nonspecific and are often the same, with or without meningitis, it is imperative to begin empiric therapy once suspicion is established. Empiric therapy for sepsis of unknown etiology remains initiation of broad-spectrum antibiotics, generally ampicillin and gentamicin. When meningitis is highly suspected, cefotaxime is also used. It is important to realize that cephalosporin-resistant strains of many gram-negative bacteria are emerging. Resistance of *E. coli* and *Klebsiella* species to ampicillin, gentamicin, and the cephalosporins continues to make treatment choices more difficult (Gupta et al., 2018).

Prevention. Preventive measures are in place for the most common causes of neonatal meningitis. GBS prophylaxis and IAP for mothers who tested positive for GBS or have certain risk factors has shown a steady decrease in EOS GBS sepsis and meningitis. Control measures for *Listeria* and *E. coli* include avoidance of certain foods by pregnant women as well as those who may become pregnant. Foods that are known to be at risk for being contaminated with listeria include soft cheeses made with unpasteurized milk, uncanned smoked seafood, and unpasteurized milk. The

food industry must be strict with the handling of foods in order to prevent the growth of *Listeria* and *E. coli*. The most likely foods for contamination are raw sprouts, melons, and meats such as hot dogs, deli meats, and cold cuts (Gupta et al., 2018).

Prognosis. Mortality from neonatal meningitis has decreased dramatically with higher rates among preterm infants; substantial neurologic morbidity continues to be seen among survivors. Complications of neonatal meningitis include mental and motor problems, seizure disorders, hydrocephalus, hearing loss, blindness, and abnormal speech patterns. It is estimated that 21% to 38% will have mild deficits and 24% to 29% will have severe neurologic sequelae (Leonard & Dobbs, 2015).

Congenital TORCH Infections

The microorganisms most often responsible for congenitally acquired infections have been grouped together as the TORCH infections. These include toxoplasmosis, others, rubella, cytomegalovirus (CMV), and herpes. The "others" category includes various microorganisms that have been responsible for congenital infections. However, the list of microorganisms implicated in congenital infections has grown, so the acronym is no longer inclusive. A more appropriate acronym, ToRCHES CLAP, is suggested by Maldonado et al. (2016). This new acronym includes: **To**, *Toxoplasma gondii*; **R**, rubella; **C**, CMV; **H**, HSV; **E**, enteroviruses; **S**, syphilis (*Treponema pallidum*); **C**, chickenpox (varicella-zoster virus [VZV]); **L**, Lyme disease (*Borrelia burgdorferi*); **A**, acquired immunodeficiency syndrome (AIDS/HIV); and **P**, Parvovirus B19 (Maldonado et al., 2016).

Toxoplasmosis. Initially thought to be an animal disease, the clinical importance of the parasite *T. gondii* in humans gained importance throughout the 1900s. Toxoplasma is a pathogen that is ever present in nature worldwide (Peyron, Wallon, Kieffer, & Garweg, 2016). The life cycle of Toxoplasma is complicated. The predominant host of this organism is the ordinary house cat that has ingested contaminated meat or fomites excreted by other infected cats; however, other animals, such as farm animals (cows, pigs, and sheep), can become infected if they ingest food or water containing cat feces with oocytes present (Kaufman & Manzoni, 2015). The oocyte form of the parasite persists in soil contaminated by cat feces.

Epidemiology. Congenital toxoplasmosis is transmitted from the mother to the fetus after ingestion of undercooked meat or food or from fomites in cat feces. Risk of infection by the pregnant woman is related to certain activities such as changing litter boxes, playing with children in sandboxes, and gardening in soil used by cats. Congenital toxoplasmosis is almost exclusively the result of primary maternal infection. Transmission rate during pregnancy is directly related to the gestational age of the fetus when maternal infection occurs (lowest during the first trimester increasing up to as high as 60% transmission during the third trimester). On the other hand, there is an inverse relationship between timing of infection and fetal damage (first trimester infection will have more devastating fetal effects compared with third trimester acquisition; McAuley, 2014). The risk of infection when the mother was infected prior to pregnancy is extremely low, except in the immunocompromised woman (McLeod, VanTubbergen, & Boyer, 2016). After infection in the mother, the microorganisms invade and multiply within the placenta and eventually enter the fetal circulation. The greatest risk is when a nonimmune pregnant woman is exposed to *T. gondii* during fetal organogenesis (weeks 4–8 of gestation), when the risk for congenital anomalies is high. In the United States, approximately 20% to 70% of the population has been exposed to this protozoan. There is wide variability in the prevalence of seropositive women of childbearing age among countries, geographic regions of the same country, and ethnic origin; different cultural practices regarding food are probably the major cause of this difference. Since meat is the main vector for transmission, areas where there is less *T. gondii* present in meat because of improved methods for processing or cooking meat have lower prevalence rates (Peyron et al., 2016).

Clinical Manifestations and Diagnosis. Acute toxoplasmosis in a pregnant woman often goes undetected and undiagnosed because the signs and symptoms are not severe. Clinical questioning after the identification of an infected newborn or infant often leads to reflection and memories of a period of enlarged lymph nodes and fatigue without fever. Women sometimes report a mononucleosis-like or flulike syndrome that may have a febrile course, with malaise, headache, fatigue, sore throat, and sore muscles. These symptoms may persist for several months. A newborn with congenital toxoplasmosis can present with the classic triad of hydrocephalus, chorioretinitis, and intracranial calcifications, especially in infants of mothers who were not treated during pregnancy. There are a wide variety of clinical signs in the scope of the disease and many of these closely mimic congenital CMV. The newborn can appear normal at birth, or exhibit severe erythroblastosis, hydrops fetalis, and other clinical signs. Neurologic signs similar to encephalitis (e.g., convulsions, bulging fontanelles, nystagmus, and increased head circumference) may be the only significant presentation of this clinical problem. If the newborn receives treatment, signs may disappear, allowing normal cerebral growth and development, if there was no permanent neurologic damage (McLeod et al., 2016; Peyron et al., 2016).

Mild cases of the disease may not be recognized in the newborn period. Signs of delayed onset of disease in premature newborns include severe CNS or eye lesions appearing at 3 months of age. In term newborns, delayed disease may occur in the first 2 months of life and is usually mild. Clinical signs include generalized infection, enlarged liver and spleen, late-onset jaundice, enlarged lymph nodes, or late-onset CNS problems, including hydrocephalus and chorioretinitis. Infants with congenital toxoplasmosis may have new lesions appearing until age 5 years (Peyron et al., 2016). When congenital toxoplasmosis is suspected, neonatal peripheral blood for Toxoplasma IgG and IgM immunosorbent agglutination assay should be sent to a reference laboratory. Serum transaminase tests and a CBC with differential should also be obtained (Kimberlin et al., 2018).

Treatment. Treatment for congenital toxoplasmosis is pyrimethamine plus sulfonamides. The suggested dose is 2 mg/kg/day orally for 2 days followed by 1 mg/kg/day for 2 or 6 months, then 1 mg/kg/day every Monday, Wednesday, and Friday for a 12-month total duration of treatment. Sulfadiazine is given in doses of 100 mg/kg/day in two divided oral doses. Leucovorin 10 mg is given three times weekly during and for 1 week after pyrimethamine therapy to minimize toxicity. Close monitoring is necessary during therapy due to the possibility of toxicity. Corticosteroids are given in the form of prednisone at 1 mg/kg/day in two divided doses until there is resolution of elevated protein in CSF or active chorioretinitis. As expected, it is evident that the outcome for infants with congenital toxoplasmosis is much better when treatment is given than for those without treatment (Kimberlin et al., 2018; Peyron et al., 2016). Nursing management is supportive and dependent on the severity of the infection. Neurologic impairment at birth can be significant, requiring ventilation and seizure control.

Prevention. The best and most effective treatments are prevention and early recognition. The cost-effectiveness of pregnancy serology screening depends on the costs of the tests and the estimated cost of treating the infection, if identified early. At present, in the United

States, screening is done erratically and there are no particular screening standards. Counseling education for the prevention of toxoplasmosis in seronegative women should focus on avoidance of raw meat and use of gloves during feline litter box handling and during gardening in what may be contaminated soil. Toxoplasmosis cannot be contracted by merely handling or being around a cat, so it is not necessary for the family cat to be banished. It is imperative for pregnant women to inform their healthcare provider if they experience any signs that could be attributed to *T. gondii* infection. Transmission of toxoplasmosis in humans occurs only from mother to child; therefore, the risk to healthcare personnel is negligible. There is a theoretical risk from contaminated urine, however (Kimberlin et al., 2018).

Rubella. Rubella (German measles) is usually a mild disease of infants and children involving a variable rash and fever; it is more severe and associated with more complications in adults. The clinical significance for infants is transplacental infection leading to congenital rubella syndrome (CRS). CRS is commonly recognized as a constellation of defects seen in a newborn with congenital rubella infection. These include a combination of ophthalmological defects, congenital heart defects, and hearing loss, with or without CNS complications (Mason, 2016; Reef & Plotkin, 2016).

Epidemiology. The spread of endemic rubella, and consequently CRS, has been eliminated in the United States. The only reported cases of rubella appear to have been imported from countries where the disease remains endemic. Prior to the initiation of the rubella vaccine in 1996, the incidence of rubella was 78% higher and the incidence of CRS was 69% higher than after 1996. A two-dose regime was implemented following a resurgence of both rubella and CRS between 1989 and 1991. This new schedule has been successful in controlling the disease in the United States but elimination of rubella has not been achieved nationally. Due to this, high levels of immunity must be maintained in the United States (Mason, 2016; Reef & Plotkin, 2016).

Most cases of CRS occur after a primary maternal infection with subsequent viremia and intrauterine transmission. Effects on the fetus are related to the timing of the infection during the pregnancy. First trimester infection carries the highest morbidity for the fetus. There may be fetal death, stillbirth, or CRS. Some fetuses are unaffected and not all affected fetuses develop CRS. The placenta is an effective barrier during the 12th to 28th weeks; however, the fetus is very vulnerable in the first and third trimesters (Baley & Gonzalez, 2015).

Clinical Manifestations and Diagnosis. A presumptive diagnosis of CRS should be high on the differential diagnosis list for any infant born to a mother with documented or suspected rubella during her pregnancy. The diagnosis should also be considered for any infant with presenting signs known to be associated with CRS. The abnormalities most commonly associated with CRS are auditory (e.g., sensorineural deafness), ophthalmic (e.g., cataracts, microphthalmia, glaucoma, chorioretinitis), cardiac (e.g., patent ductus arteriosus, peripheral pulmonary artery stenosis, atrial or ventricular septal defects), and neurologic (e.g., microcephaly, meningoencephalitis, intellectual disability). In addition, infants with CRS frequently exhibit both intrauterine and postnatal growth restriction. Other conditions sometimes observed among babies who have CRS include radiolucent bone defects, hepatosplenomegaly, thrombocytopenia, and purpuric skin lesions. Newborns who are moderately or severely affected by CRS are readily recognizable at birth, but mild CRS (e.g., slight cardiac involvement or deafness) may be detected months or years after birth, or not at all (Baley & Gonzalez, 2015; Mason, 2016; Reef & Plotkin, 2016).

The possibility of subclinical infection with rubella highlights the need for laboratory confirmation. Attempting to isolate rubella virus in tissue culture is very valuable in the diagnosis of CRS. The virus is readily obtainable from the posterior pharynx with less reliability from specimens obtained from the conjunctivae, spinal fluid, or urine. Specimens should be obtained as soon as CRS is suspected as viral shedding decreases during infancy. The detection of rubella antibody confirms the presence of the infection. Cord serum is a reliable source of assay for the presence of rubella-specific IgM because IgM is fetally derived. Rubella-specific IgG persists for life and can be detected by enzyme immunoassay (EIA). Demonstration of rubella-specific IgM in fetal blood obtained by cordocentesis has been used to establish diagnosis in utero. Chorionic villus sampling has also demonstrated recovery of the virus during the first trimester (Baley & Gonzalez, 2015; Reef & Plotkin, 2016).

Treatment. Unfortunately, there are no specific treatment modalities available for either rubella or CRS. Treatment is supportive and related to the associated complications. CRS is not a static disease and the primary physician must take efforts to define the extent of the associated problems and coordinate efforts to maintain a broad, multidisciplinary approach to the infant's care. Ongoing care of an infant with CRS involves follow-up and evaluation by pediatricians, cardiologists, audiologists, ophthalmologists, and neurologists. Hearing screens are particularly important, as intervention is known to improve outcome in hearing (Mason, 2016).

Prevention. The primary goal in the United States is to eliminate rubella with vaccination as active immunization is the only practical means to prevent CRS. Control techniques include isolation of those infected with rubella. Patients are considered infectious from the seventh day before onset of symptoms to the fifth to seventh day after onset of rash. Children with CRS are considered infectious for the first year unless repeated pharyngeal or urine cultures are negative (Reef & Plotkin, 2016). Reports of rubella epidemics in Japan, Poland, and Romania, with cases of CRS, are mostly attributed to cost, lack of public awareness, and public health commitments (Lambert, Strebel, Orenstein, Icenogle, & Poland, 2015). These recent epidemics highlight the importance of possible resurgence as a result of misunderstandings and parental refusal for vaccinations during childhood. There is much speculation that the incidence of many preventable infections will increase as a result of parental refusal of childhood immunizations. It will be prudent to follow any trends.

Cytomegalovirus. CMV, a member of the herpes family, is the most common congenital viral infection in developed countries. CMV is a DNA virus covered with a glycoprotein coat that closely resembles the herpes virus and VZV.

Epidemiology. CMV infection is endemic and, although it has been identified in the great apes, it is believed that humans are the only host. By adulthood, most people have been exposed to CMV, and antibodies have developed to it. CMV infection is more prevalent in lower socioeconomic groups and is especially common in developing countries. In the United States, CMV prevalence is thought to be 58.9% with racial differences noted. African American and Hispanic populations show higher seroprevalence than do white populations. The virus is usually transmitted from person to person through body fluids and secretions. Blood, urine, breast milk, cervical mucus, semen, and saliva harbor CMV. The virus can cause an infectious mononucleosis-like syndrome, with general malaise, liver complications, fever, and general fatigue (Baley & Gonzalez, 2015; Britt, 2016). Transplacental transmission is directly related to advancing gestational age with up to 75% risk during the third trimester. Congenital infection is associated with more severe sequelae when acquired during the first half of pregnancy (Kimberlin et al.,

2018). Although infection of the fetus can occur at any time during pregnancy, the risk of malformations and developmental delays is most common during the period of organogenesis (Baley & Gonzalez, 2015). Perinatal transmission can occur within 2 to 3 days of infection by transplacental crossing of the organism. The fetus can also contract the virus intrapartally from infected maternal cervical secretions while descending through the birth canal. CMV can also be transmitted through infected breast milk. CMV infection may occur at any stage of gestation and is not always the result of a primary maternal infection. Congenital CMV occurs in approximately 0.15% to 2% of all newborn infants (Britt, 2016).

Clinical Manifestations and Diagnosis. Congenital CMV is divided into two categories, symptomatic congenital CMV and asymptomatic congenital CMV. The majority of infants identified with congenital CMV will not present with symptoms at birth (asymptomatic). Infants who do not present with symptoms at birth generally have a better prognosis; however, approximately 10% will develop sensorineural hearing loss (SNHL). Congenital CMV infection is the leading nongenetic cause of SNHL in the United States, occurring in up to 50% of children with symptomatic illness at birth (Kimberlin et al., 2018). These infants require close follow-up for neurologic and motor defects as well as chorioretinitis. Symptomatic disease is most often accompanied by intrauterine growth restriction, microcephaly, periventricular calcifications, SNHL, chorioretinitis, congenital cataracts, profound intellectual disability, hepatosplenomegaly, and jaundice (Boppana, Ross, & Fowler, 2013; Britt, 2016; Swanson & Schleiss, 2013).

Suspicious clinical findings or obstetric history warrant further investigation for CMV infection. Diagnosis in the neonate can be confirmed by viral detection in bodily fluids or PCR, culture, or antigen testing. Preferred specimens include urine and saliva due to the high viral load found in these specimens. After the first 3 weeks of life, congenital versus postnatally acquired disease cannot be distinguished. IgG and IgM antibody titers cannot reliably be used in diagnosis. Elevated IgM in the first 2 weeks of life reflects fetal antibody response to CMV; however, after 2 weeks, elevated titers may be related to postnatal acquisition of the virus. Elevated neonatal IgG titers may reflect seropositive status of mothers with the IgG antibodies becoming undetectable between 4 and 9 months in the uninfected infant; in the infected infant, these antibodies persist for a much longer interval (Britt, 2016; Kimberlin et al., 2018; Swanson & Schleiss, 2013).

Treatment. Newborns infected with CMV display a wide range of signs and symptoms. General supportive therapy is based on the presence of these clinical manifestations. Treatment with antivirals offers the best outcome for infants with symptomatic CMV. The most beneficial treatment is ganciclovir, whose structure is similar to that of acyclovir (ACV). This drug has been found to be generally safe and well tolerated by newborns. IV therapy is typically started until a PCR response is noted; therapy can then be completed by oral route with valganciclovir. It is important to involve an infectious disease specialist, who can follow the infant after discharge and recommend length of needed therapy (Britt, 2016; Kimberlin et al., 2018; Swanson & Schleiss, 2013). IV immunoglobulin therapy provides passive immunity to at-risk infants but not to those already infected. Two live attenuated vaccines for CMV have been developed and tested on renal transplant patients. Theoretically, these vaccines would be useful preconceptionally or perinatally to prevent vertical transmission; however, only limited research has been done with this population. Chemotherapy offers the most promise for treatment of neonatal CMV infection; however, clinically, it has not been shown to be effective in improving long-term outcome (Britt, 2016; Swanson & Scheiss, 2013).

Prevention. CMV is a common and often undiagnosed infection. Prevention of spread of the virus is virtually impossible due to the lack of symptoms in most hosts. Careful surveillance of childbearing women will assist in recognizing the risk of infection in the newborn. Hospital workers who are of childbearing age are often concerned about their risk for contracting CMV from their virus-shedding patients. Generally, this risk is dependent on the prevalence of CMV secretion, the susceptibility of the worker, and the degree of exposure. Since implementation of universal precautions, the risk of nosocomial transmission of the virus has been very low and is considered lower than the risk of acquiring the infection in the community (Britt, 2016). Transmission of CMV via infected blood products has been significantly decreased through the use of CMV-negative donors or irradiation of blood products. Premature and LBW infants are especially vulnerable to the infusion of this virus in blood products. The best method of prevention is the institution of universal precautions, including good handwashing techniques.

Herpes Simplex Virus.

HSV Types 1 and 2 are members of a family of large DNA viruses. Common sites of infection include the skin, oral mucosa, eyes, and genital tract. Although these two types are capable of causing primary infection at any site, Type 1 is more likely to cause recurrence at oral mucosal sites and Type 2 has a greater propensity for recurrence at genital sites (Stanberry, 2006).

Epidemiology. Neonatal infection can result from either type with a worldwide estimate of 75% of cases caused by HSV Type 2 and 25% of cases of Type 1 (Allen & Robinson, 2014). HSV possesses the quality of "latency," whereby the virus can persist in a latent state for a period of time and then be reactivated by certain stimuli. A strand of the viral DNA persists in an infected individual for a lifetime; thus, the virus maintains a "foothold" in its host. Clinical experiences demonstrate that, after primary HSV infection, at the site of the infection (perhaps an oral or genital site) the microorganism invades the sensory nerve endings and remains there (Kimberlin & Gutierrez, 2016). Primary infections appear to be more severe as the host is seronegative. Potential stimuli for HSV reactivation include periods of stress, emotional trauma, and prolonged exposure to the sun (Baley & Gonzalez, 2015). Maintenance of the latency state and recurrence of the virus are topics of intense current research. There are many unanswered questions about what triggers latency and about the cofactors for reactivation of the virus.

Greater than 90% of neonatal HSV infection is the result of maternal–fetal transmission, with up to two-thirds of cases occurring in women with an asymptomatic primary infection. Transmission of the infection to the fetus can be caused by passage through infected genital secretions in the intrapartum period or by ascending infection from the vaginal vault via ruptured (or not) membranes. Many women can be asymptomatic and still be shedding HSV. Recurrent infections are the most common problem in pregnancy. The risk is greater with primary or non-primary first infection than with exposure from a recurrent infection. Although primary infection is less common, it causes the most severe neonatal disease, most likely including CNS problems, disseminated disease into other organ systems, and probable death. During a primary maternal genital infection there is a higher viral load, prolonged viral shedding, and little or no passive maternal antibodies resulting in higher incidence of fetal or neonatal infection. The incidence of intrapartum transmission with a primary infection or non-primary first infection is approximately 30% to 50%. Many neonatal complications such as prematurity, intrauterine restriction, and respiratory distress syndrome can potentiate the neonate's illness, limiting the ability

to fight off HSV. There is a broad range of severity of neonatal infection, from severe to benign and asymptomatic. HSV is the most reported cause of fatal encephalitis in both children and adults (Stanberry, 2006).

Intrapartal transmission is more likely to occur in the presence of ruptured membranes. Other risk factors include intrauterine fetal monitoring, fetal scalp sampling, and other instrumentation such as forceps or vacuum-assisted delivery. It is recommended that women infected with HSV not be monitored by these methods (Baley & Gonzalez, 2015). Transmission from mother to infant from an infected breast lesion has been reported. Transmission has also been documented from oral lesions.

Clinical Manifestations and Diagnosis. Acquisition of HSV in utero can result in spontaneous abortion, preterm birth, or a normal baby. Clinical manifestations of the disease are broad and are related to the initial site of infection or category. The clinical presentation of the congenital acquisition of the infection includes skin vesicles or scarring, hypopigmentation, chorioretinitis, microcephaly, and hydranencephaly. There are three categories of neonatal HSV disease. These categories may occur in isolation or there can be overlap of presentation. The first category, the most common, includes patients with localized infections of the skin, eyes, or mouth (SEM disease). The typical skin finding is a cluster of discrete vesicles on an erythematous base. The second category includes patients with encephalitis (CNS disease). In this group, neurologic sequelae occur in approximately 50% and mortality is high in untreated HSV encephalitis. Approximately one-third of these patients do not have skin vesicles, and they are identified by history alone. CSF is positive for the virus in 25% to 40% of these cases. Presence of cells and increased protein are very common in the CSF of patients with encephalitis. The third category of neonatal patients includes those with disseminated disease characterized by irritability, seizures, respiratory distress, jaundice, DIC, shock, and other symptoms of viral and bacterial infection. All major neonatal organs may be involved. Liver and the adrenals are the most common reservoirs for the virus. The CNS is involved in 70% to 90% of affected neonates. In greater than 40% of the newborns with disseminated disease, skin vesicles do not develop or develop late, making identification of positive infants more difficult. The mortality rate for untreated disseminated disease is greater than 80%, making early and accurate diagnosis a priority in the ill newborn (Baley & Gonzalez, 2015; Kimberlin & Gutierrez, 2016). **Emergency Alert: HSV infection should be considered in any clinically ill, septic appearing neonate with negative bacterial cultures. Fever is also highly suggestive, especially within the first 3 weeks of life.**

Expert consultation is important in the early stages of identification and evaluation. Laboratory tests are available to differentiate HSV infection from other bacterial and viral infections but must be interpreted with consideration of the clinical context (Allen & Robinson, 2014). Routine surface cultures of the newborn from oral mucous membranes, rectum, nasopharynx, and conjunctivae should be delayed to 24 to 48 hours after birth to differentiate viral replication from transient colonization of the newborn at birth. Earlier testing from these sites may confound the results (Baley & Gonzalez, 2015; Kimberlin & Gutierrez, 2016). The clinical diagnosis of neonatal HSV is necessary for proper treatment and continuing management. Standard diagnostic tests include CSF PCR and swabs of any vesicular lesions. Serum for HSV PCR may be tested and is showing promising diagnostic value. Positive HSV cultures from non-CNS sites are diagnostic for neonatal HSV infection and remain the gold standard. Viral DNA detection by PCR assay is the gold standard diagnostic method for CNS disease (Kimberlin & Gutierrez, 2016).

Treatment. Early and consistent therapy with IV ACV has been determined to be the standard of care for all three presentation types of neonatal HSV infection. Because definitive results may take days to obtain, treatment must be begun when HSV infection has been suspected. There is convincing evidence that early therapy has the potential to decrease mortality and morbidity and improve long-term outcomes for infants with neonatal HSV infection (Allen & Robinson, 2014; Baley & Gonzalez, 2015; Kimberlin & Gutierrez, 2016). The recommended dose of ACV for neonates is 60 mg/kg/day in three divided doses given every 8 hours, if renal function is normal: for SEM disease, treatment is continued for 14 days. For disseminated or CNS disease, treatment should be continued for a minimum of 21 days, with weekly CSF sampling at the end of 21 days. ACV may be discontinued for suspected SEM disease when it is determined that the infant is not infected and after 21 days of treatment for the infant with CNS involvement who is shown to have negative CSF studies (Allen & Robinson, 2014; Stanberry, 2006). A topical agent should be administered along with ACV in neonates with eye disease (Kimberlin et al., 2018).

Prevention. Great progress has been made in surveillance for, and treatment of, neonatal HSV infection. However, the ideal approach to prevention is prevention of exposure of the fetus to the virus or the newborn to active maternal infection at the time of delivery. There is growing concern about transmission of the virus to unborn children with the concomitant increase in genital herpes as a sexually transmitted disease. Increases in risky sexual practices and the high incidence of HSV type 2 in the United States lead to increasing numbers of women of childbearing age who are at risk for newly acquired infection (Kimberlin & Gutierrez, 2016). The presence of maternal active HSV genital lesions or prodromal symptoms is a contraindication to vaginal delivery. If the membranes have been ruptured 4 hours or longer, cesarean section may or may not prevent transmission to the neonate. Daily use of oral antiviral prophylaxis with valganciclovir or ACV in the last trimester of pregnancy may reduce the risk to the infant and may reduce the number of elective cesarean sections (Baley & Gonzalez, 2015; Kimberlin & Gutierrez, 2016).

Quality and Safety: Postnatal nosocomial transmission is greatly reduced with good handwashing techniques and universal precautions. Hospitalized infected infants must be isolated because viral shedding provides a reservoir for infecting other infants in the nursery. HSV continues to be a life-threatening neonatal infection in the United States. It is important for all healthcare providers in the perinatal arena to maintain a high index of suspicion in infants whose symptoms may be compatible with HSV infection. Early identification allows prompt treatment or necessary continued observation, or both. Continued research may produce a more rapid method of virus identification and perhaps a safe and effective vaccine. Prevention of neonatal HSV depends on improved knowledge regarding the factors of virus transmission between mother and infant (Kimberlin & Gutierrez, 2016).

Primary nursing responsibilities in the management of a family with HSV infection are education and support. Mothers should be educated as to the mode, methods, and possible origins of the HSV, and concerns should be addressed regarding potential transmission to newborns. Nurses are often the first to document a mother's comment that she "had a small bump or blister and fever" right before her infant was born. **Quality and Safety: Careful history taking and thorough questioning can often identify potentially infected patients early.** With the diagnosis of genital herpes and subsequent monitoring procedures, families often feel stigmatized as well as anxious. Parents and responsible family members need education and support. Mothers with a history of genital HSV should be investigated for findings of active infection during the

peripartum period. Breastfeeding is contraindicated if the mother has a lesion on her breast. Infants are not isolated unless they themselves are infected. Many nurseries have guidelines regarding a 24- to 48-hour observation period to check cultures on an infant who was delivered vaginally through an infected genital area. An uninfected neonate does not require prolonged hospitalization, and, on discharge, the family needs information and education. Families should be informed that immediate medical consultation should be obtained with the development of major findings, including malaise, irritability, fever, temperature instability, respiratory distress, apnea, large abdomen or liver, sudden changes in skin color, new skin vesicles, lesions on the mucous membranes, or conjunctivitis. Sudden onset of systemic disease in a small, recovering preterm infant can include DIC and shock. Skin lesions are often absent in these severe cases, which may delay diagnosis (Kimberlin & Gutierrez, 2016).

All family members with active lesions anywhere on the body should be taught careful handwashing techniques to use before handling the baby. Any person with an oral HSV infection who handles the infant must wash well, wear a mask, and not kiss the infant anywhere until the lesions are completely crusted over and healed (Kimberlin & Gutierrez, 2016). The implementation of contact isolation provides healthcare workers as well as other patients with excellent protection against HSV infection in the workplace. Healthcare workers with active oral–facial lesions (cold sores) should take precautions, particularly when caring for high-risk patients such as newborns, immunocompromised individuals, and patients with chronic skin conditions (Stanberry, 2006).

Nonpolio Enteroviruses (EV). The genus *Enterovirus* consists of a broad range of viruses belonging to the family Picornaviride. The original classification system listed the EV into three main groups based on their replication patterns known at the time: Polioviruses, Coxsackieviruses (A & B), and Echoviruses (Abzug, 2014; Cherry & Krogstad, 2016). This section will focus on the nonpolio neonatal diseases caused by coxsackievirus A, coxsackievirus B, and echovirus.

Epidemiology. As the genus name implies, the GI tract is the main site for replication and source of transmission (Abzug, 2014). The EV have a worldwide distribution with seasonal prevalence in the more temperate regions (summer and fall). In tropical climates, there is year wide prevalence. The overall prevalence is difficult to estimate since the nonpolio viruses are not reportable and unrecognized infections mask the known numbers. Experts estimate EV disease incidence to be equal to or exceed that of GBS, HSV, and CMV (Abzug, 2014). Because of the seasonal occurrence, swimming pools may be a threat to children, who are the main susceptible group. Oral transmission is also possible through the air or by ingestion of contaminated materials or by contamination from objects in the environment. The incidence of infection and antibodies in general does not differ between males and females (Cherry & Krogstad, 2016). The human neonate is particularly susceptible in the first 2 weeks of life when associated with maternal illness and prematurity, with this unique group demonstrating a higher incidence in males. Prenatal and perinatal infection is also possible leading to infection of the neonate. The infant may present with typical signs of sepsis, although a wide variety of more serious findings may accompany EV infections (Modlin, 2015). The incubation period is typically 3 to 6 days, except for acute hemorrhagic conjunctivitis with an incubation period of 1 to 3 days. Infected children, both symptomatic and asymptomatic, frequently shed the virus from the respiratory tract for up to 3 weeks, whereas fecal shedding may continue for almost 3 months (Abzug, 2014).

Clinical Manifestations and Diagnosis. Although the majority of infants infected with EV may remain asymptomatic, those with severe disease have devastating disease with death or long-term sequelae resulting. It is important to emphasize that fatal infections account for only a small fraction of all congenital and neonatal EV infections. The most serious infections present with myocarditis, hepatitis, and encephalitis, with pneumonitis being seen less frequently (Modlin, 2015). Unfortunately, pathology reports are only available from postmortem examinations. Because of the similarity of presentation of EV infection with other viral, bacterial, and fungal infections, diagnosis cannot be made based on clinical findings alone, although suspicion may be increased based on time of year, exposure, incubation period, and certain clinical symptoms (Cherry & Krogstad, 2016).

Definitive diagnosis is made by detection of the virus from a variety of sources, including stool, rectal swab, CSF fluid, oral swabs, serum, and urine. PCR assays have a higher sensitivity than viral cultures and provide a quicker turnaround time (Abzug, 2014; Cherry & Krogstad, 2016).

Treatment. There are no approved definitive treatments for EV infections in the United States. Human immune globulin may be offered to infected infants in an effort to boost antibodies, although efficacy for acute illness has not been established. The antiviral drug pleconaril shows promise in neonatal EV infection. Serial studies have demonstrated important evidence that may lead to a treatment option. Pleconaril is not available for even compassionate use in the United States at this time. Supportive therapy is the mainstay of current treatment modalities. Infants who require intensive care may require respiratory support, cardiovascular agents, and eventually heart or liver transplants. Family support and involvement is needed with breastfeeding encouraged (Cherry & Krogstad, 2016; Modlin, 2015).

Prevention. As with any congenital or neonatal disease, elimination of the agent is the only way to eradicate the EV diseases. Vaccine development may be the best direction to follow globally. There has been a 99% reduction in infection with poliomyelitis, mostly because of vaccination, but the disease still exists. Infection control practices are in place and, with careful attention, should be effective in preventing outbreaks in hospital nurseries. When illness is detected, isolation and use of the cohort system is paramount (Cherry & Krogstad, 2016; Nikonov, Chernykh, Garber, & Nikonova, 2017).

Congenital Syphilis. Syphilis is a sexually transmitted disease caused by the bacterium *T. pallidum*. This bacterium is a gram-negative spirochete and is one of the few bacteria that can readily cross the placenta, resulting in fetal infection. Although most cases are the result of transplacental transmission, a few cases may result from contact with genital lesions during the delivery process (Baley & Gonzalez, 2015; Kollmann & Dobson, 2016).

Epidemiology. The World Health Organization (WHO) reports that more than two million pregnancies are complicated by syphilis annually and approximately two-thirds of those pregnancies end in poor outcome (Kollmann & Dobson, 2016). After reaching an historic low between 2000 and 2001, the national rate of syphilis has increased 17.6% to 8.7 cases per 100,000 population during 2015 to 2016. This increase is mostly attributable to sexual practices, particularly among gay and bisexual men (CDC, 2016).

Clinical Manifestations and Diagnosis. Untreated syphilis adversely affects pregnancy outcome. Vertical transmission of treponemas can occur at any time during pregnancy, with the likelihood increasing with advanced gestational age. The microorganisms can cause preterm labor, stillbirth, hydrops fetalis, congenital infection, or neonatal death. The incidence of congenital infection

where the mother was untreated or inadequately treated is highest during the 4-year period following acquisition of primary infection, secondary infection, and early latent disease. When newborns acquire syphilis from hematogenous spread across the placenta, the effects are on the major organ systems of the fetus, especially the CNS. Common presentations of the infected infant are hepatosplenomegaly, jaundice, LBW, intrauterine growth restriction, snuffles, mucocutaneous lesions, anemia, and osteochondritis. There is often a bilateral superficial peeling of the skin (desquamation) on the neonatal palms and soles. Nonimmune hydrops is a common presentation in congenital syphilis. The symptoms of perinatal syphilis are similar to those of any other viral infection that spreads hematogenously from the mother to the placenta and on to the developing fetus (Kimberlin et al., 2018; Kollmann & Dobson, 2016).

The serological status of all women who deliver in a hospital should be determined before the newborn is discharged (Kimberlin et al., 2018). All infants born to seropositive women require, at a minimum, careful physical examination and a nontreponemal test such as the Venereal Disease Research Laboratory (VDRL) slide test and the rapid plasma regain (RPR) test. In the event of a positive nontreponemal test or abnormal neonatal physical examination, further testing, such as chest radiograph, eye examination, liver function tests, neuroimaging, and auditory brainstem response, is required. Because an infant's RPR/VDRL will be positive if born to a RPR/VDRL-positive woman, the titers are more diagnostic than the positive result. The infant's quantitative nontreponemal test is considered significant if the titers are fourfold (or greater) higher than the mothers. A test positive at two dilutions is the same as a fourfold increase. An LP for CSF analysis (including quantitative VDRL) and radiographs of the long bones can further the definitive diagnosis of syphilis in the neonate and should be performed in all cases of probable congenital syphilis. Radiologic changes such as osteochondritis (a blurring of the epiphyseal borders) demonstrate recent fetal infection and periostitis represents prolonged involvement, probably within 16 weeks or second trimester infection (Kimberlin et al., 2018; Kollmann & Dobson, 2016).

Treatment. The recommended treatment for a newborn presumed to be infected with congenital syphilis is aqueous penicillin G. Treatment plans are based on whether the infant is suspected to have or is proven to have congenital syphilis. Treatment guidelines are available on the CDC website (www.cdc.gov/std/syphilis/treatment.htm) and in the 2018 AAP Red Book (Kimberlin et al., 2018). A newborn with an antibody titer four or more times higher than the maternal level should be treated as if a definitive diagnosis has been obtained. For proven or highly probably congenital syphilis, aqueous crystalline penicillin G, 50,000 U/kg, given intravenously every 12 hours for the first week and then every 8 hours after the first week for a total of 10 days is the preferred treatment. When the IV route is not feasible, procaine penicillin G, 50,000 U/kg, intramuscularly (IM) as a single daily dose for 10 days is acceptable. For asymptomatic infants whose mothers were treated adequately during pregnancy, treatment is not necessary unless follow-up cannot be ensured. Some clinicians recommend a single dose of benzathine penicillin: 50,000 U/kg IM, if the infant is not likely to be followed up on. If maternal treatment did not include penicillin and if neonatal follow-up is likely to be unreliable, the neonate is given a full 10-day course (Kimberlin et al., 2018; Kollmann & Dobson, 2016).

Emergency Alert: It is imperative for the physician or nurse practitioner (NP) writing the order for penicillin to be clear on the form of penicillin to use. Aqueous crystalline penicillin G is approved for IV usage. Benzathine penicillin G and procaine penicillin G can only be administered IM. IV administration may cause life-threatening side effects or death.

Isolation of an infant with suspicious symptoms may be necessary until appropriate treatment is given. There is a definite role for nursing education and support in the treatment of an infant exposed to syphilis. The 10-day course of penicillin treatment may lead to the establishment of a trusting relationship between the nurse and family, thus providing an opportunity to give more information regarding sexual risk factors. Families often need encouragement and support to get treatment for other sexual partners and to obtain other necessary medical evaluations (such as HIV screening or drug counseling).

Prevention. Prevention of congenital syphilis is accomplished by prevention of syphilis in childbearing women. Identification and adequate treatment of pregnant women is necessary. Infants with confirmed congenital syphilis should receive careful follow-up evaluations. Regular childhood well-child visits should be ensured. Serologic nontreponemal measurements can be made at follow-up visits with their primary care physician (Kimberlin et al., 2018). In the infant with congenital neurosyphilis, CSF examinations should be done every 6 months, with retreatment as needed, until the studies are normal. The infection can be effectively treated, but the physiologic and developmental prognosis depends on the degree of organ damage sustained during fetal development.

Other Sexually Transmitted Diseases

Gonorrheal Ophthalmia. Ophthalmia neonatorum is the result of infection of the mucous membranes by *Neisseria gonorrhoeae* or *Chlamydia trachomatis;* these infections may be found simultaneously. Neonatal conjunctivitis caused by *N. gonorrhoeae* is the primary concern when maternal gonorrhea has been diagnosed. Although infection of mucosal surfaces is more common in the infant born to an infected mother, scalp abscesses and systemic infection can occur (Embree, 2016).

Epidemiology. *Neisseria gonorrhoeae* is a species of small gram-negative diploid bacteria. Infection with this organism is seen most frequently in young adults less than 24 years of age. Other risk factors include unprotected sex, multiple sex partners, drug and alcohol abuse, and low-income status. In the United States, rates are higher in the non-white communities. In the United States, there were 104.1 cases per 100,000 population in 2011 (Embree, 2016). *Neisseria gonorrhoeae* is the second most reported of sexually transmitted diseases, exceeded only by *C. trachomatis* (Kimberlin et al., 2018). In females, infection may be asymptomatic, which compromises detection of the disease. Neonatal gonococcal conjunctivitis is known to occur in 30% to 40% of cases where maternal cervical infection is present (Leonard & Dobbs, 2015). The incubation period is typically 2 to 7 days; however, gonococcal infection should be considered in any infant with conjunctivitis present after 24 hours of birth (Embree, 2016).

Clinical Manifestations and Diagnosis. Gonococcal conjunctivitis in the newborn has historically been a risk from transmission via the birth canal. Although asymptomatic colonization has been reported, typically the infected infant presents with acute purulent conjunctivitis and edema of the eyelids. Other possible neonatal findings include scalp infection or systemic manifestations including pneumonia, sepsis, osteomyelitis, or meningitis. Untreated, the illness may spread to the connective tissues and cornea (Embree, 2016).

Although conjunctivitis may be obvious based on clinical signs, definitive diagnosis is necessary in planning the management and treatment. Ophthalmia neonatorum from other organisms must be differentiated from conjunctivitis from other organisms. Gram stain of the drainage will reveal the gram-negative diplococcic typical of *N. gonorrhoeae*. This provides a presumptive diagnosis. If Gram stain is positive, cultures should be obtained of the eye drainage as well as from additional mucosal sites in the infant.

Testing of the mother and her sexual partner is essential. Specifics for testing of adults is beyond the scope of this chapter on neonatal illnesses but is a prerequisite for management and treatment of the newborn (Darville, 2016; Embree, 2016).

Treatment. Infants who are delivered to an infected, untreated mother are usually given a complete infection workup, including an LP, and given a single dose of ceftriaxone. Globally, *N. gonorrhoeae* is increasingly resistant to penicillin; therefore, this antibiotic is no longer recommended, unless the specific isolate has been proven to be sensitive. If cultures confirm the presence of the microorganism, the infant should be treated with ceftriaxone, 25 to 50 mg/kg/day (maximum of 125 mg) IV or IM in a single dose for 7 days (10–14 days if meningitis is confirmed). Cefotaxime is recommended for infants with hyperbilirubinemia, especially if born prematurely, because ceftriaxone competes for bilirubin binding sites on albumin (Darville, 2016; Embree, 2016). For gonococcal ophthalmia neonatorum, a one-time single dose of ceftriaxone is recommended to prevent progression to corneal ulceration and/or perforation (Kimberlin et al., 2018). Irrigation of the eyes with a normal saline solution frequently, until drainage is no longer seen, is also an important addition to the management plan. This practice has been shown to decrease long-term consequences. Addition of ophthalmic antibiotic drops has not been shown to improve outcome and is not deemed necessary. Education and support regarding the origin of the infectious agent are important in the treatment of gonorrhea. Sexual partners of infected persons should be encouraged to seek testing and appropriate antibiotic treatment for gonorrhea (Embree, 2016; Kimberlin et al., 2018).

Prevention. Use of silver nitrate solution or erythromycin for the prevention of gonococcal ophthalmia neonatorum is one of the early achievements in preventive medicine. Silver nitrate was discontinued due to the universal development of chemical conjunctivitis. Routine prophylaxis is mandated by law in the United States and has made a significant difference in the treatment of ocular disease if administered within 1 hour of birth. Erythromycin ointment in both eyes is a well-established and efficacious prophylactic practice for the prevention of gonococcal ophthalmia (Embree, 2016). Chlamydia conjunctivitis has become far more common than gonococcal conjunctivitis in the neonate because of the continual screening for gonorrhea.

Chlamydia Conjunctivitis. *Chlamydia* is a genus of intracellular bacteria that may affect virtually all animal species. Although the genus *Chlamydia* is divided into at least four groups, this chapter will focus on the organism *C. trachomatis*. *Chlamydia trachomatis* infection is the most common sexually transmitted disease. Maternal infection may lead to neonatal conjunctivitis and chlamydia pneumonia. Neonatal conjunctivitis can be expected in 30% to 50% of infants born to infected but untreated mothers. Pneumonia caused by *C. trachomatis* will develop in 10% to 20% of newborns of women with active, untreated chlamydia infection. Conjunctivitis will be the focus of this section.

Epidemiology. *Chlamydia trachomatis* is the most common sexually transmitted disease in the Western industrialized nations. Most infected men and women are asymptomatic, leading to underestimation of the prevalence. This is a worrisome fact since this could theoretically support a large reservoir within our societies that can sustain the pathogen. Risk factors are the same as for other sexually transmitted diseases—young age (<20 years), socioeconomically disadvantaged, geography, and number of sexual partners. The infection can present in women as cervicitis, salpingitis, urethritis, or pelvic inflammatory disease. *Chlamydia trachomatis* infection has been identified as causing a significant increase in the incidence of PROM, the number of LBW babies, and the rate of infant mortality (Darville, 2016). Thus, screening pregnant women for chlamydia is an essential part of prenatal care.

Clinical Manifestations and Diagnosis. Chlamydia conjunctivitis can present in the newborn with a very watery discharge that may progress to purulent exudate. The incubation period is anywhere from 5 to 14 days but may be shorter in cases of prematurely ruptured membranes. Prior to treatment, the eyelids may swell and a "pseudomembrane" consisting of inflammatory excaudate may form and stick to the conjunctiva (Darville, 2016).

Diagnosis of chlamydial infections is based on physical and laboratory examination. In cases of conjunctivitis, Giemsa-stained conjunctival scrapings provide a method of direct fluorescent antibody (DFA) testing. This method is the only Food and Drug Administration (FDA)-approved culture-independent method for detecting chlamydia from conjunctival swabs. The organism is not detectable on routine Gram stains. Cell culture demonstrates high specificity but is expensive. The definitive diagnosis for chlamydial pneumonia is made by culture of the respiratory tract or identification of high levels of IgM antibodies to chlamydia (Darville, 2016; Kimberlin et al., 2018).

Treatment. Universal eye prophylaxis with antibiotics is required by law in the United States for every newborn. Application of erythromycin ointment at birth for ocular prophylaxis successfully treats gonococcal conjunctivitis but has not been as successful in treating chlamydial conjunctivitis. Even for infants born to mothers known to have untreated chlamydial infection, prophylactic antimicrobial treatment is not indicated due to the unknown efficacy of such treatment. In these cases, the infants should be monitored clinically with appropriate diagnostic workup and appropriate treatment if the infant becomes symptomatic (Kimberlin et al., 2018). The treatment of highly suspected chlamydia infection in the newborn usually begins with ampicillin and gentamicin if the infant's workup is for generic infection. Once the chlamydia organism is identified, treatment with "oral erythromycin base or ethylsuccinate (50 mg/kg/day in 4 divided doses daily) for 14 days or with azithromycin (20 mg/kg as a single daily dose) for 3 days" is recommended (Kimberlin et al., 2018, p. 280). In the case of neonatal conjunctivitis, topical therapy in addition to systemic treatment is indicated. Follow-up of infants treated for chlamydial conjunctivitis is recommended to determine if treatment was effective. If chlamydia is confirmed in a pregnant woman and treated, her sexual partners also require treatment. This organism may be present for many years in the female genital tract and produce no symptoms. The organism does not respond to partial treatment; an infected woman and all her sexual partners must receive full treatment as soon as possible (Darville, 2016).

Prevention. Prevention of sexually transmitted diseases is the same regardless of the organism in question. The only definitive method of prevention is screening and treating the infected pregnant woman. Education and counseling regarding the method of transmission of chlamydia are important. This organism may be present for many years in the female genital tract and produce no symptoms. The organism does not respond to partial treatment; an infected woman and all her sexual partners must receive full treatment as soon as possible. Men should wear condoms during sexual relations to prevent transmission. Without treatment, the severe complications for the woman include pelvic inflammatory disease, ectopic pregnancy, and endometritis (Darville, 2016).

Varicella-Zoster. Varicella is a member of the human DNA herpes viruses. Primary infection with the VZV causes chickenpox. This primary infection is followed by a lifelong period of latent infection of the sensory ganglion neurons. Herpes zoster (shingles) may develop later in life in those who had varicella, especially the elderly and

those with immune deficiency. Chickenpox is extremely contagious and commonly occurs in childhood. Varicella is known as the most communicable of all diseases and is only found in humans (Gershon, Marin, & Seward, 2016; Kimberlin et al., 2018; LaRussa & Marin, 2016). Because of the devastating effects of congenital varicella syndrome (CVS), varicella will be the focus of this section.

Epidemiology. The incidence of this virus in pregnant women is very low, approximately in the range of 0.5 in 10,000 pregnancies, mostly due to success of the varicella vaccine. Transmission of the virus is by direct contact with the virus in vesicular lesions or by airborne droplet spread via the respiratory tract. Symptoms of varicella are usually present 10 to 21 days after exposure and include fever, malaise, and an itchy rash. Administration of varicella-zoster immune globulin (VZIG) may delay onset for up to 28 days. An infected individual is considered contagious from 1 to 2 days before onset of symptoms until all lesions have crusted. The maculopapular rash eventually forms vesicles and crusts over at around 6 days after onset (Baley & Gonzalez, 2015; Gershon et al., 2016; Kimberlin et al., 2018). In utero infection occurs as a result of transplacental passage of the virus during gestation in the infected mother. The severity of the effect on the fetus or newborn is related to the timing during gestation. The lowest risk of CVS occurs when the mother is infected during the first trimester and rises slightly during weeks 13 through 20. CVS rarely occurs after the 20th week of gestation. There is a higher case-fatality rate in offspring when illness develops in the mother from 5 days before to 2 days after birth of the infant. The severity of CVS is decreased when varicella develops in the mother more than 5 days before delivery and after 28 weeks' gestation. It is thought that maternal transfer of varicella-zoster–specific IgG is responsible (Kimberlin et al., 2018).

Clinical Manifestations and Diagnosis. CVS is characterized by cicatricial skin lesions with scarring, limb hypoplasia, CNS involvement, and abnormalities of the eye, renal system, and autonomic nervous system. Neonatal death is most often the result of pneumonia (Baley & Gonzalez, 2015; LaRussa & Marin, 2016).

In the neonate, identified infection in the mother will easily lead to a diagnosis of CVS when clinical manifestations are obvious, such as a widespread vesicular exanthema. A similar presentation is more difficult to identify when there is no known maternal infection. The definitive diagnosis of varicella is made by identification of VZV from vesicular fluid using a PCR test. Other methods are available but the PCR assay is the diagnostic method of choice. Culture and DFA testing are less sensitive and, therefore, unreliable. The presence of specific IgM may only indicate recent exposure or infection and is not a reliable indicator for CVS (Baley & Gonzalez, 2015; Kimberlin et al., 2018).

Treatment. Although there are those who believe that the consequences of CVS do not progress in severity after birth, ACV can be used for treatment of severe disease in newborns, whether congenital or postnatally acquired. The recommended dosage for immunocompromised host less than 2 years of age is 30 mg/kg/day for 7 to 10 days (Kimberlin et al., 2018). There is a limited window for best outcome with antiviral therapy for varicella. Early therapy maximizes benefit. VZIG can be given to newborns to decrease the severity of infection in those exposed and should be administered within 96 hours of exposure (Baley & Gonzalez, 2015; Kimberlin et al., 2018). **Emergency Alert: Children with varicella should not be given salicylate or salicylate-containing products (aspirin, bismuth subsalicylate). These products are known to increase the risk of Reye syndrome.**

Prevention. The primary approach to prevention of CVS is vaccination of women of childbearing age before pregnancy. Although not 100% effective, vaccination could protect 85% of women, and, therefore, their infants. Strict isolation of identified infants or of those whose symptoms are highly suspicious for infection is necessary. Infants should be vaccinated according to established vaccination schedules. Hospitals should initiate and strictly enforce guidelines for maintaining immunity of hospital personnel. Isolation for airborne and contact illnesses should be followed. Typically, if a mother has contracted varicella infection late in pregnancy, other persons, such as healthcare workers, family members, or other newborns, may have been exposed (Gershon et al., 2016). In cases where the mother was infected during pregnancy, and the infant does not show evidence of disease at birth, the mother and infant should be isolated separately until the mother's lesions have crusted over. If the infant develops clinical evidence of disease, the mother may care for the infant if she is well enough. Isolation should continue during hospitalization and after discharge for a total of 21 days (28 days if IVIG was given; Kimberlin et al., 2018).

VZIG can be given to newborns to decrease the severity of infection in those exposed; it does not prevent infection. If exposure occurs within a neonatal intensive care unit (NICU), it is recommended that if there is risk of significant exposure (such as in an open bed environment as opposed to single room environment) all premature infants less than 28 weeks or less than 1 kg receive VZIG regardless of maternal immunity status as there has been inadequate transfer of maternal antibodies. VZIG should also be given in the NICU setting when there is significant exposure in the 28th week of gestation or more and in neonates with maternal seronegative immunity status (Kimberlin et al., 2018).

Lyme Disease.

Lyme disease is the most common vector-borne disease in the United States. It is caused by the spirochete *B. burgdorferi*. Lyme disease is transmitted to humans by the bite of the blacklegged tick, commonly known as the deer tick. Because other spirochetes are known to cause significant, and often devastating, outcomes, when transplacental infections occur, the risk of disease in the newborn from Lyme disease is of considerable interest (Feder, 2016).

Epidemiology. Lyme disease has been identified in more than 50 countries. In the United States, in excess of 30,000 cases are reported to the CDC each year. It is known that this is only a proportion of the actual cases. The CDC estimates that the number of people diagnosed may be around 300,000. There is a concentration of cases in the Northeast and Upper Midwest, with 14 states accounting for over 96% of reported cases (CDC, 2018). Tick larvae become infected by feeding on animals that are infected. The nymphal stage is the stage most likely to infect humans with the spirochete. This stage emerges in the spring to early fall, when deer activity is greatest, making this season the most likely time for humans to become infected. Evidence indicates that the risk of Lyme disease after a deer tick bite is only 1% to 3%. Late disease, mainly arthritis, occurs at any time. Although infection can occur at any age, the reported incidence is greater in children from 5 to 9 years of age, with a second peak occurring in middle-aged adults (Eppes, 2016; Feder, 2016).

Clinical Manifestations and Diagnosis. In adults, clinical manifestations can be divided into early (early localized or early disseminated) disease or late disease. Early-localized disease is characterized by a distinct lesion at the site of a recent tick bite, although the person may not be aware of having been bitten by a tick. There is a classic "bull's eye" appearance in some, but not all, cases. There may be an accompanying clinical presentation of extreme tiredness, headache, mild neck stiffness, muscle pain, and maybe fever. In early-disseminated disease, multiple lesions of erythema migrans may appear 3 to 5 weeks after the tick bite. These lesions are smaller but similar to the primary lesion. There may be palsies

of the cranial nerves, lymphocytic meningitis, and rarely carditis. The signs of early-localized disease can be expected as well. Late Lyme disease occurs in people who were not treated early in the disease and most commonly presents in Lyme arthritis in children who were not treated (Eppes, 2016; Kimberlin et al., 2018).

In areas where Lyme disease is endemic, transplacental infection is known to occur, although congenital infection is rare. There are case reports of fetal loss and newborns with anomalies. Although skin anomalies and cardiac defects have been noted in infants born to mothers with Lyme disease, the inconsistency in findings suggests that there is no recognized syndrome associated with fetal infection. Attempts to investigate the significance of gestational Lyme disease on the newborn have been limited. First, the prevalence is low and, second, diagnosis based on current methods of seropositivity, history of tick bite, and reports of clinical symptoms in the mother is unreliable. Because of increased awareness of the problems associated with Lyme disease, most childbearing women are being identified and treated, especially if pregnancy is suspected. *Borrelia burgdorferi* has been identified from several abortuses and from a few live born children with congenital anomalies. Furthermore, evidence suggests that there is no difference in the prevalence of congenital malformations in infants born to women with serum antibodies against *B. burgdorferi* and the offspring of those without such antibodies (Eppes, 2016; Feder, 2016). The CDC currently recommends a two-step process in the testing for evidence of Lyme disease. These steps can be done together, using the same blood sample. The first step uses an EIA or enzyme-linked immunosorbent assay (ELISA). Rarely, an indirect immunofluorescence assay (IFA) is used. If this first step is negative, no further testing of the specimen is recommended. If the first step is positive or equivocal, the second step should be performed. The second step consists of the Western immunoblot (Western blot). Results are considered positive only if both steps render a positive result. The two steps of Lyme disease testing are designed to be done together. Skipping the first step is not recommended due to many false-positive reports (APA, 2018k; CDC, 2018).

Treatment. Current treatment protocols include an oral regimen of doxycycline, amoxicillin, or cefuroxime axetil. Doxycycline is not recommended for use in young children under the age of 2 years due to reports of permanent teeth staining. All persons receiving doxycycline should be warned of the side effect of photosensitivity in sun-exposed areas. Early use of appropriate antibiotics is associated with rapid and complete recovery. People with certain neurologic or cardiac forms of illness with neurologic or cardiac involvement may require IV treatment with ceftriaxone or penicillin (CDC, 2018; Eppes, 2016).

Prevention. Reducing the risk of tick bites is the only definitive preventive measure. Methods to reduce the risk involve decreasing the known habitat of the deer tick. Keeping yards clear of brush and frequently mowed may reduce exposure in endemic areas. Pesticides may be effective in reducing the tick population, but many unwanted and undesirable side effects are inherent in their usage (Feder, 2016).

Human Immunodeficiency Virus. HIV is one of the greatest public health concerns of the past three decades and remains so in the 21st century. Both HIV-1 and HIV-2 are RNA-containing retroviruses of the Retroviridae family and belong to the *Lentivirus* genus (Kimberlin et al., 2018). Retroviruses are characterized by the presence of a viral reverse transcriptase enzyme that converts single-stranded viral RNA into double-stranded DNA. This double-stranded DNA copy integrates into the host cell genome. Because HIV-1 is more prevalent in the United States, HIV-1 will be the focus of this section, especially as it affects the newborn.

Epidemiology. Although a virus very closely related to HIV was originally identified in chimpanzees and monkeys in Africa, it has long been known that HIV affects humans, attacking cells containing the surface molecule, $CD4^+$, particularly T lymphocytes and macrophages. Originally thought to be a disease mainly affecting men who have sex with men (MSM), HIV is now known to occur in both men and women and in children. HIV is no respecter of socioeconomic status, gender, age, or nationality; however, disparities still exist. Sub-Saharan Africa is devastated by the epidemic with 69% of HIV infections or approximately 23.5 million people infected by HIV. China follows sub-Saharan Africa, with 4 million infected, and then the Americas (including the Caribbean), with 3 million HIV-infected people. HIV often leads to AIDS in the untreated patient and may advance to AIDS despite treatment. Chronic immune activation, with depletion of $CD4^+$ cells, via the adaptive and innate immune systems, plays an important role in the immunopathogenesis of HIV/AIDS. The good news is that rates are declining, with the most significant declines noted in the Caribbean and sub-Saharan Africa (Kimberlin et al., 2018; Shetty & Maldonado, 2016). The only epidemiologically implicated ways of transmission are through contact with blood, semen, cervicovaginal secretions, and human milk (Kimberlin et al., 2018). Mother-to-child transmission has declined dramatically, due to early recognition and treatment of women of childbearing age; therefore, there is a relatively stable incidence of infection. Although rates are declining, the incidence is still unacceptable. The vast majority of children living with HIV are infected as a result of vertical transmission from an HIV-infected mother. In utero infection occurs through transplacental infection or by fetal exposure of infected amniotic fluid. Current data suggest that in utero infection occurs during the last few weeks of gestation when placental vasculature is proliferative. Intrapartum infection may be the result of direct exposure of the fetus or infant with infected maternal secretions or exposure to maternal blood during labor (Shetty & Maldonado, 2016). Although maternal-to-child transmission occurs across a large range of viral loads, maternal viral load is the most critical determinant of maternal transfer of the virus. The risk increases with ROM and increases in a direct relationship to the time of ROM. Cesarean delivery before ROM is known to reduce maternal-to-child transmission. Postnatal transmission is most likely the result of breastfeeding as prolonged breastfeeding is a common practice in low-to-middle-income families, where safe alternatives to feeding the infant may not be available or may be unsafe (Kimberlin et al., 2018; Shetty & Maldonado, 2016).

Clinical Manifestations and Diagnosis. Perinatal HIV infection results in a wide variety of manifestations and depends on the stage at diagnosis. Most HIV-infected newborns are asymptomatic at birth because infection most likely occurs during the peripartum period. Clinical signs typically begin to manifest around age 1 or 2. For some poorly understood reason, there are some infants, termed rapid progressors, who may become symptomatic in the first 2 months (Baley & Gonzalez, 2015). In the untreated pediatric population, early clinical signs include fevers of unknown cause, lymphadenopathy, enlargement of the liver and spleen, failure to thrive, persistent candidiasis, diarrhea, encephalopathy, either hyporeflexia or hyperreflexia, and developmental delays. Recurrent opportunistic infections are common and may increase the risk of death (Kimberlin et al., 2018). Prognosis for survival for the neonate, infant, or child infected with HIV is based on timing of infection and treatment modality. Death in untreated infants is invariable.

Unless assay results are negative, antibody assays are not helpful in the diagnosis of HIV in children under the age of 24 months because these infants and toddlers will have maternally acquired passive antibodies. These maternal antibodies make the EIA, Western blot, inappropriate in infants up to 18 to 24 months of age. Currently,

in the United States, the most sensitive and, therefore, the most preferred test is the HIV DNA PCR or RNA assay, referred to as HIV nucleic acid amplification tests (NAATs). If the test becomes positive within 48 hours of birth, in utero transmission is assumed (Kimberlin et al., 2018; Shetty & Maldonado, 2016). Some experts recommend viral testing in the first 2 days of life for all infants suspected to have in utero infection to increase the chance of early identification and treatment. Umbilical cord testing is not acceptable due to the possibility of contamination with maternal blood. Refer to the AAP Report of the Committee on Infectious Diseases, 2018, Redbook, for an algorithm for interpreting the test results (Kimberlin et al., 2018).

Treatment. It is important to know that treatment with antiviral therapy does not cure HIV; instead, it suppresses the virus with the goal of converting the active disease to a chronic disease. Because of the options available for treatment of HIV-infected infants and children, consultation with an expert in pediatric HIV infection is the standard of care for these individuals (Kimberlin et al., 2018). The most important factor in the outcome for infants exposed to or infected with HIV is whether or not the mother received antepartum/intrapartum antiretroviral therapy (ART) and her viral load. Maternal treatment is not the purpose of this section but whether or not, and when, the mother received treatment is paramount in the decisions around treatment of the infant. ART resistance is becoming more evident and treatment protocols change with current findings. The newborn infant, exposed to HIV in utero, should be bathed as soon as possible after birth to remove all blood and maternal secretions. Antiretrovial (ARV) prophylaxis should be started as early as possible, preferably within 12 hours after birth. Current treatment guidelines may be found online at: https://aidsinfo.nih.gov/guidelines. Enrollment of HIV-infected infants in clinical trials may provide opportunities for exposure to the newest treatment modalities (Kimberlin et al., 2018).

Prevention. Theoretically, prevention of HIV in adults and adolescents can be accomplished by safe sexual practices, limiting exposure to HIV-infected blood, and education to all sexually active individuals about the risk factors and ways to avoid them. Prevention of HIV transmission to the infant has been the focus of research since the first recognition of maternal-to-infant transmission. The result has been the use of ART for the pregnant woman with known HIV infection. Current recommendations are that all pregnant women are tested early in pregnancy and ARV therapy begun. Increased research effort on adherence to recommendations and how they affect youth are needed.

Parvovirus.

The parvoviruses are a family of small, single-stranded DNA viruses of the family Parvoviridae. The parvoviruses are animal viruses and seem to be species specific. Parvovirus B19 is the member that replicates in humans and is known to be a pathogen. Bocavirus has been recently recognized as a human parvovirus but only infects children. Parvovirus B19 will be the focus of this section (Baley & Gonzalez, 2015).

Epidemiology. The human parvovirus, B19, often referred to as "fifth disease," is a common and highly contagious pathogen around the world. The majority of adults in the United States are seropositive, indicating a previous infection during childhood. The incidence is twice as high in Caucasian Americans as in African Americans. The virus is transmitted mainly by droplets from oral or nasal secretions but can also occur from percutaneous exposure to blood or blood products (Kimberlin et al., 2018). Rapid transmission occurs due to close contact between family members or school classmates (Adler & Koch, 2016).

Clinical Manifestations and Diagnosis. The focus of this chapter is on the effects of disease on the neonate; therefore, this section will discuss the clinical manifestations and diagnostic tests necessary when an infant is suspected of having Parvovirus B19. There have been reports of serious, and often devastating, outcomes for the fetus and newborn when the mother has primary infection of Parvovirus B19. Adverse outcomes include hydrops fetalis, isolated pleural or pericardial effusions, intrauterine growth restriction, and intrauterine fetal demise. Although poor outcomes are possible, the infected neonate will likely be asymptomatic at birth. The risk of maternal-to-infant transmission is low (≤10%); the greatest risk occurs with maternal infection during the first 20 weeks of gestation. Other reported fetal outcomes from maternal Parvovirus B19 infection include occasional birth defects (ocular defects), although this finding could not be attributed to the virus in repeated studies. Meconium ileus and peritonitis have also been reported in neonates following maternal infection during pregnancy (Adler & Koch, 2016; Baley & Gonzalez, 2015).

The diagnosis of Parvovirus B19 in the newborn infant is based on identification of the infection in the mother. Most infants are asymptomatic at birth and rarely require virologic confirmation. The preferred diagnostic tests for acute or recent Parvovirus B19 is detection of serum-specific IgM antibodies. Prenatal diagnosis, when fetal hydrops is suspected, can be verified by detection of viral DNA in fetal blood or amniotic fluid by these methods (Kimberlin et al., 2018; Koch, 2016).

Treatment. Treatment for the prenatally infected infant is based on clinical manifestations, if present. Fetal transfusion may be indicated in cases of hydrops fetalis with significant fetal anemia. Several separate transfusions may be necessary for resolution of the hydrops. Each transfusion is associated with an increase in risk to the fetus; however, the benefit certainly exceeds the risk (Adler & Koch, 2016).

Prevention. Pregnant healthcare providers should be informed of the potential risks to their fetus from Parvovirus B19 infections. The best strategy to decrease the risk of infection is to pay attention to strict infection control procedures including standard precautions and droplet precautions if the hydrops has not resolved in the neonate at the time of birth (Kimberlin et al., 2018).

Other Viruses

Hepatitis B Virus. The hepatitis B virus (HBV) is a fairly large, double-stranded DNA–containing virus in the family Hepadnaviridae. Hepatitis B surface antigen (HBsAg) is present in the chronic carrier state. A chronic carrier state is defined as persistence of the HBsAg in serum for at least 6 months (AAP, 2018g).

Epidemiology. HBV has been detected worldwide, with an estimated 400,000 persons known to be chronic carriers. In the United States, the prevalence of HBV infection in pregnant women shows a distinct disparity by race and ethnicity, with the highest rates reported in Asian women; rates in African American, Caucasian, and Hispanic women are similar with the lowest rates in Hispanic women. Chronic HBV infection is endemic in sub-Saharan Africa, China, parts of the Middle East, the Amazon basin, and the Pacific Islands. In these areas, carrier rates are estimated to be 35%. In the United States, where a successful vaccination program exists, there are still an estimated 1.25 million chronic HBV carriers (Jensen & Balistreri, 2016; Karnsakul & Schwarz, 2016). The primary route of transmission is through infected blood or bodily fluids. The surface antigen, HBsAg, has also been noted in human milk, saliva, and tears. Blood, serum, semen, vaginal secretions, CSF, and other bodily fluids, such as synovial, pleural, pericardial, peritoneal, and amniotic fluid, present the most potential for transmission of the virus. Transmission by blood or blood products in the United States has been virtually eliminated due to routine screening of donors (AAP, 2018g). HBV infection in a pregnant woman does not appear to have teratogenic abilities, although there are reports of a higher incidence of LBW and prematurity. Acute HBV infection in the mother early in pregnancy has a 10% transmission rate with a higher incidence when acute infection occurs in the third trimester.

Chronic infection in the pregnant woman does not appear to have an effect on pregnancy outcome (Karnsakul & Schwarz, 2016). HBV is most often the result of IV drug use but transmission also occurs through sexual contact with an infected partner and via mother-to-infant transmission. The majority of infections from mother to infant occur at birth or in the postpartum period. A large percent of infants born to mothers with a high viral load develop chronic HBV infection (Baley & Gonzalez, 2015).

Clinical Manifestations and Diagnosis. Clinical manifestations of HBV infection are age dependent. In the adult, HBsAg is detected 1 to 3 months after exposure to the virus. Elevation of liver enzymes occurs between 2 weeks and 2 months after detection of HBsAg. The symptoms most often reported are nausea, vomiting, headache, and lethargy. This period progresses to the development of jaundice. Most adults with HBV infection have a self-limited course. A few will develop hepatic failure and many of these will die. A chronic carrier state, or persistent HBV infection, is also possible. In the United States, 20% to 30% of all cases of chronic infection are in children. Chronic liver disease and hepatocarcinoma may result from a chronic carrier state (Baley & Gonzalez, 2015; Jensen & Balistreri, 2016).

Ninety percent of infants born to women who are positive for both HBsAg and hepatitis B e antigen (HBeAg) are at risk for development of HBV infection by their first birthday if they are not given treatment. Infants born to women who are positive for HBsAg but negative for HBeAg have lower rates of perinatal infection (20%). Infants who do not receive treatment are likely to become carriers, which may eventually lead to cirrhosis or primary hepatocellular carcinoma. A few (6%) may develop acute hepatitis at around 2 months of age. Symptoms most reported for infants are fever, jaundice, and hepatic tenderness. Serum aminotransferases are elevated (Karnsakul & Schwarz, 2016).

The serologic diagnosis of HBV is complex and is different depending on whether the disease is acute or chronic. HBsAg is used to detect acutely or chronically infected people. HBsAg is an important test in assessing a woman's risk of transmitting HBV to her unborn child. HBeAg is used in the identification of people who are at the greatest risk of transmitting the virus. The presence of HBsAg and HBeAg is the best indication of infectiousness. It is currently recommended that all pregnant women be screened at their first prenatal visit for HBsAg and HBeAg to prevent prenatal transmission; for high-risk populations, this should be repeated in the third trimester (Jensen & Balistreri, 2016).

Treatment. Hepatitis B vaccine is the golden standard for prevention of HBV. All infants should receive the first vaccine before discharge from the birth hospital, preferably within 24 hours of birth. Infants born to mothers who are at risk of transmitting the virus should receive the HBV vaccine along with hepatitis B immunoglobulin. An algorithm exists for determining the timing and dosage for infants according to birth weight as well as for prophylaxis according to maternal HBV status (AAP, 2018g; Baley & Gonzalez, 2015). Vaccination is recommended for individuals who are at risk for exposure to HBV, including healthcare workers, family members of chronic carriers, persons with large numbers of heterosexual partners, and IV drug users. Hep B vaccine is administered to the deltoid muscle once and then again 1 and 6 months later (AAP, 2018g).

Prevention. Proper and prompt identification of women in high-risk groups and knowledge of HBV status are important in the delivery room to determine whether the infant is at risk for infection. In accordance with universal infection control measures, appropriate barriers are used to protect healthcare workers from blood and body secretions. Delivery room and nursery personnel should always wear gloves when handling any new infant. The infant of a mother with confirmed HBV infection should be bathed with soap and water immediately, with special attention to removing all blood and secretions present on the skin and hair. The infant may be breastfed (unless the mother's nipples are cracked) and cared for routinely. Family clustering of HBV has been identified and spread via household contact (AAP, 2018g; Baley & Gonzalez, 2015).

Fungal Agents

Candida albicans. *Candida* species are a group of fungi that are frequently found in humans; *Candida albicans* is the most prevalent form in neonates, followed by *Candida parapsilosis*. *Candida* organisms are oval, yeast-like cells that can bud to reproduce.

Epidemiology. *Candida* bloodstream infections are a major cause of LOS in the newborn, especially in extremely LBW infants. The incidence of candidemia is reported to range from 6.6% to 26% in VLBW infants who are the most fragile and prone to morbidities. Outcomes, such as blindness, severe neurologic impairment, renal failure, and endocarditis, have been reported (Bodin, Godoy, & Phillips, 2015). Early recognition and treatment of fungal infection are imperative to prevent severe CNS complications and death. Prolonged broad-spectrum antibiotic treatment for small premature infants may predispose infants to *Candida* overgrowth in the GI tract. This overgrowth may predispose the infant to disseminated fungemia. Administration of hyperalimentation, frequent use of indwelling venous lines, and invasive procedures may also predispose the infant to *C. albicans* infection. Several studies have implicated previous antibiotic therapy and assisted ventilation as the major factors that correlate with neonatal *Candida* infection. Congenital candidiasis may present at birth and results from a maternal intrauterine infection or exposure to extensive vaginal infection. Chorioamnionitis is associated with intrauterine fetal death and preterm delivery (Bendel, 2016).

Clinical Manifestations and Diagnosis. *Candida* species are responsible for a variety of clinical presentations in the newborn. Mild thrush diaper dermatitis is a common finding in infants who have been on antibiotics. Systemic candidemia can be life-threatening, especially in the extremely premature infant. The newborn infected with disseminated *C. albicans* presents a picture similar to that of any septic infant. Early cultures reported as negative in the clinically ill infant with risk factors for fungal infection should alert the caregiver to the possibility of candidemia. In the NICU, the median age at onset of symptoms is 9 to 10 days. The infant may have respiratory distress, abdominal distention, guaiac-positive stools, carbohydrate intolerance (evidenced by hyperglycemia), candiduria, temperature instability, and hypotension. Infants with congenital candidiasis most likely present with diffuse cutaneous disease, with widespread erythematous maculopapular rash. More severe disease presents with manifestations of systemic viral or bacterial infection (Bendel, 2016).

Mucocutaneous disease can be tentatively diagnosed based on clinical characteristics. It is rarely necessary to obtain cultures of skin or mucous membranes. A potassium hydroxide (KOH) test for budding yeast can be used to distinguish oral thrush from other causes of white coating of the tongue and mucous membranes; KOH is also a rapid screening technique for candiduria (Ericson, Smith, & Benjamin, 2016). A positive *Candida* blood culture should never be considered a contaminated specimen. Intermittently positive cultures may reflect transient candidemia, and, usually, removal of any indwelling catheters and lines and changing of antibiotic therapy may be indicated. Cultures of blood, urine, and spinal fluid should be obtained in fulminant disease. Brain imaging, echocardiogram, renal ultrasound, and dilated retinal examination are warranted for any neonate/infant with candidemia due to the higher risk for dissemination in the preterm population.

Treatment. For mucocutaneous disease, topical agents are indicated. Nystatin is the most commonly used therapy. Oral nystatin should be applied directly to the lesions to improve efficacy. Nystatin ointment or powder is very effective in treating skin lesions, including diaper dermatitis. Some clinicians prescribe oral nystatin when severe diaper dermatitis is present. This regimen is not recommended, however, because the reservoir is usually the lower GI tract. Gentian violet was extensively used in the past and is still prescribed when nystatin is ineffective in the short term. Because of the inconvenience of staining and some local irritation, most clinicians choose systemic therapy when topical treatment is ineffective. The drug of choice for infants with systemic *C. albicans* infection is amphotericin B. This toxic, potent antifungal agent must be used cautiously. The recommended treatment is 1 mg/kg given every 24 hours IV. Therapy should continue for 2 weeks after the first negative blood culture and clearance of clinical signs of the disease. Therapy for CNS involvement should include the addition of 5-fluorouracil (5-FU) as amphotericin B does not cross the blood–brain barrier well. Therapy should be continued at least 3 weeks and until all signs and symptoms of CNS infection have cleared, including negative CSF cultures. Prompt central line removal is advised (AAP, 2018a; Bendel, 2016).

Kidney toxicity is a major side effect of amphotericin B therapy because it causes renal vasoconstriction and decreases both renal blood flow and glomerular filtration rate. This damage can result in hyponatremia, hypokalemia, increased blood urea nitrogen, and increased creatinine, as well as acidosis. If the medication makes the patient oliguric, most providers recommend stopping the drug until the next day. Thrombocytopenia, granulocytopenia, fever, nausea, and vomiting are the common side effects associated with amphotericin B (Bendel, 2016).

Prevention. NICUs with a high incidence of invasive candidiasis are advised to implement a prophylaxis protocol. At this time, antifungal drug prophylaxis is the only regimen shown to be efficacious in randomized controlled trials. Most units use an IV fluconazole prevention protocol. Some use an oral nystatin protocol. A small retrospective descriptive study in one hospital demonstrated that a topical nystatin cream protocol was associated with a very low rate of *Candida* species in extremely LBW infants with central catheters in that NICU (Bodin et al, 2015). More evidence is needed to determine when prophylaxis is needed, what agents are most efficacious, and which agents are considered safe for use in newborn infants of all gestational ages and birthweights.

NOSOCOMIAL INFECTIONS

Both colonization and infection are nosocomial events, meaning "of or related to a hospital." The common meaning of the term *nosocomial* is "hospital acquired." In the neonate, LOS is mostly the result of nosocomial transmission, with the exception of late-onset GBS and HSV infection. Rates of nosocomial infections have declined over the past decade as efforts have been put in place for surveillance and prevention. Risk factors are prematurity, LBW, and extended hospitalization, where many invasive procedures are required. Incidence is indirectly related to birthweight and gestational age, where the highest incidence is found in extremely premature infants. There is considerable variability between nosocomial infection rates among NICUs with reported rates ranging from 10.3% to 31.7% after adjusting for birthweight, gestational age, race, and sex (Ramasethu, 2017). Hospitals in low-to-middle-income countries have higher (3–20 times higher) nosocomial infection rates, mostly due to being poorly equipped to provide aseptic technique for procedures involving sick neonates (Maldonado et al., 2016).

Nosocomial infections are predominantly caused by gram-positive organisms, gram-negative organisms, and yeast. Coagulase-negative staphylococcus has been identified as a major cause of nosocomial infections in the United States since the early 1980s and still remains so. Yeast infections often occur if previous antibiotic therapy has been given. This infection is also associated with colonization of vascular catheters, assisted ventilation, and necrotizing enterocolitis. The most common device-related infections are central line–associated bloodstream infections (CLABSIs), ventilator-associated pneumonia (VAP), urinary catheter-associated urinary tract infections (CAUTI), and ventricular shunt–associated infections (Ramasethu, 2017; Sammons & Coffin, 2016).

Nursery epidemics can be caused by gram-negative and gram-positive or viral organisms because they have (a) the ability to colonize or infect human skin or the GI tract, (b) the ability to be carried from person to person by hand contact, and (c) characteristics that allow existence on hands of personnel or in fluids or on inanimate objects, including IV fluids, respiratory support equipment, solutions used for medications, disinfectants, and banked breast milk.

Resistance to antibiotics is a serious problem in many NICUs, particularly with gram-negative enteric pathogens. Aminoglycoside resistance is a problem in many nurseries, as are colonization and infection with MRSA. Respiratory infections with respiratory syncytial virus (RSV), influenza virus, parainfluenza virus, rhinovirus, and echovirus occur in many nurseries. These are more difficult to identify and thus more difficult to report. CMV infection has been reported as a transfusion-related problem in LBW infants, thus prompting the current policy of using CMV-screened blood donors.

INFECTION CONTROL POLICIES

Policies and procedures in nurseries should be set up by the hospital infection control committee based on the recommendations of the AAP and the CDC. The significance of these policies to newborns should be detailed in a hospital policy book. The following topics should be covered: (a) oclar prophylaxis, (b) skin and cord care, (c) nursery staff ratios, (d) nursery design and environment, (e) handwashing, (f) staff apparel, (g) isolation, (h) visitors, (i) employee health, and (j) epidemic control (Sammons & Coffin, 2016). The simplest, most effective weapon for preventing infection is the liberal use of soap and water!

SUMMARY

Many factors place the neonate at high risk for infection. The nurse is in a unique role to implement methods for prevention of infection in nurseries, to detect early signs and symptoms of infection, and to participate in infection control. A better understanding of the neonatal immune system, methods of perinatal acquisition of organisms, common microorganisms, signs and symptoms of infections, and appropriate therapy provide the nurse with a sound basis for management of care as well as the development and implementation of hospital infection control policies for the NICU. Antibiotic stewardship remains one of the best practices to decrease resistance organisms and, therefore, decrease neonatal morbidity and mortality (McPherson, Liviskie, Zeller, Nelson, & Newland, 2018).

CASE STUDY

Identification of the Problem. Term, female infant admitted to Well Baby Nursery following repeat C-section. Presented with grunting respirations, nasal flaring, and retractions (GFR) by 15 minutes of age.

Assessment: History. Baby S was delivered via repeat C-section under spinal anesthesia to a G2P1001 female with estimated gestational age (EGA) of 39 weeks. Maternal labs: Blood type A+, GBS negative at 35 weeks. RPR nonreactive, Hep B negative, HIV negative, and Rubella immune. Perinatal history: Mother reports a UTI at 36 weeks' gestation, which was treated with Macrodantin. No other problems were noted. Other than this treatment, only prenatal vitamins were taken during pregnancy. Membranes ruptured at delivery with clear amniotic fluid. Apgars: 8 at 1 minute and 9 at 5 minutes. The infant only required drying and stimulation at delivery. She was admitted to the well baby nursery (WBN) at 10 minutes of age for usual newborn care. The neonatal nurse practitioner (NNP) was called to evaluate the infant at 15 minutes of age for GFR. An arterial blood gas (ABG), CBC with diff, and CRP were obtained. The ABG results were: pH 7.223 $Paco_2$ 66 Pao_2 44. CBC and CRP results pending. The infant was transferred to the NICU with blow-by O_2 for further evaluation and treatment.

Physical Examination on Admission to the NICU

- GENERAL: term female infant with marked acrocyanosis. Resting supine with marked grunting, nasal flaring, and subcostal retractions; Spo_2 91% with blow-by O_2 at 5 L/minute
- HEENT: normocephalic, AF soft and slightly concave; bilateral red reflexes and pupils equally reactive to light; ears normally placed; nares patent
- RESP: BBS clear to auscultation; marked GFR; RR 40
- CV: HR regular with normal sinus rhythm; HR 170; no murmur noted; brachial and femoral pulses 2+; capillary refill 4 seconds; BP: 76/35; mean BP: 37
- ABD: abdomen soft and nontender with no hepatosplenomegaly or masses palpable; three-vessel cord
- GI/GU: normal female infant genitalia; patent anus; anal wink present
- NEURO: decreased responses, with eyes open and unblinking; muscle tone markedly decreased
- SKIN: pale pink with mottling; no bruises or "birthmarks" noted
- EXTREMITIES: good passive ROM with 10 fingers and toes each extremity; no hip clunks noted

Differential Diagnoses

- Transient tachypnea of the newborn
- Pneumothorax
- Sepsis
- Pneumonia
- Shock

Diagnostic Tests

Laboratory tests:

- CBC/differential: WBC: 4.7; Hgb: 14.2; Hct: 45.2; Platelet count: 105,000; Segs: 35; Bands: 21; Metas: 2; Myelos: 1
- CRP: 6.8
- Repeat ABG: pH 7.12; $PaCO_2$ 71; PaO_2 49
- Blood cultures X 2. Endotracheal secretion culture. Blood cultures positive at 12 hours for gram-positive cocci; minimal inhibitory concentration (MIC) pending

Imaging tests:

- Chest x-ray: Good expansion with mild reticulogranular appearance; no pneumothorax
- Working diagnosis. GBS sepsis with possible GBS pneumonia (based on preliminary BC report and chest x-ray appearance).
- Development of management plan
- Respiratory support with mechanical ventilation as needed
- Umbilical arterial catheter (UAC) and umbilical venus catheter (UVC) placement for monitoring, sampling, and fluid management
- Continuous monitoring of arterial blood pressure, vital signs, and neurologic status, every 2 to 4 hours
- CBC/diff and CRP every a.m.
- BMP at 12 hours of life and every a.m.
- ABG every 3 to 4 hours as needed for ventilator management
- Maintenance fluid support; fluid boluses to support intravascular volume
- Vasopressors to maintain adequate blood pressure and cerebral blood flow
- Ampicillin and gentamicin IV
- CSF cultures when stable

Implementation and Evaluation of Effectiveness

- Implementation of management plan (immediately after initial assessment in the NICU):
- Infant intubated within the first 30 minutes of life and placed on mechanical ventilation with following settings: SIMV: 40; PIP: 24; Peep: 4; PSV: 12; Fio_2 50% (adjusted to keep Spo_2 90%–97%)
- Chest x-ray to verify endotracheal tube (ETT) placement
- UAC and UVC placed; abdominal x-ray to verify umbilical line placement
- Dopamine 10 mcg/kg/minute initiated by 1 hour of life; weaned to 5 mcg/kg/minute by 36 hours
- Effectiveness of management plan:
- Despite maximum ventilatory support, Baby S developed severe persistent pulmonary hypertension of the newborn (PPHN) and was transferred to a Children's Hospital for possible extracorporeal membrane oxygenation (ECMO) on day 3 of life
- Blood cultures and ETT cultures were positive for group B strep
- CSF cultures were negative
- GBS sepsis and GBS pneumonia were successfully treated with antibiotics

Outcome. The infant did well at the receiving hospital and did not require ECMO. She was treated with iNO for 3 days and was extubated by day 9 of life. Follow-up blood cultures were negative after 14 days of IV antibiotics. She was discharged home at 3 weeks of age and is developmentally appropriate at 3 years of age.

Discussion. Although the incidence of GBS sepsis is decreasing, it still remains the number one cause of EOS in the newborn. In the case presented, a high level of suspicion for sepsis was based on the history of the UTI in the mother. Although a woman's GBS screen is negative at the time it is tested, she may become positive later or the test may reveal a false negative, depending on timing and the technique used. Early recognition and rapid treatment can mean the difference between a poor outcome and a good outcome for the neonate (Committee on Infectious Diseases and Committee on Fetus and Newborn, 2011).

Committee on Infectious Diseases and Committee on Fetus and Newborn. (2011). Policy statement: Recommendations for the prevention of perinatal group B streptococcal (GBS) disease. *Pediatrics, 128*(3), 1–5. doi:10.1542/peds.2011–1466

EVIDENCE-BASED PRACTICE BOX

One of the most successful evidence-based practice changes in recent history has been the implementation of a group B beta-hemolytic streptococcus (GBS) prophylaxis protocol for the prevention of GBS sepsis in the newborn. During the 1970s, GBS sepsis exceeded *Escherichia coli* as the leading cause of sepsis and meningitis in newborns (Edwards, Nizet, & Baker, 2016). Cases of GBS sepsis continued to increase over the next two decades. In 1996, the Centers for Disease Control and Prevention (CDC) published the first guidelines for the prevention of perinatal group B streptococcal disease, which were based on case reports and clinical trials demonstrating the effectiveness of intrapartum administration of antibiotics to women who were considered at risk for transmitting GBS to their newborns. These guidelines offered two prevention methods: a risk-based approach or a culture-based approach. Although there was a decrease in cases, GBS disease remained a leading cause of neonatal sepsis. Further studies comparing the two strategies revealed data that supported the culture-based method as the most effective strategy in preventing neonatal GBS disease. Therefore, in 2002, the CDC replaced the 1996 guidelines with recommendations that all pregnant women be screened for GBS between 35 and 37 weeks' gestation with the use of intrapartum antibiotic administration during labor for culture-positive women.

Significant declines in the incidence of GBS disease occurred after the implementation of the 1996 guidelines, but a more dramatic decrease occurred after the updated guidelines in 2002. The CDC and other organizations continued to collect data and the guidelines were updated again in 2010. Few changes were made except for information related to testing methods and recommendations for antibiotics for women with penicillin allergy (Verani, McGee, & Schrag, 2010). Since the implementation of intrapartum antibiotic prophylaxis for prevention of neonatal GBS disease, rates of EOS with GBS have declined; however, GBS sepsis continues to be the most common pathogen in term infants and remains the leading cause of disease-related morbidity and mortality among newborns. It is important that we continue to evaluate our practices and make changes that are based on current evidence (Nizet & Klein, 2011).

PARENT VOICES

Deborah A. Discenza

We were about 3 weeks into my daughter's stay in the NICU and had just started doing Kangaroo Care at my request. I was so excited to see how I personally could help my daughter thrive in the NICU environment. Well, one day I walked in, eager to hold her and kangaroo her when the nurse came up to us immediately and said my daughter was not well. Sure enough, we looked into her incubator and she was totally still and very sick. We were told not to touch our daughter nor to stimulate her in any way. They never told us what was wrong and I sat there by her bedside staring at her with a sense of dread. But the nurses said not to touch her, not to comfort her. There was nothing I could do. I felt completely powerless to help my daughter and I had no idea what lay ahead for her. Later we learned it was sepsis and we felt grateful for the care and the antibiotics that helped her through it. The experience left its mark on Becky but also on us, her parents. Things can change in a second.

ACKNOWLEDGMENT

The authors are indebted to Carole Kenner and Judy Wright Lott, whose contributions to past editions of this chapter and the tables provided the strong baseline framework and inspiration for the current version.

CHAPTER 12

Integumentary System

Carolyn Houska Lund and
Joanne McManus Kuller

INTRODUCTION

Skin phenomena, along with other examination findings, are used to assess the maturity, duration of pregnancy, and neonatal vitality. The skin of a preterm infant makes up 13% of the body weight, compared with 3% in adults. This large organ provides a barrier against infection, protects internal organs, assists in acid mantle development, contributes to temperature regulation and prevention of insensible water loss (ISWL), stores fats, excretes electrolytes and water, and provides tactile sensory input. The sensations of touch, pressure, temperature, pain, and itch are received by millions of microscopic dermal nerve endings. The skin is instrumental in early establishment of the mother–infant relationship in that the quality of touch and stimulation that an infant receives is responsible for the infant's later responses to other people and to the environment. Thus, the skin fulfills a task of vital importance, particularly in the area of maternal–child nursing.

Care practices that affect the fragile, underdeveloped skin of the premature infant present major concerns as well as dilemmas for care providers. Life support and monitoring equipment must be securely attached and frequently removed or replaced; this practice can cause trauma to the skin. Necessary invasive procedures, such as vascular access, blood sampling, and chest tube insertion, invade the skin's barrier. Trauma to skin can result in the diversion of an excessive proportion of caloric intake to tissue repair. Other effects of trauma to premature skin include the energy demands of electrolyte imbalances and increased evaporative heat loss through damaged or immature skin and the risk of toxicity when substances are applied to the skin surface.

Trauma to the skin creates portals of entry for bacteria and fungus in an already immune-compromised host. Significant morbidity and mortality can be attributed to practices that cause either trauma to skin or alterations in normal skin function. Iatrogenically -caused skin problems—including burns and caustic lesions from isopropyl alcohol and erythema and skin craters from transcutaneous oxygen monitoring—have been reported. Increased skin permeability and percutaneous toxicity from drugs and chemicals have also been documented in neonates.

This chapter covers the development and structure of skin, the normal physiological variations in newborn skin, and dermatologic diseases. This information is then incorporated into the management of neonatal skin.

SKIN STRUCTURE AND FUNCTION

Skin consists of three anatomically distinct layers: the epidermis, the dermis, and the subcutaneous tissue. The uppermost layer of the epidermis is the *stratum corneum*, primarily composed of nonliving cells made of protein with layers of lipids that bind them; this has been described as similar to the "bricks and mortar of a wall." These cells, once exfoliated in utero, form part of the *vernix caseosa*, the cheese-like substance that covers and protects fetal skin. The bottom, living basal layer contain keratinocytes, which constantly replace the keratin cells in the *stratum corneum*; it takes approximately 26 days for keratinocytes to migrate up to the *stratum corneum*. Approximately 20% of an adult's protein requirement is needed for this purpose. Keratin-forming cells—which cornify the outer layer of the epidermis—and melanocytes are contained in the lower levels of the epidermis. Melanocytes begin producing melanin, or pigment, before birth and distribute it to the epidermal cells. Active pigmentary activity can be observed before birth in the epidermis of infants of dark-skinned races but little evidence of such activity exists in white fetuses (Moore & Persaud, 2015).

The dermis lies directly under the epidermis and is 2 to 4 mm thick at birth. It is a closely woven layer of collagen, a fibrous protein, and elastin fibers. This fibrous complex provides mechanical strength as well as elasticity and allows the skin to withstand frictional stress while extending easily over joints. At term, the dermis is well organized but is thinner and has higher water content compared to the adult dermis (Loomis, Koss, & Chu, 2008). Many nerves and a rich supply of blood vessels are contained there. They nourish the skin cells and act as carriers of the sensations of heat, touch, pressure, and pain from the skin to the brain.

Hair originates from deep in the dermis. Down-growths, called epidermal ridges, which extend into the developing dermis, result from a proliferation of cells in the basal layer. These ridges are permanently established by 17 weeks' gestation and produce ridges and grooves on the surface of the palms, including the fingers, and on the soles of the feet, including the toes.

Determined genetically, this type of pattern constitutes the basis for the use of fingerprints in criminal investigations and medical genetics. Dermatoglyphics is the study of the pattern of these epidermal ridges. The presence of abnormal chromosome complements affects the development of the ridge patterns. For example,

infants with Down syndrome exhibit distinctive hand and feet patterns that are of diagnostic value (Moore & Persaud, 2015).

The major component of the subcutaneous layer is fatty connective tissue. The subcutaneous fat functions as a heat insulator, a shock absorber, and a calorie reserve area. Fat accumulation occurs predominantly in the last trimester. Sebaceous glands are found in both the dermis and the subcutaneous layer. Well-developed and potentially functional at birth, these glands have only minimal function until puberty. Sweat glands are also found in the dermis and the subcutaneous layer and are affected directly by external environmental temperature. In premature infants, sweat gland maturation occurs between 21 and 33 days of age. In term infants, this maturation occurs at about 5 days of age. Poor sweat production in the premature infant is caused by sweat gland immaturity. However, adult function is not achieved until the second or third year of life.

Term infant skin is soft, wrinkled, velvety, and covered with *vernix caseosa* (Visscher et al., 2005). Transformation of the fetal circulation is evident soon after the cord is cut, as the skin develops the intense red coloration characteristic of the newborn. This color may remain for hours. A blue, blotchy appearance may occur if the infant is exposed to a cool environment.

The insulating layer of vernix is usually lost during the first few days of life through traditional newborn skin care (Dyer, 2013). This results in a loss of insulation for the *stratum corneum*, which then peels off, thus resulting in skin with a grayish-white or yellowish hue. Visible desquamation of newborn skin comes to an end after about 7 days. The vernix protects the fetus from maceration by the amniotic fluid, facilitates the development of the *stratum corneum*, assists in the development of the acid mantle, provides bactericidal protection, and contributes to the development of epidermal barrier function (Visscher, Adam, Brink, & Odio, 2015).

In comparison with the skin of the term infant, the premature infant's skin is more transparent, gelatinous, and unwrinkled. Lanugo, which has been lost in the full-term infant, may be present in varying degrees and is one criterion used to estimate gestational age. Additionally, subcutaneous edema may be present and is clinical evidence of a cutaneous excess of water and sodium. This edema decreases within the first few days of life and the skin then lies loosely over the infant's entire body. The immaturity of the infant's skin is linked to the premature newborn's difficulty maintaining body temperature. A poorly developed fat supply and a large body surface area in relation to body weight add to temperature instability.

The premature infant has been shown to have a less well-developed *stratum corneum*; at less than 30 weeks' gestation there may be only two to three layers of *stratum corneum*. This immaturity results in the premature infant's decreased capacity to resist particles, viruses, parasites, and bacteria in the external environment, leaving the infant readily susceptible to infection and irritation of the skin (Lawton, 2013).

Transferring from the intrauterine aquatic environment to the external atmospheric environment stimulates and accelerates the maturation of skin functions. Embryologic skin development is described in Exhibit 12.1.

Developmental Variations

Several factors are responsible for the functional differences between premature and term infants' skins. These differences subside with increasing gestational and postnatal ages (Table 12.1).

EXHIBIT 12.1

Embryologic Development of Skin

The skin consists of two morphologically different layers derived from two different germ layers. The epithelial structures (epidermis, pilosebaceous-apocrine unit, eccrine unit, and nails) are ectodermal derivatives. The ectoderm also gives rise to the hair, the teeth, and the sense organs of smell, taste, hearing, vision, and touch—everything involved with events that occur outside the organism. Mesenchymal structures (collagen, reticular, and elastic fibers; blood vessels; muscles; and fat) originate from the mesoderm. These developments are outlined in Table 12.2.

The epidermis, which develops from the surface ectoderm, consists of one layer of undifferentiated cells in a 3-week-old embryo. By 4 weeks' gestational age, it has an inner germinative layer of cuboidal cells with dark, compact nuclei and an outer layer of slightly flatter cells covered by microvilli. By about the middle of the second month of gestation, some of the cells begin to be crowded to the surface and form a thin, protective layer of flattened cells known as the periderm. The cells of this layer continually undergo keratinization and desquamation and are replaced by cells arising from the basal layer. The periderm is often called the epitrichial ("upon the hair") layer of the epidermis because the hairs that later grow up from the deeper layers are said not to penetrate this thin surface layer but to push it up on their growing tips, thus causing it to be cast off if it has not already disappeared. These exfoliated cells form part of the *vernix caseosa*.

During the latter part of the second month, the epithelium tends to become thicker. This occurs (at first) by a staggering of the nuclei and the beginning of cell rearrangement, which leads rapidly to the formation of an intermediate layer between the flattened cells of the epitrichial layer and the basal layer adjacent to the underlying dermis. The cells of this intermediate layer tend to become enlarged and show a high degree of vacuolation. The basal layer of the epidermis is later called the stratum germinativum (Moore & Persaud, 2015).

At the end of the second month of gestation, the cutaneous nerves, detectable in the embryonic dermis by about the fifth week of gestation, appear to be functional, although the skin is primitive by comparison with that of an adult.

At about 10 weeks' gestation, fingernail development begins at the tips of the digits. A thickened area of epithelium on the dorsum of each digit is the first sign of nail formation. Our nails are adaptations of the epidermis, homologous to the claws and hooves of lower mammals, and are formed by a modified process of keratinization. Development of the fingernails is begun and completed (30–34 weeks) before that of the toenails (35–38 weeks).

By about 11 weeks' gestation, collagen and elastic connective tissue fibers begin to develop in the dermis. The epidermal-dermal junction, which has been smooth up to this time, now becomes wavy as epidermal thickenings grow down into the dermis of the palm and the soles of the feet. Dermal papillae develop in

(*continued*)

EXHIBIT 12.1 (*continued*)

these dermal projections. Capillary loops develop in some dermal papillae and Meissner's corpuscles, which are the sensory nerve endings of touch, form in others (Moore & Persaud, 2015). These epidermal ridges produce ridges and grooves in a genetically determined pattern and are the basis for fingerprinting and footprinting. The development of these ridges can be distinctly affected by the presence of abnormal chromosome complements (e.g., as occurs in Down syndrome). These ridges are permanently established by about 17 weeks of gestation.

During the third to fourth month of gestation, the *stratum germinativum* differentiates from the rest of the epithelium. These cells are termed the germinative layer because they undergo the repeated cell divisions that are responsible for the growth of the epidermis.

During the fourth month of gestation, the epithelium starts to become many cells thick and keratin begins to accumulate in the cells above the stratum germinativum layer. Daughter cells from the basal layer are crowded upward and undergo progressive changes in each layer and finalize in cornification. The thin stratum *granulosum epidermidis*, which contains keratohyalin granules, is the layer directly above the stratum germinativum. The next higher layer is the thin and clear stratum *lucidum epidermidis*, the content of which is a fluid—eleidin—that replaces the granules. Above that is the keratinized multilayered stratum *corneum epidermidis* (Moore & Persaud, 2015). As the keratin accumulates in these cells, they become more and more sluggish and finally die, so that the surface layer of the epidermis is made up of tough, scale-like, dead cells that form a relatively impermeable membrane.

In areas such as the soles of the feet and the palms of the hands, where the skin is subjected to more than ordinary wear, the keratinization of the outer layer is much heavier than in the general body surface. Of interest, however, is that the greater thickness of palmar and plantar epidermis becomes evident in the embryo long before it is possible for these areas to have been subjected to any more wear than other parts of the skin. When the aforementioned layers are all completely differentiated, the structure of fetal epidermis resembles that of adult epidermis.

During the early fetal period, neural crest cells migrate into the dermis and differentiate into melanoblasts. At about 17 to 20 weeks of gestation, these melanoblasts differentiate into melanocytes, migrate to the epidermal–dermal border, and begin to produce melanin. Fetal melanocytes in white races contain little or no pigment, whereas in dark-skinned races, they produce melanin granules. The skin of black newborns is only a little darker than that of white newborns. The skin at the bases of the fingernails and toenails is often noticeably darker, however.

The skin of black infants continues to darken after birth as increased melanin production occurs in response to light. When melanocytes remain behind in the dermis, they appear bluish through the overlying cutaneous tissue and are called mongolian spots. Some believe that it is not the number of melanocytes present that is important but rather their activity level. The hormone secreted by the pituitary gland that controls the clumping or dispersion of the melanin granules is a melanocyte-stimulating hormone.

At around 20 weeks' gestation, the eyebrows, upper lip, and chin hair are first recognizable. On the general body surface, the hair makes its appearance about a month later. These fine hairs are called lanugo. The emergence of this hair breaks off the periderm and the periderm becomes one component of the *vernix caseosa*. The other components of vernix are sebum from the sebaceous glands, fetal hair, and desquamated cells from the amnion (Moore & Persaud, 2015). The vernix protects the epidermis against a macerating influence that would be exerted by the amniotic fluid and acts as a lubricant to prevent chafing injuries from the amnion as the growing fetus becomes progressively confined in its fluid-filled sac.

Between 21 and 24 weeks' gestation, the fetus's skin is wrinkled, translucent, and pinkish-red because blood in the capillaries has become visible. Head and lanugo hair are well developed in a 26- to 29-week fetus. At this same time, eccrine sweat glands are anatomically developed and are found over the entire body. Their function, however, is somewhat immature in the perinatal period.

Brown adipose tissue cells begin to differentiate in the seventh month of gestation, and the accumulation of subcutaneous fat begins to smooth out the many skin wrinkles. Between the 30th and 34th week of gestation, the skin is pink and smooth and the lanugo is beginning to shed. The fingernails reach the fingertips but the distal part of the nail is still thin and soft (Moore & Persaud, 2015). During the last trimester of pregnancy, subcutaneous fat accumulates and the fetus acquires a plump appearance. The composition of amniotic fluid tested at this time reflects skin function. The number of anucleated cells and keratinized lipid-containing skin flakes increases.

Thickness of the *Stratum Corneum* and Permeability

The *stratum corneum* layer provides the barrier properties of the skin. This barrier is composed of keratinocytes coated by intercellular lipids. The *stratum corneum* begins to develop in the fetus after 21 weeks estimated gestational age (EGA). The *stratum corneum* in infants of 28 weeks' gestation consists of only a few cell layers and is markedly thinner than that of term infants. These findings correlate with the immaturity of barrier function of the *stratum corneum* and are characterized by increased permeability and increased transepidermal water loss (TEWL; Bhatia, 2006). By 34 to 35 weeks EGA, the *stratum corneum* has developed sufficiently to offer some protection (Visscher et al., 2015).

The full-term infant has a fully functional *stratum corneum*. The *stratum corneum*, the nonliving layer of the epidermis, contains 10 to 20 layers in adults and term infants. The *stratum corneum* of term newborns has been shown to have lower TEWL and hydration (SCH) than that of adult skin, with the lowest levels seen on the first day of life. This suggests that the barrier is relatively impermeable to water to protect from maceration in utero and that a gradual drying process occurs over the first few days of life. In addition, the TEWL in different areas—such as the forehead, palms, and soles—is lower in newborns, whereas levels are higher on the forearm region (Yosipovitch, Maayan-Metzger, Merlob, & Sirota, 2000).

Despite reports of normal barrier function at birth, studies indicate that infant skin is prone to higher percutaneous absorption

TABLE 12.1

STRUCTURAL DIFFERENCES BETWEEN INFANT AND ADULT SKIN

	Premature	Full Term	Adult
Epidermis	Thinner cells compressed	*Stratum corneum* appears as adherent cell layers	Good resistance to penetration
	Fewer desmosomes	Melanin production low	
	Fewer layers of *stratum corneum*		
	Melanin production low		
Dermoepidermal junction	Fewer hemidesmosomes		
	Less cohesion between layers		
Dermis	Fewer elastin fibers	Fewer elastin fibers	Full complement of elastin fibers
	Thinner than in the adult	Thinner than in the adult	
Eccrine glands	May be more typical of fetus than adult	Equivalent in structure to adult	Distribution less dense than in infant
	Ducts patent	Denser distribution	
	Secretory cells undifferentiated		
Hair	Lanugo hair may be present	Vellus hair characteristic	Both vellus and terminal hairs
	Hair growth synchronous	Hair growth synchronous	Hair growth dyssynchronous
Sebaceous glands	Large and active	Large and active but diminishing rapidly in both size and activity for several weeks after birth	Large and active
Nerve and vascular system	Not fully organized	Vascular system not fully organized until 3 months	Adult pattern
	Most nerves are small in diameter, unmyelinated, sensory, and autonomic	Cutaneous nerve network not fully developed; may continue to develop until puberty	
	Unmyelinated nerves are typically fetal in structure	Most nerves are small in diameter, unmyelinated, sensory, and autonomic	
	Meissner's touch receptors not fully formed	Meissner's touch receptors not fully formed	
		Good resistance to penetration	
Permeability	Highly permeable	Good resistance to penetration	
	Higher penetrability of fat-soluble substances	Higher penetrability of fat-soluble substances	
	Greater absorption because of higher skin surface: body weight ratio	Greater absorption because of higher skin surface: body weight ratio	

(*continued*)

TABLE 12.1

STRUCTURAL DIFFERENCES BETWEEN INFANT AND ADULT SKIN (*continued*)

	Premature	Full Term	Adult
Eccrine sweating	Reduced sweating capability, especially for first 13–24 days	Reduced sweating capability, especially for first 2–5 days	Full sweating capability
Photosensitivity	Melanin production low; will sunburn readily	Melanin production low; will sunburn readily	Sensitivity to sun depends on skin type
Related conditions	Reduced ability to ward off infection because of deficient immune system	Reduced ability to ward off infection	Readily sensitized to allergens
	Low reactivity to allergens	Low reactivity to allergens

TABLE 12.2

EMBRYONIC AND FETAL DEVELOPMENT OF SKIN

Weeks of Gestation	Development
3	Epidermis, which develops from surface ectoderm, consists of one layer of cells.
5	Cutaneous nerves are detectable in embryonic dermis.
6–7	Periderm, a thin, protective layer of flattened cells, is formed.
11	Collagen and elastic fibers are developing in the dermis. Epidermal ridges (fingerprints) are forming. Nails begin to develop at the tips of the digits.
13–16	Scalp hair patterning is determined.
17–20	Melanocytes migrate to the epidermal-dermal junction and begin to produce melanin. Skin is covered with *vernix caseosa* and lanugo. Keratin is accumulating in the epidermis.
21–25	Skin is wrinkled, translucent, and pink to red because blood in the capillaries has become visible.
26–29	Subcutaneous fat begins to be deposited and starts to smooth out the many wrinkles in the skin. Eccrine sweat glands are anatomically developed and found over the entire body; their function, however, is somewhat immature in the perinatal period.
30–34	Skin is pink and smooth. Fingernails reach fingertips. Lanugo begins to shed.
35–38	Fetuses are usually plump. Skin is usually white or bluish-pink. Toenails reach toe tips.

Embryonic period: undoubtedly the most important period of human development because the beginnings of all major external and internal structures develop. Fetal period (ninth week to birth): primarily concerned with growth and differentiation of tissue and organs that started to develop during the embryonic period.

Source: Adapted from Ackerman, A. (1985). Structure and function of the skin. In S. Moschella & H. Hurley (Eds.), *Dermatology* (2nd ed., Vol. 2). Philadelphia, PA: Saunders.

and exhibits a greater tendency to irritant and allergic contact dermatitis, prompting some to say that barrier function is not fully developed at birth (Hoeger & Enzmann, 2002). In addition, infant *stratum corneum* is 30% thinner than adult, with the overall epidermis 20% to 30% smaller. Keratinocyte cells are smaller; with higher cell turnover rate that may explain observations of faster wound healing in infant skin (Stamatas, Nikolovski, Mack, & Kollias, 2011).

The *stratum corneum* of premature infants was once thought to rapidly mature and reach adult barrier function within approximately 2 weeks after birth. However, this has been shown to be a slower process in premature infants less than 27 weeks' gestation; rates of TEWL are nearly double adult levels, even at 28 days of life (Hammarlund & Sedin, 1979). In infants of 23 to 25 weeks' gestation, skin barrier function reaches mature levels much more slowly (Agren, Sjors, & Sedin, 1998), as long as 8 weeks after birth in a 23-week gestation infant (Kalia, Nonato, Lund, & Guy, 1998). The undeveloped *stratum corneum* of the premature infant's skin results in increased TEWL and evaporative heat loss and contributes to the difficulty the premature newborn experiences in maintaining fluid balance and body temperature.

Neonatal skin is 40% to 60% thinner than adult skin and the body surface/weight ratio is nearly five times greater, placing the newborn at risk for toxicity from topically applied substances (Mancini, 2004; Siegfried, 2008). The skin of a premature infant is remarkably permeable; permeability correlates inversely with gestational age. Sekkat, Kalia, and Guy (2004) have developed an in vitro model to examine the biophysical characteristics of TEWL in premature infants. This model will help clinicians understand how procedures coupled with gestational age can affect skin integrity, permeability, and TEWL.

Toxicity due to topically applied substances secondary to the increased permeability of both preterm and term infants' skin has been reported in numerous cases (Siegfried, 2008). All topical solutions during the first month of life should be carefully evaluated in relation to potential benefits, risks, and effectiveness.

Dermal Instability

Collagen in the dermis increases with gestational age as the tendency toward water fixation and edema decreases. The other component of the dermis, the elastin fibers, is formed mostly after birth and may not become fully mature until 3 years of age. **Quality and Safety: Protection from pressure and ischemic injury includes routine turning and repositioning on surfaces such as gelled pads or water mattresses** (Association of Women's Health, Obstetric, and Neonatal Nurses [AWHONN], 2018).

Diminished Cohesion

Another variation in the premature infant's skin structure and function is the diminished cohesion between the dermis and the epidermis. The junction of the epidermis and the dermis, normally connected by numerous fibrils, has fewer and more widely spaced fibrils in the premature infant than in term infants or adults. These fibrils become stronger with increasing gestational and postnatal age (Holbrook, 1982). Because care of the premature infant in the NICU often requires intravenous lines, cardiorespiratory electrodes, endotracheal tubes, and umbilical artery catheters, the premature infant is at higher risk of blistering and stripping of the epidermis when adhesives used to secure these devices and monitors are removed (Cousins, 2014). **Emergency Alert: The cohesion between many of the currently used adhesives and the *stratum corneum* may be stronger than the bond between the dermis and the epidermis.**

Skin pH

Another developmental variation of infant skin resides in the functional capacity of the skin to form a surface pH of less than 5.0, which is the acid mantle. A skin surface pH of less than 5.0 is ordinarily seen in both children and adults.

Full-term newborns' skin was found to have a mean pH of 6.34 immediately after birth. Within 4 days, the pH decreased to a mean of 4.95, and between 7 and 30 days it further decreased to 4.7. In a later study of 127 low-birth-weight infants, these authors documented that the mean pH decreased from 6.7 (day 1) to 5.04 (day 9). However, a different technique for measuring pH was used than in the previous study; thus, the absolute values for pH may not be comparable. They concluded that acidification of the skin is independent of gestational age (C. Fox, Nelson, & Wareham, 1998).

An acidic skin surface is credited with having bactericidal qualities against some pathogens and serves in the defense against microorganisms. This acid mantle contributes to the *stratum corneum*'s innate immune function by inhibiting the growth of pathogenic bacteria (Larson & Dinulos, 2005; Visscher et al., 2011). The retention of *vernix caseosa* has been shown to assist in earlier acidification of the newborn skin and may help to facilitate colonization by normal flora after birth (Tollin et al., 2005), while an increased pH may reduce *stratum corneum* integrity and enhance susceptibility to mechanical damage (Visscher et al., 2011).

Melanin Production

One of the primary functions of melanin is to screen the skin from the sun's harmful rays by absorbing their radiant energy. Although melanin production—and therefore pigmentation—are lower during the neonatal period than later in life, certain areas—such as the linea alba, the areola, and the scrotum—are often deeply pigmented as a result of high circulating levels of maternal and placental hormones. Melanin production in premature infants is even less than in term infants, thus placing them at greater risk for damage from sunlight and ultraviolet light (Williams, 2008).

Assessment and Physiologic Variations

Acrocyanosis, or peripheral cyanosis involving the hands, feet, and circumoral area, is a common finding in the newborn. It occurs because of sluggish blood flow in the feet and hands that results from limited development of the peripheral capillary circulation. Acrocyanosis usually resolves within the first few days of life but may reappear with cold stress (Lucky, 2015). It occurs more often in premature infants.

Pallor is most commonly a sign of anemia, hypoxia, or poor peripheral perfusion that results from hypotension or infection. Meconium staining is caused by the passage of meconium in utero and usually requires at least 6 hours of meconium contact to stain the skin.

Jaundice, which occurs in 50% to 70% of newborns, is a yellowing of the skin and develops because of the presence of indirect bilirubin in the blood formed from the body's normal breakdown of red blood cells. Bilirubin is normally processed by the liver and is eliminated in the urine and feces. In newborns, the body cannot eliminate bilirubin as fast as it is produced.

For visible staining of the skin and sclera, a bilirubin level of at least 5 mg/100 mL is required. The predictable head-to-toe progression of jaundice over the body gives a crude estimate of the level of bilirubin. Typically, the bilirubin level is highest at 3 to 5 days (Bromiker, Bin-Nun, Schimmel, Hammerman, & Kaplan, 2012).

Risk factors for high bilirubin levels or kernicterus, a neurologically damaging condition caused by hyperbilirubinemia, are: bruising at birth, prematurity, breastfeeding and poor feeding,

glucose-6-phosphate dehydrogenase deficiency (G6PD), East Asian or Mediterranean descent, jaundice prior to 24 hours, and a prior sibling with jaundice. Jaundice fades after the bilirubin level returns to normal. *Linea nigra* is a line of increased pigmentation from the umbilicus to the genitals. This area of benign pigmentation may become less noticeable as the infant's skin darkens. Mongolian spots are collections of melanocytes located in the dermis that are most frequently seen at birth. They are slate blue, gray, or black, shaped as irregular, bruise-like spots that are seen primarily over the sacrum and the buttocks but may extend over the back and shoulders. Most commonly seen in newborns with darkly pigmented skin, they are found in 96% of African American, 86% of Asian, and 13% of Caucasian infants (Lucky, 2008). Although they look like bruises, they are harmless and resolve over several years.

Lanugo is the fine downy hair that is most commonly seen over the back, shoulders, and facial areas of a premature newborn. It is shed at the seventh to eighth month of gestation and is one criterion used to estimate gestational age.

Milia are common papules that occur primarily on the face but may also occur in other locations. They are seen as small, white, pinhead-sized bumps scattered over the chins, cheeks, noses, and foreheads of 25% to 40% of full-term babies (Dinulos & Darmstadt, 2005). They spontaneously resolve within the first month of life. Mothers should be instructed not to squeeze or prick these pimple-like spots. Milia can develop on the foreskins of infant boys; these are called epidermal inclusion cysts. When they occur on the palate, they are called Epstein's pearls.

Miliaria (prickly heat) is a general term for describing obstructions of the eccrine duct. The cause is retention of sweat as a result of edema of the *stratum corneum*; this edema blocks eccrine pores, thus resulting in four types of miliaria: rubra, crystallina, pustulosa, and profunda. Most common locations are the forehead and upper trunk (Howard & Frieden, 2015).

Miliaria pustulosa and *miliaria profunda* are rarely seen in temperate climates. *Miliaria rubra* is commonly observed in infants exposed to excessive environmental temperatures with humidity. It appears as pink or white pimples with a little redness around them. They resolve when the infant is moved to cooler temperatures. *Miliaria crystallina* presents as clear, 1- to 2-mm superficial water blisters without inflammation. The distribution and grouping of vesicles that contain no eosinophils help to differentiate them from *erythema toxicum neonatorum*.

Harlequin color change is a dramatic but benign phenomenon in which the color on the dependent half of an infant in a side-lying position turns deep red while the upper half is pale. The face and genitalia may be spared and the color reverses when the infant is turned. Attributed to a temporary imbalance in the autonomic regulatory mechanism of the cutaneous vessels, this phenomenon is more common in low-birth-weight infants—whether well or sick—but can affect up to 10% of full-term babies (Lucky, 2015).

Vernix caseosa is a grayish-white cheesy substance that is a mixture of 80% water, protein, lipids, and desquamating cells (Visscher et al., 2015). This covering is protective to the fetal skin while the fetus is in utero and helps the infant slide through the birth canal. Vernix production begins at the end of the second trimester and accumulates in a cephalocaudal manner (Haubrich, 2003). The vernix covering diminishes as pulmonary surfactant rises and the fetus reaches term (Moraille, Pickens, Visscher, & Hoath, 2005). Surface distribution is dependent on gestational age, type of delivery, birth weight, race, gender, and the presence of meconium. The World Health Organization (WHO; 2015) recommends leaving residual vernix in place, after initial drying, to wear off with normal care and handling for at least 6 hours before bathing. **Quality and Safety:** *The AWHONN Neonatal Skin Care Evidence-Based Practice Guideline*, Fourth Edition, **recommends leaving vernix on the skin and delaying the first bath until between 6 and 24 hours of age** (AWHONN, 2018). In clinical care, vernix has been thought of as an unwanted soil from intrauterine life but recent research has revealed that vernix has many functions and potential benefits for the newborn. These functions and potential benefits include: protection against infection (Tollin et al., 2005), decreased skin permeability and TEWL (Visscher & Narendran, 2014; Yoshio, Lagercrantz, Gudmundsson, & Agerberth, 2004), skin cleansing (Moraille et al., 2005), moisturization of the skin surface (Visscher & Narendran, 2014), development of the epidermal barrier (Tansirikongkol, Visscher, & Wickett, 2007), pH development (Colwell, 2015), and temperature regulation.

Cutis marmorata, or mottling, is a normal physiological vascular response to cool air. This generalized mottling reflects the infant's vasomotor instability. The marbling disappears with rewarming and is uncommon after several months of age. Mottling is often prominent in infants with Cornelia de Lange syndrome and Down syndrome (Trisomy 21).

TERMINOLOGY

Ecchymoses appear as black and blue bruises of varying sizes anywhere on the body. Primarily seen over the presenting part in a difficult vertex delivery or a vaginal breech delivery, ecchymosis is most frequently due to trauma associated with labor and delivery. It occurs more commonly in the fragile premature infant. This bruising, however, can be indicative of serious infection or bleeding disorders. Large areas of bruising may require phototherapy as a result of hyperbilirubinemia (Jensen & Galbraith, 2015).

Petechiae are pinpoint hemorrhagic areas, less than 1 mm in diameter, scattered over the upper trunk and face as a result of pressure during the descent and rotation of birth. Their incidence is increased when the umbilical cord has been around the neck or when the cervix clamps down after delivery of the head. They do not disappear with blanching because the blood is contained in the tissues. They usually fade within 24 to 48 hours. If they continue to develop or are unusually numerous, a complete workup for infection or bleeding disorders should be performed.

Thrombocytopenia should be suspected when the infant presents with general cutaneous petechiae. It frequently accompanies neonatal infections and is most commonly associated with the TORCH diseases (toxoplasmosis, others, rubella, cytomegalovirus [CMV], and herpes simplex).

Macules are nonpalpable, nonraised lesions less than 1 cm in diameter identified only by color change. They are seen in measles, rubella, scarlet fever, roseola, typhoid fever, and drug reactions.

Papules are superficial elevated solid lesions less than 1 cm in diameter. They are firm and not fluid-filled. They may follow the macular stage in many eruptive diseases. Vesicles are skin elevations that contain serous fluid (blisters). They are commonly seen with herpes simplex, insect bites, and poison ivy.

Pustules are localized accumulations of pus in, or just beneath, the epidermis. They are often centered around appendageal structures (e.g., hair follicles) and are usually caused by bacterial infections or skin abscesses. When a pustule breaks, the degree of crusting is more marked than occurs with the rupture of a vesicle.

Nodules are deep solid lesions larger than 1 cm in diameter. Nodules are similar to papules but are larger. Because of their size, they are more likely to have a dermal component than are papules.

Lesions Related to the Birth Process

Caput succedaneum is a diffuse, generalized edema of the presenting part of the scalp. It is the result of venous congestion caused by the pressure of the uterus, cervix, and vaginal wall on the infant's head during prolonged labor. The borders are not well-defined and the swelling crosses suture lines since the fluid accumulates outside the periosteum. Cephalohematoma is a subperiosteal hemorrhage caused by the rupture of the emissary or diploic veins of the skull during a prolonged labor and delivery. The margins of the suture lines are clearly demarcated, almost always unilateral, and the swelling never crosses suture lines. It is seen more commonly in vacuum-assisted vaginal deliveries. Estimates of underlying skull fractures range from 5% to 25% (Jensen & Galbraith, 2015).

Forceps marks are identified by their rounded contours and position. The bruised area should be checked for underlying tissue and nerve damage. Scalp lacerations can occur in many ways. A laceration can be caused by the placement of an internal fetal monitoring lead or by the artificial rupture of membranes.

A circular red or ecchymotic area may be caused by the use of a vacuum extractor. Any abraded area may serve as a portal of entry for infection; therefore, a scalp laceration should be carefully and continuously assessed for the presence of infection.

Lacerations can also occur to other body surfaces from scalpel injuries during cesarean birth; an incidence of 1.9% was noted in a series of 896 cesarean section deliveries. Usually the laceration or abscess remains confined to the skin; however, reported complications include osteomyelitis.

Internal fetal monitoring sites are at risk for infection, owing to the introduction of the maternal vaginal flora directly into the subcutaneous tissue of the fetus. Scalp abscesses caused by implantation of a fetal electrode are generally benign, self-limited occurrences. Rare instances of major complications have been reported, however—including significant areas of cellulitis, osteomyelitis, and sepsis (Jensen & Galbraith, 2015).

Subcutaneous fat necrosis is an uncommon subcutaneous tissue disorder that occurs primarily in full-term and postterm infants. It has been associated with birth trauma, shock, asphyxia, hypothermia including therapeutic hypotheria, seizures, and peripheral circulatory collapse. One or several indurated, violet or red plaques or sharply defined subcutaneous nodules on the buttocks, thighs, back, cheek, or arms may appear (Hoath & Narendran, 2015). Hypercalcemia has been associated with subcutaneous fat necrosis so serum calcium levels should be monitored. Most areas of subcutaneous fat necrosis gradually reabsorb over weeks to months if left alone. Residual atrophy or scarring is unusual.

Sclerema neonatorum may have the same cause and adipose tissue abnormality in the subcutaneous tissues as those noted in fat necrosis. However, sclerema more commonly affects the premature or debilitated infant. It is a diffuse hardening of the subcutaneous tissue that results in cold, nonpitting skin. The extremities may be involved at first but generalized involvement occurs within 3 to 4 days. Infants with this disorder are usually critically ill and there is a high mortality rate. If the infant survives, the sclerodermatous changes rarely last beyond 2 weeks. Treatment is based on therapy for the underlying systemic disease, restoration of body temperature, and adequate nutrition. Exchange transfusions and systemic administration of steroids have been used with unconfirmed efficacy (Hoath & Narendran, 2015).

TRANSIENT SKIN LESIONS

Erythema toxicum neonatorum, the most common rash of newborns, usually occurs within 5 days of birth and affects approximately half of term infants, although it is almost never seen in premature infants or those weighing less than 2,500 g. It appears as small, firm, white, or pale yellow pustules with an erythematous margin. Lesions may first appear on the face and spread to the trunk and extremities, but may appear anywhere on the body, except the soles and palms (Howard & Frieden, 2015). Macules, papules, and pustules are seen in varying combinations. A smear and Wright's stain of the pustules reveal numerous infiltrates of eosinophils that are devoid of bacteria. The differential diagnosis includes transient neonatal pustular melanosis, candidiasis, staphylococcal pyoderma, and miliaria. No treatment is necessary.

Neonatal and infantile acne are two distinct conditions distinguished by the time of onset and clinical features. Neonatal acne (neonatal cephalic pustulosis) involves inflammatory, erythematous papules and pustules located primarily on the cheeks, often scattered over the face and extending into the scalp. Usual age of onset is days to weeks. Treatment with low potency topical corticosteroids such as hydrocortisone or imidazole creams such as ketoconazole can result in quicker resolution (Howard & Frieden, 2015). Infantile acne is considered to result in hyperplasia of sebaceous activity. It is found primarily on the face and presents after 1 month of age. Infantile acne can persist for months to years but generally resolves without treatment. Infantile acne may be more persistent and even cause scarring. Some experts suggest that neonatal acne is related to sebum excretion rate while the infantile form is related to high androgen levels but both have genetic influences (Herane & Ando, 2003).

Transient neonatal pustular melanosis is a lesion that is similar to miliaria but is present at birth, usually causing the infant to be unnecessarily isolated. It occurs most commonly on the forehead, behind the ears, and on the palms of the hands and the soles of the feet of term infants. It is most commonly seen in black infants. The differential diagnosis includes *erythema toxicum neonatorum*, staphylococcal impetigo, congenital candidiasis, *miliaria crystallina* or rubra, and acropustulosis of infancy. If the lesions are ruptured, smeared on a slide, and stained, the contents are found to be amorphous debris. The lesion is neither infectious nor contagious. It is self-limiting and requires no treatment.

Sucking blisters that contain sterile, serous fluid may be seen on the thumb, index finger, wrist, or lip. Presumably the result of vigorous sucking in utero, they are seen in approximately 1 in every 250 live births, and resolve without treatment (Howard & Frieden, 2015).

Pigmentary Lesions

Hyperpigmented lesions may be present at birth or during the first weeks of life. Some pigmentary problems are benign, such as mongolian spots, whereas others can be signs of a systemic or genetic disorder. Some of the more common ones are included in this section.

Café au lait spots are irregularly shaped, flat, oval lesions. Their color resembles coffee to which milk has been added. They are present in up to 20% of infants usually over the buttocks. They should be noted on the newborn's initial physical examination; if they are larger than 4 to 6 cm or if more than six are present, a diagnosis of neurofibromatosis should be considered (Hoath & Narendran, 2015). Pigmented lesion lasers can provide a safe and effective therapy for removing café-au-lait spots (Mavropoulos & Cohen, 2013).

Mongolian spots are a collection of melanocytes deep in the dermis. Commonly located over the buttocks and sacrum, they are gray, slate blue, or black in color. They appear in 13% of Caucasian, 65% of Latino, 86% of Asian, and 96% of African American infants (Lucky, 2015).

Hyperpigmentation that presents in a diffuse pattern is unusual in the newborn. When present, congenital Addison's disease,

hepatic or biliary atresia, metabolic disease (Hartnup disease, porphyria), nutritional disorders (pellagra, sprue), hereditary disorders (lentiginosis, melanism), or unknown causes (the bronze discoloration seen in Niemann–Pick disease) may be the cause. Hyperpigmentation of the labial folds with clitoral hypertrophy may result from the transplacental passage of androgens (Dinulos & Darmstadt, 2005).

Neonatal/infantile hypopigmentation results from a diverse group of conditions. It can occur due to any defect in melanocyte development, melanin synthesis and transport, or distribution of melanosomes to keratinocytes. Hypopigmentation can present as a generalized, diffuse, or localized loss of pigment in the neonate which may stem from metabolic (phenylketonuria), endocrine (Addison's disease), genetic (vitiligo, piebaldism, tuberous sclerosis, albinism), traumatic, or postinflammatory causes (Dinulos & Darmstadt, 2005).

Albinism refers to a group of genetic disorders involving abnormal melanin synthesis during embryogenesis (Chan & Tay, 2015). It may occur in any race, with the incidence approximately 1 in 20,000, with a slightly higher rate in African Americans (Sethi, Schwartz, & Janniger, 1996). An autosomal recessive gene usually causes it but rare cases of autosomal dominant inheritance have occurred (Dinulos & Darmstadt, 2005).

Partial albinism (piebaldism) is a localized, autosomal dominant disorder present at birth and easily detected in the dark-skinned infant. Off-white macules are seen on the scalp, widow's peak, and forehead and extend to the base of the nose, trunk, and extremities. A white forelock, a tuft of white hair over the midfrontal scalp, is present in 80% to 90% of patients and is associated with depigmentaion of the underlying scalp (Chan & Tay, 2015). When illuminated with a Wood light, the amelanotic areas of piebaldism exhibit a brilliant whiteness. Differential diagnoses are Waardenburg syndrome, vitiligo, *nevus anemicus*, Addison's disease, and white macules of tuberous sclerosis. Photoprotection of the depigmented areas beginning early in infancy is important to protect from sunburn and to avoid skin cancers later in life.

White leaf macules are the earliest cutaneous manifestations of tuberous sclerosis, an autosomal dominant neurocutaneous syndrome with both cutaneous and neurologic abnormalities (Chan & Tay, 2015). The macules vary in size and shape but most often resemble a mountain ash leaflet. They may be difficult to see in a newborn infant and may be more readily observed by examination with a Wood lamp, which heightens the contrast between the macule and normal skin. Normal infants occasionally have a single lesion but the presence of one or more of these macules in an infant with neurologic problems strongly suggests the diagnosis of tuberous sclerosis. Retinal hamartomas, cardiac rhabdomyomas, and benign renal tumors are some of the other possible findings. A careful family history, detailed physical examination, and multidisciplinary management are indicated in infants with these lesions.

Waardenburg syndrome is a rare autosomal disorder characterized by depigmented patches of skin and hair, congenital nerve deafness, craniofacial anomalies, and heterochromia iris.

Dermatologic Diseases

Diseases of the skin in newborns often present patterns different from the presentation of the same disease in adults. Therefore, a careful physical examination of the skin is necessary for an accurate dermatologic diagnosis to be made. All lesions should be described and their locations and patterns noted.

Lesions can be classified as either primary or secondary. Primary lesions are described as the initial or principal lesions identified when the disease begins. Primary lesions are classified as macule, patch, papule, plaque, nodule, tumor, vesicle, bulla, wheal, pustule, or abscess. Some conditions that present with blister and pustules can be life-threatening (Howard & Frieden, 2015). Secondary lesions are brought about by the modification of a primary lesion resulting in a crust, scale, erosion, ulcer, fissure, lichenification, atrophy, or scar.

Developmental Vascular Abnormalities

The following two major groups of vascular birthmarks are seen:

1. Vascular malformations composed of dysplastic vessels
2. Vascular tumors that demonstrate cellular hyperplasia

Vascular malformations have various subcategories determined by the anomalous vessels involved—including capillary, venous, arteriovenous, or lymphatic. They remain relatively stable in size; any growth is commensurate with growth of the child.

Port-Wine Stain. A port-wine stain is a capillary malformation consisting of dilated and congested capillaries lying directly beneath the epidermis. It appears in approximately 3 out of 1,000 newborns. This birthmark appears pink at birth but gradually darkens to purple. Most commonly found on the face and neck, it is a permanent developmental defect. They are most sharply demarcated and flat in infancy but over time develop a thickened or pebbly surface. Although a port-wine stain is primarily a cosmetic problem, it is occasionally an indicator of a multisystem disorder, such as Sturge–Weber syndrome or Klippel–Trenaunay–Weber syndrome. The presence of seizures, mental retardation, hemiplegia, or intracortical calcification suggests the presence of Sturge–Weber syndrome (Hoath & Narendran, 2015). An ophthalmologic examination is extremely important in these infants. Gradual thickening and nodule formation can occur with port-wine stain and thus support the need for early treatment in infancy and childhood. Although the timing of intervention is somewhat controversial, many dermatologists now advise laser treatment as early as possible in infancy to decrease the stigma associated with this lesion and to prevent skin thickening (Enjolras & Garzon, 2008). Pulsed dye laser is the gold standard for treatment of port-wine stain birthmarks but multiple treatments are required. While laser is effective at fading these lesions, complete resolution is achieved in only 15% to 20% of cases (Hoath & Narendan, 2015; Tremaine et al., 2012).

Pigmented Nevus. Congenital melanocytic nevi are benign nested clumps of melanocytes. In contrast to melanocytes, they tend to lie in groups or nests. Congenital pigmented nevi are different from pigmented nevi that arise later in that they are usually larger and more extensive. As the infant grows, the area becomes thicker and darker (Dinulos & Darmstadt, 2005).

Flat, junctional nevi are seen in about 1% of newborns. They are brown or black and their size varies from one to several centimeters. Conservative management consists of serial observations since there is no evidence that they are a premalignant lesion. Surgical excision may be considered based on location and appearance of the lesion (Hoath & Narendran, 2015).

Large Congenital Melanocytic Nevi. A giant hairy nevus (>20 cm) is characterized by a pigmented and softly infiltrated area. The color varies from pale brown to black. When the nevi are large, they tend to have a dermatomic distribution, and their location and size give them their name (e.g., bathing trunk nevus, vest nevus, shoulder stole nevus; Figure 12.1). On histologic examination of a biopsy specimen, the nevus cells are seen penetrating deeply into the dermis and subcutaneous tissue.

When a giant nevus is situated on the head or neck, it may be associated with mental retardation, epilepsy, or hydrocephalus. *Spina bifida* or meningocele may occur when this nevus is present over the spine (Dinulos & Darmstadt, 2005). Other abnormalities

FIGURE 12.1 The giant pigmented hairy nevus of this infant involves the thorax, abdomen, and back and is commonly called a "bathing trunk" nevus. It is raised with fleshy elements and has a somewhat leathery texture.

FIGURE 12.2 This photograph shows the early hemangioma in a 28 weeks' gestation premature infant. Approximately 5 weeks after birth the first area of discoloration appeared. The irregular surface with sharp demarcation is typical of strawberry hemangioma, which eventually enlarges to twice the size it appears in this photograph before involution.

Source: Reprinted with permission from Clark, D., & Thompson, J. (1986). Dermatology of the newborn, Parts 1 and 2. In *Pathology of the neonate slide series* (Vol. 3, No. 4). Philadelphia, PA: Wyeth-Ayerst Laboratories.

sometimes associated with a giant pigmented nevus are clubfoot, hypertrophy or hypotrophy of the affected limb, and von Recklinghausen's disease (neurofibromatosis). Besides being a cosmetic problem, the giant nevus is associated with a higher incidence of malignancy. Malignant melanomas develop in as many as 8% of these patients. Management involves surgical excision of the entire lesion to prevent the development of skin cancer in the lesion. Dermabrasion, lasers, and tissue expansion techniques have been used in conjunction with surgery. Plastic surgical reconstruction may be needed if the excision is extensive.

Hemangiomas. Infantile hemangioma (IH) is the most common vascular tumor seen during early infancy. They are characterized by the proliferation of capillary endothelium cells. These cells possess histochemical markers also present in placental vessels (Chen, Eichenfield, & Friedlander, 2013). Hypoxia has been identified as the main factor for vascular proliferation in IH (Laken, 2016). Hemangiomas appear on 1% to 3% of infants at birth and develop on another 10%, usually within the first 3 to 4 weeks of life. Females are 2 to 3 times more likely to be affected than males (Haggstrom & Chamlin, 2014). Besides gender, the other infants at highest risk are non-Hispanic whites, premature infants, and multiple gestation infants. The incidence is 22% in preterm babies who weigh less than 1,000 g and 15% in infants with birth weights of 1,000 to 1,500 g.

Classified by their depth, hemangioma types include superficial, deep, and compound. The treatment for most hemangiomas is "active" nonintervention. Up to 40% will develop complications requiring intervention (Hoath & Narendran, 2015). Congenital hemangiomas that resolve rapidly often leave pronounced atrophic changes in their place.

They most often appear in the skin as a single tumor, but multiple cutaneous lesions also occur, often with involvement of other organ systems.

The natural history of the hemangioma is characterized by its appearance during the first few weeks of life, rapid postnatal growth for 3 to 18 months (proliferative phase), a phase of stabilization for 12 to 18 months, which is followed by very slow but inevitable regression for the next 5 to 8 years (involutive phase; Droitcourt et al., 2018). Infantile hemangiomas completely resolve in more than 80% of children by 4 years of age and continued improvement occurs in the remaining children. The rate of regression does not seem to be related to the sex or age of the infant or to the site, size, or appearance of the hemangioma or the duration of the proliferative phase.

Strawberry or superficial hemangiomas consist of a dilated mass of capillaries in the dermal and subdermal layers that protrude above the skin's surface. They are bright red, soft, compressible tumors that can appear anywhere on the body (Figure 12.2). They generally increase in size for approximately 6 months and then gradually begin to regress or involute spontaneously. Complete involution may take several years to occur. These marks require no treatment but 20% to 40% of patients may have residual skin changes. When these lesions interfere with vital functions such as vision, feeding, and respiration, intervention is required (Enjolras & Garzon, 2008).

Cavernous or deep hemangiomas are more deeply situated in the skin than are superficial strawberry hemangiomas. They are bluish-red, feel spongy when touched, and may not appear until 1 to 3 months after birth. Most hemangiomas are small, harmless birthmarks that involute to leave either normal or slightly blemished skin. However, even a small hemangioma can obstruct the airway or impair vision. A large hemangioma in the liver or an extensive cutaneous hemangioma can divert a considerable volume of blood through its extensive labyrinth of capillaries and produce high-output heart failure. The increased capillary endothelial surface that characterizes a giant hemangioma can also trap platelets and may cause thrombocytopenic coagulopathy as seen in the Kasabach–Merritt syndrome. This syndrome carries significant mortality and requires aggressive treatment such as transcutaneous arterial embolization (Hoath & Narendran, 2015).

A few hemangiomas grow to an alarming size or proliferate simultaneously in several organs and cause life-endangering conditions, such as soft-tissue destruction, deformation or obstruction of vital structures, serious bleeding, ulceration, and sepsis. Large lesions can expand the skin and, even after they regress, result in excess slack skin, pigment changes, and a fibro-fatty residuum.

Visceral hemangiomas may arise in many organs, most commonly in the liver and larynx, with or without cutaneous

involvement; a single lesion or multiple hemangiomas may occur. Having five or more lesions puts the infant at higher risk of a hepatic hemangioma (Laken, 2016). Flow through extensive hemangiomas increases the total blood volume, causes hemodeviation, and disturbs the hemodynamic equilibrium. The hyperdynamic cardiovascular state of the hemangiomas decreases or shunts blood away from other tissues, thus resulting in hypoperfusion of other tissues. This hypoperfusion may cause brain hypoxia, acidosis, and predisposition to seizures, as seen in some cases. Close surveillance of the cardiovascular system is necessary to determine the proper time to begin digitalization.

Large, complex or segmental lesions around the head, neck, lumbosacral, perineal and lower extremities have been associated with congenital anomalies. Large segmental lesions on the face can indicate PHACE syndrome. This neurocutaneous syndrome includes **P**osterior fossa brain formations, **H**emangioma greater than 5 cm, **A**rterial anomalies of head or neck, **C**ardiac abnormalities, and **E**ye abnormalities. Chest wall abnormalities may be present, also (Drolet et al., 2013).

Management. Management of both superficial and deep hemangiomas consists of a detailed history; close scrutiny of the lesion or lesions, including three-dimensional measurements; and evaluation of the growth pattern of the hemangioma. Ulceration, the most common complication that occurs in about 15% to 25% of all infants, can be very painful and result in infection, hemorrhage, scarring, and functional impairment (Hoath & Narendran, 2015). As involution progresses, the color gradually changes from grayish-pink to white or pink and the tension of the lesion decreases. Ulcerated hemangiomas should be treated with topical antibiotics to prevent infection.

While the cutaneous lesions are being monitored, the infant's clinical course and physical development must be closely observed for poor growth, altered cry, stridor, dyspnea, cyanosis, feeding difficulties, or swallowing impairment. **Emergency Alert: If any abnormal sign or symptoms appear—such as tachycardia, heart murmur, hepatomegaly, or bruit that can be *heard* over the liver—the infant should be examined for evidence of heart failure.** Ultrasonography, echocardiography, and computed tomography may be needed.

In general, management consists of planned neglect, which is essential in avoiding disfiguring scars. Complications of therapy may be significant but residual scarring after complete involution is uncommon. Hemangiomas located in exposed areas often cause great parental anxiety, which increases as the hemangioma grows. This anxiety often puts pressure on the physician to do something. However, the hemangioma should be left to regress spontaneously and preconceived notions about birthmarks should be discussed with the family.

In some cases, treatment of hemangiomas may be needed. The following indications for treatment have been proposed: life-threatening or function-threatening hemangiomas, including those that cause impairment of vision, respiratory compromise, or congestive heart failure; hemangiomas occurring in certain anatomical locations such as the nose, lip, glabellar areas, and ear that may cause permanent deformity or scars; large facial hemangiomas, especially those with a large dermal component; and ulcerated hemangiomas (Enjolras & Garzon, 2008).

Alarming hemangiomas is a term used to categorize lesions that impair vital functions or cause life-threatening complications. A vascular mark was present at birth in 68% of these infants. Visceral hemangiomas are associated with cervicocephalic hemangiomas or with small hemangiomas scattered over the body. About a third of these life-threatening hemangiomas respond to treatment with corticosteroids. The mortality rate can be as high as 54% for life-threatening visceral or hepatic hemangiomas and may be up to 30% to 40% with platelet-consumptive coagulopathy, despite the administration of steroids.

High-dose corticosteroid therapy is the primary means of pharmacologically controlling hemangiomas . These agents inhibit the activators of fibrinolysis in vessel walls, decrease plasminogen activator content of endothelium, and increase sensitivity to vasoactive amines, causing constriction of the arterioles. When steroids fail, less conventional modalities, such as embolization, operative excision, pulsed dye laser, interferon-alpha, and sclerotherapy have been used (Smolinski & Yan, 2005).

Vincristine and subcutaneous interferon-alpha-2a (2 MU/m^2 of body surface area) has been used with life-threatening or vision-threatening hemangiomas that failed to respond to corticosteroid therapy. Their mechanisms of action include inhibition of motility and proliferation of endothelial cells and interference with new capillary vessel formation, preventing platelet trapping. These daily injections seemed to reduce the local and systemic complications and appeared to shorten the length of time to involution in some infants. Sustained therapy for 9 to 14 months appeared to be desirable because earlier withdrawal was followed by regrowth of the lesion that was halted and reversed by reintroduction of the drug. Interferon and vincristine have limited use due to their adverse side effects (Chen et al., 2013).

Surgical therapy involving either laser removal or surgical excision is also a treatment option. Excision is usually done once the hemangioma has involuted, so as to remove residual tissue and redundant skin. Early excision is generally not recommended.

Oral propranolol (Inderal) appears to be an effective and safe treatment for infantile hemangioma. It has been shown to decrease the size and reduce the potential for life-long complications.

Emergency Alert: Propranolol had the most significant response when it was started with infants younger than 4 months of age. Potentially harmful effects include hypoglycemia, hyperkalemia, bronchiolitis, bronchospasm, conduction disorders (bradycardia), and hypotension (Droitcourt et al., 2018). The dose should be divided into three daily doses given with a minimum of 6 hours between doses. Giving the dose with, or right after, feeding reduces the risk of hypoglycemia.

The HEMANGIOL study showed that propranolol has a high rate of efficacy with a low rate of serious side effects (Laken, 2016).

Topical management options for infantile hemangiomas includes: Timolol 0.5% gel and corticosteroids. Timolol maleate is a topical beta-blocker that may have a particular role in treatment of superficial lesions. The recommendation is to apply one drop twice a day to affected lesions (Chen et al., 2013).

Blistering Diseases

Epidermolysis Bullosa. Epidermolysis bullosa (EB) is a group of rare, congenital blistering disorders, all of which are inherited. They are considered mechanobullous diseases, meaning that trauma to or friction on the skin induces blister formation. EB is caused by defects in the complex meshwork of proteins in the epidermis, dermis, and dermoepidermal junction that allow the skin to adhere in the presence of frictional stress. The underlying defect appears to be a lack of cellular glue in squamous epithelium, responsible for the maintenance of cellular integrity. Diagnostic studies should include a skin biopsy for light and electron microscopy and immunofluorescence mapping. In all forms of EB, gentle rubbing will result in blister formation, the Nikolsky sign.

EB is classified into three major subtypes by the clinical extent and ultrastructural level of blistering, by inheritance pattern, and

by specific genetic mutations (Hoath & Narendran, 2015; Püttgen & Cohen, 2013). Although some subtypes of EB are severe in the neonatal period and milder later, others can be fatal in the first weeks as a result of severe generalized blistering and complications that arise from this. EB can be nonscarring or scarring. Inheritance may be either autosomal dominant or autosomal recessive.

EB simplex is the mildest form of EB. Most cases are autosomal dominant. The lesions occur at the basal layer of epidermis and do not lead to scarring and hyperkeratosis. Usually present at birth, the vesicles and bullae appear over the joints and the bony protuberances and at sites subjected to repeated trauma.

Junctional EB is a very severe but the least common type of EB with autosomal recessive inheritance. In junctional EB, severe generalized blistering is present at birth, with subsequent extensive denudation. Marked mucosal blistering occurs, and erosions of the larynx, respiratory, gastrointestinal, and urinary tract may also be present. It may be fatal in a few days to a couple of years because of significant loss of electrolytes and protein or sepsis. Histopathologically, a separation occurs between the plasma membrane of the basal cells and the basal lamina at the dermal-epidermal junction (Püttgen & Cohen, 2013). In junctional EB, healing is poor, and scarring is extensive.

Dystrophic or scarring EB results in blistering that occurs below the dermoepidermal junction and has either dominant or recessive inheritance. In the recessive form, blistering, infection, and scar formation can be severe; begins before birth; and can lead to severe deformities and joint contractures. Milia may mark the healed blister sites. Complications include infections and hemolytic, nutritional, orthopedic, gastrointestinal, and psychiatric sequelae. Squamous cell cancer is also associated with this life-limiting type of EB.

The dominant form of dystrophic EB is milder, with less severe blisters or red plaques seen on the distal extremities and bony protuberances (Figure 12.3). Some scar formation occurs and the nails may be mildly dystrophic but deforming scars and contractures occur infrequently. The external skin layer can be easily rubbed off by slight friction or injury. Milia, due to a functional disorder of the sweat glands, are found on the rims of the ears, the dorsa of the hands, and the extensor surfaces of the arms and legs. The oral, anal, and esophageal mucosa are frequently involved but not severely.

FIGURE 12.3 This photograph of epidermolysis bullosa shows the scaling, broken bullae with underlying erythroderma.

Management. EB can be a great challenge in the newborn period, particularly with the more severe forms. Nursing care centers around three main issues: (1) skin breakdown, (2) prevention of secondary infection, and (3) dysphagia. Many of the techniques used to protect the skin of very premature infants are useful with EB patients. Avoiding the use of tape and preventing traumatic injuries is important. Clean, soft dressings may be helpful over bony pressure points. Wound care involves providing a moist healing environment by covering open lesions with a thick coating of petrolatum-based emollients combined with topical antibiotic ointments and covering with nonstick dressings.

Many dermatologists will rotate topical antibiotics every few months to prevent resistance and may use wound cultures to guide selection of agents. Nonstick dressings include petrolatum gauze, Vigilon, Exu-dry, or silicone-based products such as Mepitel (Direct Medical Inc., Houston, TX). After this layer, wrapping with nonadhesive cotton gauze further protects the wound; some practitioners prefer cotton mesh, and others use Coban (3M, Indianapolis, IN), a wrap that adheres to itself without adhesives. When blisters are tense and fluid-filled, they should be "unroofed" to prevent extension. This procedure is done with sharp, clean scissors, leaving the blister roof in place. Dressings are changed daily and removed gently; some prefer to remove dressings during immersion bathing.

From birth to 6 months of age, the environment is easy to control through the use of sheepskin, loose-fitting clothes, and mittens for the infant's hands and feet. Cloth diapers softened with fabric softener are preferred over rougher, disposable diapers. Any person handling the infant should avoid wearing jewelry.

Protection of the infant becomes more difficult once the infant is mobile. The infant should always wear long pants; foam rubber pads sewn into the knees help avoid trauma during crawling. Contractures may form quickly as scarring begins to occur. The pathologic increase in elastic skin fiber adds to this process. Gentle range-of-motion exercises lessen contracture formation.

Dysphagia can occur from facial and pharyngeal scarring, which is secondary to erosions on the buccal mucosa, tongue, palate, esophagus, and pharynx. Feedings should be performed slowly and carefully to avoid aspiration and to maintain adequate nutrition. The metabolic needs of these infants are high because of the continuous skin healing and sloughing of epithelium, which results in large protein, fluid, and electrolyte losses. Additional iron may be required to replace chronic blood loss from the skin (Püttgen & Cohen, 2013). Adding more puncture holes to a nipple may help prevent oral mucosal trauma. If oral ulcerations do occur, several weeks of hyperalimentation and high-dose steroid therapy are instituted. Gavage feedings are discouraged because of the possibility of trauma. It is essential that the family receives genetic counseling regarding the inheritance pattern associated with EB; a negative family history does not exclude its occurrence.

Infections of the Skin

Previously, it was thought that after vaginal birth, the skin colonization with microorganisms reflected the mother's vaginal flora and after cesarean section birth without rupture of the amniotic membranes, the skin was sterile. Recent research using DNA sequencing has begun to reveal that the skin microbiome begins in utero (Gregory, 2011). The skin microbiome of vaginally born infants does appear similar to the mother's vaginal flora but the skin of cesarean section births resembles the mother's and caregiver's skin flora (Dominguez-Bello et al., 2010). It now is known that the skin and its normal flora are natural defense mechanisms against invading pathogens. Maintenance of the skin microbiome is essential to the immunological functioning of the skin (Coughlin,

Frieden, & Eichenfield, 2014). A skin surface pH of between 4.0 and 4.5 facilitates the attachment of the "good" commensal bacteria (Telofski, Morello, Mack Correa, & Stamatas, 2012).

In the newborn, an immature immune system, prematurity, stress, and medical and surgical problems contribute to vulnerability and infection. Additionally, most infants in the NICU require a variety of invasive monitoring and diagnostic procedures that allow for breaks in the normally intact physical barrier of the skin, providing direct access to blood and deep tissues (Dinulos & Pace, 2008). The origin of skin infections and skin manifestations of systemic infection can be bacterial, viral, or fungal.

Bacterial. Bacterial skin infections can vary in initial clinical findings and potential for systemic symptoms and sequelae. The pathogen involved and the route of inoculation are two factors that affect the course of bacterial cutaneous infection (Dinulos & Pace, 2008). Types of bacterial skin infections include bullous and nonbullous impetigo, omphalitis, abscesses, and cellulitis. Severe dermatological findings are also seen when endotoxins are released from bacteria, as in the case of staphylococcal scalded skin syndrome.

Staphylococcus Aureus. Infections resulting from *Staphylococcus aureus* (*S. aureus*) are seen in newborns and can result in bullous, crusted, or pustular types of skin lesions. Nonbullous impetigo is a superficial infection localized to the epidermis and is characterized by erythematous, honey-colored, crusted plaques. Bullous impetigo of the newborn involves blisters that originate in the subcorneal portion of the epidermis and are filled with clear or straw-colored fluid. Bullous impetigo often presents during the first 2 weeks of life. Few or many blisters may be dispersed widely over all areas of the body and may rupture easily, thus leaving denuded areas of skin. Bullous impetigo commonly appears on the diaper area, axilla, and periumbilical skin and is predominantly caused by *S. aureus* (Hoath & Narendran, 2015). If the bacteria are later spread via the bloodstream, the infection may result in osteomyelitis, septic arthritis, or septicemia in neonates (Dinulos & Pace, 2008). Isolation of hospitalized neonates is initiated and intravenous antibiotics are generally recommended in neonates after initial blood, blister fluid, and skin cultures are obtained. Treatment is then tailored to the specific organism when the antibiotic susceptibility profile is known.

Management. Medical and nursing management is focused on treatment of the affected infant and on prevention of the spread of infection to other infants, because this condition is highly contagious. Blood cultures should always be obtained before initiating intravenous antibiotics (Hoath & Narendran, 2015). Systemic antibiotics are administered parenterally initially, due to the release of an epidermolytic toxin by *S. aureus*, in bullous impetigo and may be followed by oral treatment once the infection begins to subside. Antibiotics include oxacillin, nafcillin, or methicillin; vancomycin is used if the culture indicated methicillin-resistant *S. aureus*. Topical antibiotics are not indicated for treatment of bullous impetigo. Additionally, mupirocin intranasally is recommended to prevent recurrent impetigo from nasal colonization. Topical antibiotics can be effectively used for nonbullous impetigo if the lesions are not extensive or involving the mouth area. Fluid and electrolyte monitoring is necessary if the denuded areas cover a large surface or if the infant is of low birth weight (Hoath & Narendran, 2015). Compresses of warm saline can be applied to the affected sites. Isolation of the affected infant is necessary to prevent the spread of the infection throughout the nursery.

Scalded Skin Syndrome. Staphylococcal scalded skin syndrome is a severe endotoxin-mediated disease with superficial, widespread blistering often leading to desquamation (Figure 12.4). The bright erythema of this bullous eruption resembles a scald. The erythema usually begins on the face and spreads downward. Multiple sites are cultured when this disease is suspected, including any bullous lesions, blood, cerebrospinal fluid, nasopharynx, urine, conjunctival sac, and umbilicus in an effort to recover an organism. Staph scalded skin syndrome is rarely seen at birth with most cases appearing between 3 and 7 days of life (Hoath & Narendran, 2015).

FIGURE 12.4 The peeling, scaling skin of this premature infant had an acute onset at approximately 2 weeks of age. This is the scalded skin syndrome that results from *Staphylococcus aureus*.

Source: Reprinted with permission from Clark, D., & Thompson, J. (1986). Dermatology of the newborn, Parts 1 and 2. In *Pathology of the neonate slide series* (Vol. 3, No. 4). Philadelphia, PA: Wyeth-Ayerst Laboratories.

Skin will appear bright red, like a burn, followed by the development of large, loose blisters that quickly progress to sheets of skin being shed. During the course of this disease, the entire epidermis may be shed. Emollients, together with semi-occlusive dressings, provide gentle lubrication and pain relief.

Management. Medical and nursing management also involves administration of the appropriate systemic antibiotic regimen and supportive measures in terms of fluid and electrolytic replacement, prevention of secondary infection through the damaged epidermis, and pain management. Applying local antibiotic solutions or ointments is not recommended; cleansing open skin areas with gentle irrigation using half normal saline followed by the application of a nonadherent dressing that promotes healing and prevents secondary infection is better (King, Stellar, Blevins, & Shah, 2014). The infant may be more comfortable in an incubator rather than in a radiant warmer because the incubator is a convective heat source that does not have a direct cutaneous effect, whereas the radiant heat source heats directly through the skin. In addition, the radiant heat source may further increase the degree of insensible water loss through the damaged epidermis. Usually, a flaking process is observed on the skin during the healing process. Emollients may be helpful in treating dry skin at this point.

Listeria Monocytogenes. Another bacterial skin disease is listeriosis, caused by *Listeria monocytogenes*. This organism, which can cause severe systemic disease, can also result in a disseminated miliary granulomatosis in neonates (Hoath & Narendran, 2015). In some cases, miliary abscesses can occur, and occasionally, more generalized erythema or petechiae may be present. Systemic listeriosis is a severe infection that causes blood hemolysis and a high mortality rate. Prompt recognition and treatment with intravenous penicillin or ampicillin are indicated for the best prognosis. No direct skin therapy has been described as being necessary in this disease.

Syphilis. Congenital syphilis is another bacterial infection that has skin manifestations. Sixty percent of infants born with congenital syphilis are asymptomatic at birth (Püttgen & Cohen, 2013). If the infant with congenital syphilis is not treated after birth, a maculopapular or bullous skin eruption develops between 2 and 6 weeks of age. Sometimes, the bullous lesions may be observed at birth on the palms or the soles, signifying the presence of more severe disease (Hoath & Narendran, 2015). Fluid contained in the blisters contains spirochetes.

The lesions most commonly seen in congenital syphilis are copper-colored and maculopapular and are located on the soles and palms. In addition, open lesions may be present around the mouth, anus, or genitals, and a highly contagious nasal discharge is occasionally seen. If the syphilis remains untreated, the lesions regress in 1 to 3 months, leaving areas on the skin with either hyperpigmentation or hypopigmentation.

Management. Medical and nursing management for the infant with congenital syphilis involves prompt, consistent administration of penicillin. Titers are obtained over the next year at 3-month intervals, and a negative serologic finding is expected at 1 year. Care of the skin lesions is primarily directed toward preventing the spread of infection during the active phase of the illness, especially when bullous lesions or open areas are apparent. No direct topical therapies have been advocated in the literature.

Viral. Viral infections can display a broad range of cutaneous manifestations in the neonate and can occur in utero, perinatally, or postnatally. Congenital infections are known by the acronym TORCH, which stands for: Toxoplasmosis, Other (syphilis, varicella), Rubella, Cytomegalovirus, Herpes Simplex (Örge & Grigorian, 2015). Skin manifestations can be a direct result of skin infection or be a consequence of viral infection in other tissues. Viral infections that result in cutaneous manifestations include herpes simplex virus, cytomegalovirus (CMV), rubella, varicella, enterovirus, parvovirus, and human immunodeficiency virus. Some of these have very specific cutaneous presentations (such as the classic "blueberry muffin" appearance of infants infected with rubella and cytomegalic virus), vesicles (as with herpes simplex), or nonspecific lesions. Toxoplasmosis, which has cutaneous manifestations and is caused by a parasite, is also discussed in this section.

Herpes Simplex. Herpes simplex virus (HSV) types 1 and 2 are serious pathogens in newborns. Intrauterine herpes infection typically presents with vesicles at birth or within the first 24 hours of life. The majority of newborns acquire infections from infectious vaginal secretions at the time of delivery. The 1- to 3-mm vesicles that occur on the skin with this disease usually develop at 6 to 13 days of life. They can vary; a few faint scars may be present, or actual vesicle formations may be present with either one large swelling or discrete groups of vesicles. Frequently, an inconspicuous cutaneous lesion is a sign of systemic infection (Hoath & Narendran, 2015). Vesicles may recede and then recur over months.

Herpes simplex virus, types 1 and 2, is one of the most serious viral infections to affect the newborn and can appear as disseminated infection, central nervous system infection, and infection localized to the skin, eyes, or mouth. Disseminated infection is the most devastating presentation, with a mortality rate of up to 75% without antiviral therapy, and about 50% if antiviral therapy is used (Friedlander & Bradley, 2008). Vesicle formations may present with either one large swelling or smaller groups of vesicles that crust over rapidly and then recede. Absence of vesicles does not rule out the disease. Management consists of early recognition and treatment with antiviral agents, such as acyclovir, along with isolation from other infants. If encephalitis develops, the prognosis is extremely poor with either a high risk of death or severe mental retardation.

Management. Medical and nursing management is centered primarily on early recognition and treatment with the antiviral medication acyclovir. A definitive diagnosis is made by scraping the base of a fresh vesicle and staining with Giemsa or Wright stain, direct fluorescent antibody staining, or enzyme immunoassay detection of HSV antigens (Püttgen & Cohen, 2013).

The prognosis of systemic herpes simplex is extremely poor if encephalitis develops, with a high risk of either death or severe mental retardation. An important consideration in the care of infants with known or suspected herpes simplex infection is isolation from other patients to prevent transmission.

Varicella. Another viral infection with manifestation in the skin is varicella. Varicella infection is rare, but when it occurs in the first 10 days of life, it is generally thought to have been acquired in the last 3 weeks of pregnancy. The vesicular eruptions are the same as those in chickenpox acquired at any age. A mortality rate of 20% is associated with varicella infection in newborns and this infection poses a significant risk for immunocompromised infants in premature and intensive care nurseries. No systemic medication or topical treatment is required for these lesions. Occasionally, scarring can occur. Strict isolation is absolutely necessary to protect other infants from exposure because this virus is airborne.

Toxoplasmosis. Toxoplasmosis, which is caused by an intracellular parasite (*Toxoplasma gondii*), can be transmitted transplacentally and can result in systemic infection. Some infants may have a generalized maculopapular rash as well as hepatosplenomegaly, jaundice, fever, and anemia. The rash may progress to desquamation and hypopigmentation in very severe cases. Direct topical therapy is not reported to be necessary or efficacious; systemic therapy may be considered.

Cytomegalovirus and Rubella. Both CMV and rubella have symptoms manifested in the skin. Petechial lesions can occur with both infections. These are the result of thrombocytopenia and dermal erythropoiesis and usually disappear in 2 to 6 weeks. In severe rubella infection, and very rarely in CMV, bluish-red papules that are 2 to 8 mm in diameter can occur on the head, trunk, and extremities (Figure 12.5), resulting in the description "blueberry muffin" syndrome. Ocular involvement in congenital rubella is common. The characteristic "salt and pepper" retinopathy is the most common finding, but cataract is responsible for the greatest

FIGURE 12.5 This is an example of the "blueberry muffin" syndrome, seen in an infant with congenital cytomegalovirus infection. The infant has multiple petechiae and purpura from thrombocytopenia in this systemic infection.

vision loss (Örge & Grigorian, 2015). Neither of these lesions requires topical therapy.

Fungal. *Candida albicans* infection is the primary fungal infection with cutaneous manifestations, although other species—such as *Candida parapsilosis*, *Candida tropicalis*, *Candida lusitaniae*, *Candida glabrata*, and Malassezia furfur—can also potentially colonize the skin of term and preterm newborns, particularly those who are hospitalized in an intensive care nursery. On routine screening, roughly one third of healthcare workers in the NICU test positive for *candida* (Hoath & Narendran, 2015). Clinical symptoms of this type of infection can range from diaper dermatitis to other mucous membranes or localized skin eruptions to systemic candidiasis, resulting in significant morbidity and mortality. *Candida* is not normally found on the skin of the newborn. The primary reservoir for this organism is the gastrointestinal and female genital tracts, so the skin can be colonized at birth during passage through the birth canal. The incidence of *Candida* colonization is also increased with the frequent use of broad-spectrum antibiotics that alter normal skin flora in infants after delivery. Nursing assessment of the low-birth-weight infant should include the observation of a monilial diaper rash or a diffuse burn-like dermatitis affecting large areas of the lower back, buttocks, chest, and abdomen (Baley & Silverman, 1988). *Candida* dermatitis is recognized as an early presentation of invasive fungal disease in the extremely-low-birth-weight infant (Benjamin et al., 2010).

Premature neonates with systemic candidiasis may demonstrate cutaneous involvement. This cutaneous pattern may be a diffuse, burn-like dermatitis that affects large areas on the lower back, buttocks, chest, and abdomen. Lesions typically appear in skin creases also (Püttgen & Cohen, 2013). In a few infants, the axilla and groin are affected. Scaling follows the erythematous macular patches and in severe cases desquamation develops in a manner similar to that seen in staphylococcal scalded skin syndrome. These infants do not always have the satellite papules and pustules normally seen with *Candida* diaper dermatitis. The onset of the generalized rash often occurs within the first 3 days to 4 weeks of life but can appear later. Skin biopsies performed on patients with this condition revealed fungal invasion that extended beyond the epidermis into the dermis. Associated factors included maternal colonization with vaginal birth, steroid administration, hyperglycemia, and skin trauma from adhesive removal. Infants who weigh less than 1,500 g are especially at risk for systemic infection. In addition to birth weight less than 1,500 g, risk factors for disseminated candidiasis include respiratory therapy, central line placement, antibiotic use, and parenteral nutrition (Hoath & Narendran, 2015).

Another important cause of necrotic and purpuric lesions in neonates with ecchymoses and crust-like plaques is cutaneous infection with mold species, such as *Aspergillus*, *Fusarium*, *Rhizopus*, and *Mucor* (Hook & Eichenfield, 2011). Biopsy is often part of the evaluation, particularly if surface cultures are not conclusive; cutaneous debridement, along with systemic antifungal agents, may improve outcomes for these rare cases.

Management. Medical and nursing management of infants with systemic or local *Candida* infection involves therapy with systemic antifungal medications and antifungal ointments and creams. Cutaneous *Candida* in the extremely premature infant less than a week of age requires aggressive monitoring for systemic infection and may warrant parenteral antifungal agents to prevent dissemination of the fungal infection. Yeast is sometimes difficult to culture; techniques include obtaining urine to look for hyphae or budding yeast, blood cultures, and skin scrapings prepared with potassium hydroxide (KOH) obtained from the margins of the affected areas since this is the area of active growth, and examined for pseudohyphae (Cunningham & Wagner, 2008). Nursing observation in low birthweight infants for evidence of the diffuse, burn-like dermatitis or a spreading monilial diaper rash is essential and may expedite the initiation of parenteral antifungal therapy for systemic candidiasis. Most candidiasis species found in the NICU are sensitive to fluconazole and amphotericin (Lin et al., 2013).

Treatment for *Candida* diaper dermatitis consists of keeping the area clean and dry and applying an antifungal ointment or cream several times a day. Thrush, an oral fungal infection, appears as patches of white material scattered over the tongue that cannot be scraped off. It is treated with an oral form of nystatin.

Scaling Disorders

A scaly appearance in the skin of a newborn can have a range of causes, from relatively benign to long term and potentially life-threatening. In this section, scaly skin due to postmaturity, essential fatty acid deficiency, congenital ichthyosis, and eczema is discussed and areas of nursing management determined.

Postmaturity. Many term infants born between 40 and 42 weeks' gestation experience a period of shedding or desquamation considered to be a normal physiological process. Postmature infants born after 42 weeks' gestation may also have this appearance but other characteristics are different. The postmature infant may have a lean appearance, with little subcutaneous fat; the weight is low in relationship to length. The skin resembles parchment paper and may literally peel off in sheets, peaking near the eighth day of life (Hoath & Narendran, 2015). Fingernails may be stained with meconium and may be long. Long hair may also be present.

Skin care is not the major problem, nor is it the focus of medical or nursing management. Eventually, the skin underneath the peeling layers predominates; even during the period of desquamation, the skin functions well as a barrier because these infants have all the layers of *stratum corneum* of a term infant or adult. Aside from bathing with a mild baby wash initially, moisturizing with a petrolatum-based ointment may be appropriate. More careful attention is paid to the more compelling problems associated with postmaturity, such as hypoglycemia and meconium aspiration.

Essential Fatty Acid Deficiency. In newborns unable to receive an adequate diet because of other illnesses or surgical conditions, scaly dry skin may signify the development of essential fatty acid deficiency syndrome. Infants may be more prone to the development of this syndrome, especially if they are premature or postmature because of the decreased fat stores available. It may also occur in infants with severe fat malabsorption, such as those with cystic fibrosis.

The skin appearance in essential fatty acid deficiency includes a superficial scaling and, in some cases, desquamation. Later presentation may involve oozing and irritation in the neck, groin, or perianal region.

This syndrome is sometimes confused with other conditions that cause scaling or other skin disruptions, including ichthyosis, acrodermatitis enteropathica, and candidal infection. Laboratory findings that confirm this diagnosis are decreased serum essential fatty acid levels, possibly in conjunction with thrombocytopenia and impaired platelet aggregation, because essential fatty acids are necessary to ensure platelet function.

Management. Medical and nursing management consists of replacement of essential fatty acids through the administration of intravenous lipid solutions or diet. Human breast milk and most infant formulas contain more than adequate amounts of essential fatty acids. However, if the gastrointestinal system is not

functioning well in the digestion and absorption of nutrients, intravenous therapy is required.

Once skin symptoms are present, administration of intravenous lipid solution can reverse the process in 1 to 2 weeks. Dietary replacement takes longer and is effective only in the presence of healthy gastrointestinal function.

Prevention of essential fatty acid deficiency is possible and should be the goal. The development of essential fatty acid deficiency can be prevented by the early administration of intravenous lipid solutions in the first weeks of life in a dose as low as 0.5 g/kg/day.

Ichthyosis. The most serious cause of dry, scaly skin in the newborn is ichthyosis dermatosis, a genetically inherited disorder of cornification (Ivich, 2015). Four major types of ichthyosis exist: (1) X-linked ichthyosis; (2) lamellar ichthyosis; (3) bullous congenital ichthyosiform erythroderma, which is present at birth; and (4) *ichthyosis vulgaris*, which usually appears after the third month of life. Terms commonly used to describe infants with ichthyosis may include harlequin fetus and collodion baby, but these terms do not define which form of ichthyosis is present.

In the X-linked type of ichthyosis, males are primarily affected. Some female heterozygotes may exhibit mild scaling of the arms and lower extremities. Affected male newborns have large yellow or brown plaques that cover the whole body, except the palms, soles, and midface, and over joints. At birth, some affected males may appear scaly, whereas others are often called collodion babies.

Lamellar ichthyosis, formerly called nonbullous congenital ichthyosiform erythroderma, is an autosomal recessive disorder. Initially, affected newborns may have a bright red appearance that rapidly progresses to desquamation; rarely is a collodion-baby appearance present at birth. Later, scales develop that are yellow to brown and that may eventually become thick, horny plates. Although the prognosis is usually good, infants who are severely affected with the most severe form—harlequin ichthyosis—may die of sepsis or require extensive plastic surgery (Figure 12.6). Among them, difficulties faced are eye disease, heat intolerance, finger contractures, chronic skin infections, and hearing problems (Ivich, 2015).

In bullous congenital ichthyosiform erythroderma, autosomal dominance is the mode of heredity; thus, several family members may be affected. Large bullae are initially seen, as are erythema and dry scaly skin; the blistering that recurs throughout childhood differentiates this form from the lamellar type. Extensive denuded areas of the skin can present a problem in the newborn as the blisters burst and secondary life-threatening infections with *Streptococcus* or *Staphylococcus* can occur.

FIGURE 12.6 This harlequin infant is an example of the most severely affected ichthyotic infant. The skin is hard and thick, with deep crevices. The lack of elasticity of the skin results in fleshy deformities of joints and limbs.

Source: Reprinted with permission from Clark, D., & Thompson, J. (1986). Dermatology of the newborn, Parts 1 and 2. In *Pathology of the neonate slide series* (Vol. 3, No. 4). Philadelphia, PA: Wyeth-Ayerst Laboratories.

Management. Medical and nursing management of X-linked and lamellar forms of ichthyosis involves the continual use of topical emollient, prescription bathing techniques, and the prevention of infection. **Quality and Safety: Emollients increase hydration and help restore barrier function; keratolytics, used after the newborn period, assist in scale shedding.** Bathing is performed with water-dispersible bath oil, and soaps that are excessively drying or irritating should be avoided. Collodion babies should be placed in a high-humidity incubator to increase hydration. Emollients that preserve moisturization such as Aquaphor ointment (Beiersdorf, Inc., Wilton, CT) should be applied several times daily.

Infants with severe skin involvement from ichthyosis may require protective isolation if they receive care in an intensive care nursery because of the higher risk of contact with nosocomial infections. Incubators provide a barrier to infection. Use of sterile linen and sterile gloves and other measures are needed if larger areas of denuded skin are present. Nutrition management is important due to the infant's high metabolic demands from inflammation, evaporative calorie losses, and cutaneous hyperplasia.

Multidisciplinary involvement of genetics, ophthalmology, dermatology, and physical therapy is essential to care. Comfort is another key nursing concern in the care of the infant who is significantly affected with ichthyosis. Fussy, irritable agitation may be seen and is related to pruritus or inflammation. Some form of analgesia may help, although the topical therapies prescribed have the most direct effect. Some authors describe the use of diphenhydramine (Benadryl, Pfizer, Morris Plains, NJ) if severe pruritus exists but this would be hard to determine in a neonate who lacks verbal or fine motor skills to communicate this symptom. A trial of this medication with careful observation might be helpful in the case of a frantic or irritable infant when other measures (e.g., topical treatment, pacifiers, feeding) are unsuccessful.

Working with the parents of an infant with ichthyosis has many facets. The appearance of the infant, especially if he or she is severely affected, could be shocking and traumatic to the parents and could require careful interventions. As with parents of infants with other congenital abnormalities, a period of shock, denial, and grief occurs over the loss of a perfect baby. In addition, the genetic nature of this disorder and the implications for future children must be comprehended. Parents of these infants need genetic counseling, support, and education as they come to terms with this disease.

Eczema. Atopic eczema (AE) or atopic dermatitis (AD) is a skin disorder that causes several degrees of skin irritation and has multiple causes but is rarely seen in the newborn period. It is more commonly seen within 3 months of age and involves an eruption that proceeds to the development of microvesicles and oozing, which later turns into scaling of the epidermis (Blume-Peytavi & Wahn, 2011). The scaling is due to an attempt of the skin layer to regenerate rapidly. Lichenification, or thickening of the skin, which occurs in adult skin with eczema, is not seen in infants.

Epidermal barrier dysfunction has been shown to be a contributing factor in AE. Studies have shown that maternal AE (and to a lesser extent paternal and sibling history) was a risk factor for the development of AE in infants (Deckers et al., 2012). Prevalence of food allergy has been reported to be between 20% and 80% in infants who develop AE (Newland, Warren, & Gold, 2013).

Primary irritants—such as saliva, feces, and some soaps or skin preparations—rather than allergies are the usual causes of irritant

contact dermatitis in infants (de Waard-van der Spek et al., 2013). However, it is important to have a good history of all products that have been applied to the skin to determine the cause.

Management. Improving skin barrier function early in life through the daily application of topical emollients may reduce sensitization and prevent the development of AE along with food allergies and asthma (Simpson, Berry, Brown, & Hanifin, 2010). Medical and nursing treatment of eczema also includes prevention by avoiding the primary irritant source, if it has been identified, or protection, as in the use of zinc oxide paste to the perianal area to prevent contact with feces. Short-term therapy with topical steroids may be used for more generalized eruptions.

Bathing should be carried out in lukewarm water with a synthetic surfactant-based cleanser with a pH of 5.5 to 6.0; use of irritating or drying soaps should be avoided (Telofski et al., 2012). The effectiveness of any emollient increases if it is applied directly after bathing to seal in the humidity (Fernandes, Machado, & Oliveira, 2011). If large areas of skin are involved, thermoregulation may be a concern, especially in dry climates. Humidification may be desirable in some climates, especially during the summer months. Air conditioning may also be necessary during the summer months. Discomfort is a significant concern because infants with eczema may experience considerable pruritus. Topical therapy is generally the first consideration, followed by the judicious use of diphenhydramine in severe cases.

SKIN CARE PRACTICES

The most basic aspects of skin care for newborns include bathing; moisturizing with emollients; skin preparation with disinfectant solutions; and use of medical adhesives for life-support devices, monitoring of vital signs, and oxygenation, if the newborns are hospitalized. During all these practices, the skin of the newborn has the potential for trauma or alterations in normal barrier function and pH. The literature is reviewed to determine what is currently known about these and other common nursing practices and the impact on the skin of newborns.

Bathing

First Bath

The purpose of bathing newborns includes providing overall hygiene, aesthetics, and protection of healthcare workers by removing blood and body fluids. However, bathing is not an innocuous procedure, and during the immediate postbirth period it can result in hypothermia, increased oxygen consumption, and respiratory distress. There is ongoing debate about when the first bath should be given and even whether to bathe the newborn at all (Colwell, 2015). The Neonatal Skin Care Evidence-Based Clinical Practice Guideline, developed by the AWHONN, recommends giving the first bath when thermal and cardiorespiratory stability has been achieved, between 6 and 24 hours of age (AWHONN, 2018). The WHO recommends delaying the bath for 24 hours, or, if this is not possible due to cultural reasons, waiting at least 6 hours in an effort to prevent hypothermia, especially in developing countries (WHO, 2015). However, infants born to a mother who is HIV positive should be bathed as soon as possible after delivery once their temperatures have stabilized (Kilpatrick, Papile, & Macones, 2017).

Techniques for giving the first bath include sponge bathing with a small tub such as those provided in the hospital, or an immersion bath in a larger tub. Immersion bathing places the infant's entire body, except the head and neck, into warm water (37.8°C–38.8°C), deep enough to cover the shoulders. Studies involving over 1,000 newborns report that tub or immersion bathing, compared to sponge bathing, maintains temperature better, causes less crying and distress for the infant, and does not result in increased infection, even with the umbilical cord in place (G. C. Anderson, Lane & Chang, 1995; Bryanton, Walsh, Barrett, & Gaudet, 2004; Cole, Brissette, & Lunardi, 1999; Hennigsson, Nystrom, & Tunnel, 1981). In a study of 100 late preterm infants (35–36 6/7 weeks' gestation) randomized to immersion tub bathing or sponge bathing after 24 hours of life, infants had overall higher temperatures and less variability in body temperature when immersion bathed (Loring et al., 2012).

Using a swaddle cloth during bathing adds additional comfort for the newborn. A randomized controlled study of providing this support for full-term newborns during their first bath found swaddled bathing was more effective in maintaining temperature, as well as other physiological parameters such as heart rate and oxygen saturation (Çaka & Gözen, 2017). There has also been the benefit of reducing parental stress during swaddle bathing (Fern, Graves, & L'Huillier, 2002).

The Neonatal Skin Care Guideline recommends using warm tap water with or without a mild cleansing bar or liquid cleanser that has a neutral or slightly acidic pH to assist in the removal of blood and meconium, as water alone may not easily remove some lipid-soluble substances such as meconium. For premature infants less than 32 weeks, warm water only during the first week of life is the recommendation (AWHONN, 2018),

Leaving residual *vernix caseosa* on the skin is important, as vernix facilitates skin adaptation including skin hydration and the formation of the acid mantle of the skin surface (Visscher et al., 2005). WHO guidelines for newborn care recommend leaving vernix intact for at least 6 hours (Visscher & Narendran, 2014; WHO, 2015).

Routine Bathing in NICU Patients

A number of issues surround determining the optimal frequency of bathing and best techniques for administering the bath for hospitalized neonates. The NICU population can range from full-term infants with illness, infection, or the need for surgical interventions to extremely low birth weight premature infants.

Knowledge about the impact of bathing on neonatal skin barrier function as measured by parameters such as skin surface pH, transepidermal water loss (TEWL), and hydration of the *stratum corneum* (SCH) is important to inform practice. Bathing has the potential to alter the development of the acid mantle of the skin. On the first day of life, the skin surface pH is greater than 6.0, falling to less than 5.0 during the first weeks of life (Behrendt & Green, 1971; Hoeger & Enzmann, 2002; Yosipovitch et al., 2000). Premature infants' skin develops an acidic surface, reaching a pH of 5.5 at the end of the first week, and 5.0 by the end of the first month (C. Fox et al., 1998). Once the acid mantle of the skin surface is established, bathing can transiently alter the skin pH, even with water alone, in older infants (Gfatter, Hackl, & Braun, 1997). Bathing two to three times per week with cleansing products compared to water alone has been shown to have little or no difference on skin pH, TEWL, and SCH in the neonatal period in full-term healthy infants (Dizon, Galzote, Estanislao, Matthew, & Sarkar, 2010; Garcia Bartels et al., 2010; Lavender et al., 2012). Similar studies involving measuring skin parameters have not been performed in hospitalized neonates or in premature infants.

Sponge and tub bathing in premature infants can negatively impact physiological parameters such as heart rate, oxygenation, and behavioral cues indicating distress with bathing (Liaw, Yang, Yuh, & Yin, 2006; Peters, 1998). Because of the concern about the stress on premature infants during bathing, researchers evaluated the impact of bathing with a mild cleanser every 2 versus

4 days on normal skin colonization and on pathogenic bacteria (Quinn, Newton, & Piecuch, 2005). Although an initial decrease in bacterial skin colonization was noted, bacterial colonization was restored at 48 hours and remained stable between 48 and 96 hours after bathing. Another study reported a transient decrease in skin colonization in premature infants of 28 to 35 weeks' gestation with coagulase-negative staphylococcus at 30 minutes following the bath, regardless if the bath was given with water alone or water and liquid soap (da Cunha & Procianoy, 2005). It does not appear that decreased bathing frequency from every 2 days to 4 days in premature infants leads to an increase in skin colonization, and the use of bathing products or water also does not increase skin colonization with coagulase negative staphylococcus. Therefore, less frequent bathing will subject premature infants to less physiological and behavioral stress. Swaddling the premature infant during routine bathing was shown to reduce temperature loss and crying (Edraki, Paran, Montaseri, Razavi Nejad, & Montaseri, 2014), and hand containment and postural support reduce stress as well (Liaw, Yang, Chou, Yang, & Chao, 2010).

Emollients

The skin surface of term newborns is drier than that of adults but becomes gradually better hydrated as the eccrine sweat glands mature during the first year of life. Maintaining the hydration of the *stratum corneum* is necessary for an intact skin surface and normal barrier function. Skin that is dry, scaly, or cracking is not only uncomfortable but also can be a portal of entry for microorganisms.

Treatment for dry skin includes moisturizers or emollients. Emollients are classified as oil-in-water (ointments) or water-in-oil emulsions (creams, lotions). Ointments do not require a preservative whereas creams and lotions do require preservatives due to the higher water content (Hoath & Narendran, 2000).

Several studies have evaluated emollient use in premature infants. Premature infants of 29 to 36 weeks' gestation were treated with a cream moisturizer twice daily and had less visible dermatitis but no change in skin barrier function (Lane & Drost, 1993). A randomized controlled trial of younger gestation premature infants receiving twice daily applications of a petrolatum ointment versus routine skin care reported improvements in skin barrier function, measured as a lower TEWL and less visible dermatitis. No increases in skin temperature or redness were seen if the infants were receiving phototherapy or cared for under radiant warmers and no increase in bacterial or fungal cultures was reported. In addition, although there were not enough subjects to verify this outcome, the treated infants had fewer positive blood or cerebrospinal fluid cultures (Nopper et al., 1996).

A large randomized controlled trial of 1,191 extremely low birth weight infants (510–1,000 g) was undertaken to determine if the twice daily prophylactic application of petrolatum-based ointment would reduce the combined outcomes of mortality and sepsis (Edwards, Conner, & Soll, 2004). No effect was seen in these combined outcomes, although skin integrity appeared improved in the treated infants. It is important to note that in infants less than 750 g, the incidence of bloodstream infections with coagulase-negative staphylococcus was increased in the group with prophylactic use of the emollient, although the mechanism and relationship to twice daily emollient use are not clearly understood. The control infants in this study also received emollients on an "as needed" basis for skin dryness.

A Cochrane review evaluated RCTs of emollient use in the NICU and concluded that the prophylactic application of topical ointment increases the risk of coagulase-negative staphylococcus infection as well as other nosocomial infections. The routine use of emollients in preterm infants is not recommended (Conner, Soll, & Edwards, 2004).

The benefits of emollient use in premature infants must be carefully weighed against the risk of infection. In general, emollients can be safely used in this population to treat skin with excessive drying, skin cracking, and fissures. They may also be beneficial in reducing TEWL and evaporative heat loss, although methods such as using a high-humidity environment are also available for this purpose. Small tubes or jars for single patient use are recommended to prevent contamination with microorganisms.

There is little consensus to date about the routine use of emollients for full-term newborns (Irvin & Miller, 2015). One study reports improved skin parameters in healthy full-term infants when the skin care regime included a "baby cream" emollient after bathing and did not adversely affect bacterial skin colonization (Garcia Bartels et al., 2010). However, promising studies report a decreased risk of developing atopic dermatitis in infants with a strong family history of this disorder with daily use of emollients in infancy, so the routine use of emollients may be indicated in this population (Horimukai et al., 2014; Simpson et al., 2014).

Skin Disinfectants

Use of skin disinfectants prior to invasive procedures such as inserting intravenous lines, venipuncture, arterial puncture, umbilical catheter placement, and chest tube placement is common practice in neonatal nurseries. Concerns with disinfection practices include the effects of absorption of disinfectants and skin injury resulting from topical skin preparation with these agents, which must be weighed against their effectiveness in preventing infection.

Disinfectants that are used in newborns include 70% isopropyl alcohol (IA), 10% povidone-iodine (PI), and chlorhexidine gluconate (CHG), in varying concentrations as both an aqueous solution and one combined with 70% isopropyl alcohol (CHG/IA). It is widely accepted that CHG-containing formulations are the most effective for skin disinfection in children and adults for central venous catheter insertion and dressing changes and their use is recommended as best practice in several guidelines (Chaiyakunapruk, Veenstra, Lipsky, & Saint, 2002; Loveday et al., 2014; Marschall et al., 2014). However, there are no studies in neonates that have confirmed the superior efficacy of CHG preparations over other disinfectants, such as PI, in the prevention of bloodstream infection (Ponnusamy, Venkatesh, & Clark, 2014; Sathiyamurthy, Banerjee, & Godambe, 2016). Therefore, the Centers for Disease Control and Prevention (CDC) guidelines have maintained that there is insufficient evidence to make a recommendation about the safety or efficacy of CHG products in infants younger than 2 months of age (O'Grady et al., 2011).

Use of 0.5% CHG in isopropyl alcohol reduces peripheral IV catheter colonization in premature and term newborns compared with use of povidone-iodine (Garland et al., 1995). An RCT of 344 infants admitted to the NICU and SCN settings showed significantly fewer blood-culture contaminants in infants having skin disinfection with 1% aqueous CHG compared with those using 10% PI (Nuntnarumit & Sangsuksawang, 2013).

A sequential study reported that the rate of positive blood cultures (the number of true infections or contaminated cultures during the time when 10% PI was used in this NICU) was not statistically different from a subsequent period when 0.5% CHG/IA was used (Linder et al., 1997). A pilot trial of 47 infants who weighed more than 1,500 g and were older than 7 days of age evaluated cutaneous tolerance of 2% CHG/IA compared with 10% PI for PICC placement. There were no differences in the number of bloodstream infections or sepsis evaluations between the two groups; however, this pilot study was not powered to look at bloodstream infection rates (Garland et al., 2009). An RCT of 304 preterm infants compared 2% CHG/IA to 10% PI for insertion of

815 central venous catheters, and reported no difference between the proportion of catheter-related bloodstream infections between the two disinfectants, although more infants in the PI group had thyroid dysfunction. The authors acknowledged that the study was not adequately powered to detect differences in actual numbers of catheter-related bloodstream infections and that a larger study is needed (Kieran et al., 2018).

Toxicity From Skin Disinfectants. If absorbed through the skin, PI has been shown to alter thyroid function in premature newborns. A systematic review of 15 articles reported evidence of thyroid dysfunction in premature infants exposed to iodine-containing disinfectants, with incidence ranging from 12 to 33 cases per 100 infants. The review also found no long-term neurodevelopmental studies that cited harm from exposure to iodine-containing solutions; although the researchers recommended restricting iodine-containing solutions in premature infants, more research is needed (Aitken & Williams, 2014).

Systemic toxicity from percutaneous absorption of CHG in neonates has been raised as a concern. A small study of CHG antisepsis for PICC placement and subsequent dressing changes in premature infants who weighed more than 1,500 g found measurable concentrations of CHG, ranging from 13 to 100 mcg/mL, in 7 of the 10 infants who had levels drawn. However, there were no reported systemic side effects. The role of IA in combination with CHG may be a possible contributing factor to cutaneous absorption of CHG (Garland et al., 2009). Another study involving 20 premature infants with a median gestational age of 28 weeks had an extremity disinfected with 2% aqueous CHG prior to insertion of a PICC. Ten infants had detectable serum CHG levels ranging from 1.6 to 206 mcg/mL, with the highest levels occurring 2 to 3 days after initial exposure (Chapman et al., 2013).

Past reports of neurotoxicity from exposure to hexachlorophene bathing (J. Anderson et al., 1981; CDC, 1973) have prompted research on the potential neurotoxicity from systemic absorption of CHG. An in vitro model of neurite cells was exposed to CHG levels comparable to the highest levels reported in premature infants. CHG inhibited L1-mediated neurite growth and researchers concluded that it is important to determine whether the blood–brain barrier is permeable to CHG in premature infants (Milstone et al., 2014).

There is interest in using CHG to decrease infection in adult and pediatric ICU patients and patients with central venous catheters with daily wiping of skin surfaces with CHG (Milstone et al., 2013). A study was undertaken in a NICU population using 2% CHG–impregnated wipes in a quasi-experimental design, comparing the treated infants to a historical cohort. The algorithm for wiping the skin with CHG determined the frequency based on postnatal age and weight. A decrease in central line–associated bloodstream infections was reported; however, infants weighing less than 1,000 g and younger than 28 days were excluded from CHG bathing. Serum CHG levels were not obtained (Quach et al., 2014).

A number of case reports document chemical burns in premature infants from disinfectants containing CHG; these include various concentrations of CHG, both aqueous and alcohol preparations (Andersen, Hart, Vemgal, & Harrison, 2005; Bringué Espuny et al., 2010; Kutsch & Ottinger, 2014; Lashkari, Chow, & Godambe, 2012; Mannan, Chow, Lissauer, & Godambe, 2007; Neri et al., 2017; Reynolds, Banerjee, & Meek, 2005). There have also been reports of chemical burns from IA and PI solutions in extremely low birth weight infants (Figure 12.7; Sardesai, Kornacka, Walas, & Ramanathan, 2011).

The UK Medicines and Healthcare Products Regulatory Agency published a review of 44 case reports of chemical burns after the application of aqueous or alcohol-based CHG solutions.

FIGURE 12.7 Skin injury resulting from skin disinfectant.

Most burns occurred in premature infants younger than 26 weeks of gestation or those who weighed less than 1,000 g with long-term sequelae in some infants, to include scarring, discoloration, and keloid formation (Beresford, 2015). Because of these concerns, safety labeling in the United States and Europe continues to state the potential for chemical burns from CHG solutions used for skin disinfection in premature infants (Paternoster, Niola, & Graziano, 2017).

Several studies have been undertaken to determine how CHG affects skin integrity. A prospective study of 40 infants with a mean gestational age of 32 weeks (range 23–39 weeks) found that the use of 2% CHG/IA for PICC insertion and weekly dressing changes compromised skin-barrier function, which was measured by elevated TEWL, an increase in erythema, and dryness (Visscher, deCastro, et al., 2009). A pilot trial comparing 2% CHG/IA in 47 premature infants weighing more than 1,500 g and older than 7 days of age found no increase in skin redness or breakdown when CHG was used for PICC insertion and weekly dressing changes and only one incidence of erythema in a newborn treated with PI (Garland et al., 2009).

The selection of appropriate disinfectants in neonates remains a dilemma, particularly for extremely premature infants during the first weeks of life. CHG products in the United States are limited to a 2% aqueous surgical scrub solution available only in 4-oz bottles and a 2% and 3.15% chlorhexidine solution in 70% isopropyl alcohol available in single-use packaging. The U.S. Food and Drug Administration states that chlorhexidine-containing disinfectants should be used with care in premature infants or infants less than 2 months of age, as these may cause skin irritation and chemical burns. PI continues to be used in many nurseries to avoid

the previous complications, although the issues of thyroid toxicity remain a concern.

Although removal of disinfectants with sterile water or saline after the procedure is complete is advocated (AWHONN, 2018), the manufacturer of the 2% CHG/IA product advises that removal not be attempted, as the residual effect of the disinfectant on the skin may be beneficial. However, it is not known whether this feature may contribute to skin irritancy and absorption of CHG in newborns and premature infants.

CHG should not be used as preoperative skin disinfection on the face or head because misuse has been reported to result in injury if it remains in contact with either the eye or ear during surgical procedures. However, careful use before scalp intravenous or central-line insertion is acceptable, providing that splashing or using excessive amounts of chlorhexidine is avoided. In addition, there is no clinical data to discourage the use of chlorhexidine gluconate products prior to lumbar puncture or epidural catheter placement, as this is considered skin antisepsis (Milstone, Passaretti, & Perl, 2008).

Umbilical Cord Care

The use of antibiotic ointments and skin antiseptics to the umbilical cord can prolong the time to cord separation and has no beneficial effect on the frequency of infection (Zupan & Garner, 2000). Although the umbilicus is a possible route for infection by invasive pathogenic microorganisms until healed, the evidence suggests that dry cord care, defined as keeping the cord clean and leaving it exposed to air or loosely covered by a clean cloth, is effective for infants born in high-resource countries (Stewart, Benitz, & Committee on Fetus and Newborn, 2016).

For newborns born in health facilities, dry cord care is recommended, as there are a number of studies to support this practice. A cluster randomized controlled trial in France, involving over 8,000 near-term and term newborns, found dry cord care was not inferior to antiseptic cord care in preventing omphalitis (Gras-Le Guen et al., 2017). A group of 150 consecutively born, healthy, late preterm and term infants born in a hospital setting in Taiwan (high humidity, subtropical country) was randomized to alcohol or dry cord care. Cord separation time was significantly decreased for those infants having dry cord care compared with those cleansed with 95% isopropyl alcohol, and the incidence of cord infection was not increased (Hsu et al., 2010). A meta-analysis showed the use of topical isopropyl alcohol was not superior to dry cord care in reducing the incidence of omphalitis (Imdad et al., 2013).

Medical Adhesives

Hospitalized full-term and premature newborns require the routine use of adhesives to secure life support and monitoring equipment such as endotracheal tubes, intravenous devices, oxygen saturation sensors, and electrodes. The types of medical adhesives used in the NICU are categorized as acrylates, hydrocolloids, hydrogels, and silicone-based adhesives (Lund, 2014).

Acrylate-based adhesives include products such as paper, plastic, and soft cloth tape. These types of adhesives have increased adherence over time and may leave a residue on the skin after removal (McNichol, Lund, Rosen, & Gray, 2013). However, acrylate adhesives adhere effectively to skin and medical devices and are commonly used in intensive care settings. Polyurethane films with acrylate adhesives such as transparent adhesive dressings allow visualization of catheter insertion sites and are permeable to water vapor, oxygen, and carbon dioxide, allowing the skin to breathe (Darmstadt & Dinulos, 2000).

Hydrocolloid adhesives were initially used to protect peristomal skin for ostomy patients and later became a wound dressing. They are sometimes used as a platform between skin and tape and are sometimes integrated into some products such as an endotracheal tube securement device. Initially hoped to be gentler on the skin when removed, hydrocolloids have been shown to cause skin trauma equal to acrylate tape when removed at 24 hours (Lund et al., 1997). Other studies have also reported decreased skin-barrier function, measured by increased TEWL and erythema, under hydrocolloids (Zillmer, Agren, Gottrup, & Karlsmark, 2006). However, these barriers are still used because they absorb moisture, mold well to skin surfaces, and, as noted previously, serve as a platform between skin and acrylate tapes and transparent dressings (Boswell & Waker, 2016; Cheng & Kroshinsky, 2011; O'Neil & Schumacher, 2014). One study found no statistically significant quantitative difference between a transparent dressing placed over a hydrocolloid base or a transparent dressing placed directly on the skin. Despite this lack of support for one method over the other, they found a theme of comments from nurses that they preferred transparent dressings placed over a hydrocolloid base as a more effective adhesive and a belief that it was gentle for the skin (Boswell & Waker, 2016).

Hydrogels are a low-trauma and highly breathable adhesive with high water content. Hydrogels are found in some adhesive products such as EKG electrodes and temperature probe covers; they are also available as tapes for securement of tubes. Hydrogels are also available as a dressing for wounds and may have a cooling or analgesic effect on wounds. Use of hydrogel adhesives has been shown to reduce the trauma associated with electrode removal (Darmstadt & Dinulos, 2000; Lund et al., 1997; Webster & McCosker, 1994). However, they do not adhere well enough to secure critical lines and tubes and do not function well in high humidity environments such as humidified incubators.

Silicone-based adhesive products have been shown to improve adherence to skin and reduce discomfort to patients with adhesive removal. This technology holds promise for developing products that adhere and cause minimal trauma such as erythema, skin stripping, and keratin loss, compared with acrylate-based paper tapes when removed from the skin of pediatric patients (Grove, Zerweck, Ekholm, Smith, & Koski, 2014). However, silicone adhesives do not adhere well to plastic devices, such as nasogastric tubes and cannulas, which may limit their use for attaching some medical devices. A beneficial use of silicone adhesives is as a border for dressings, which can be lifted up and replaced for wound assessment. Another application for silicone adhesives is for securing brain-monitoring electrodes, as they adhere well to hair and can be removed with minimal discomfort.

Newborns are at high risk for medical adhesive-related skin injury (MARSI), a term first used in a consensus paper involving a number of different health providers representing several specialties including pediatrics, gerontology, orthopedics, and dermatology and wound care experts (McNichol et al., 2013). Types of MARSI include skin stripping, skin tears, contact, and allergic dermatitis.

Newborns are particularly vulnerable to MARSI; the evidence-based practice project for the Neonatal Skin Care Guideline, which included skin and environment assessments for 2,820 premature and full-term newborns, found that adhesives were the primary cause of skin breakdown (Lund et al., 2001). It is known that functional changes in adult skin, including altered skin barrier function (measured as increases in TEWL), are seen after 10 consecutive applications and removals of adhesive tape (Lo, Oriba, Maibach, & Bailin, 1990), and after one application/removal in premature infants (Harpin & Rutter, 1983; Lund et al., 1997).

Liquid skin-barrier films are skin protectants wiped on the skin prior to attaching adhesives and have been shown to protect the

skin from adhesives as well as fecal and ostomy output and urine (Black, 2007). Silicone-based skin barrier films do not sting when applied, rapidly evaporate, and do not leave a residue in addition to the general benefits of silicone-based skin protectants in neonates (Irving, 2001). A study of premature infants (<33 weeks) showed both skin protection and the additional benefit of reduced TEWL (Brandon, Coe, Hudson-Barr, Oliver, & Landerman, 2010). Although this study found efficacy without any safety concerns, additional research is warranted in a larger ELBW population.

Removal of medical adhesives can cause trauma, such as skin stripping and pain. **Quality and Safety: A technique involving slowly pulling adhesives at a very low angle, parallel to the skin surface, while holding the surrounding skin in place, may reduce epidermal stripping** (Lund & Tucker, 2003; McNichol et al., 2013). Adhesive removers help to aid in the atraumatic removal of adhesives. There are three categories of adhesive removers: alcohol–organic-based solvents, oil-based solvents, and silicone-based removers (Black, 2007; Cooper, 2010). Solvents contain hydrocarbon derivatives, petrolatum distillates, or isopropyl alcohol, and carry the potential of systemic and topical toxicities. A case report of a premature infant developing a severe dermatologic reaction to an adhesive remover, including blistering and hemorrhage, suggest the lack of safety with these products in a NICU (Ittmann & Bozynski, 1993). Oil-based solvents release the bond between skin and adhesive and are based on paraffin or citrus oil extracts. These do not evaporate and leave a residue that prevents adherence during reapplication of adhesives to the site where they were previously applied.

Silicone-based removers form an interposing layer between adhesive and skin, allowing for easier removal. These evaporate readily after application without drying of the skin and are less likely to leave a residue. They do not cause stinging, even on broken skin; and are inert, reducing the risk of toxicity. Silicone-based removers are available in spray, liquid, lotion, or wipe formulations (Cooper, 2010). Researchers have demonstrated the safety and effectiveness of using silicone-based removers in the neonatal population, including infants with epidermolysis bullosa (Cooper, Russell, Stringfellow, Duguid, & Pirie, 2011; Denyer, 2011).

Transepidermal Water Loss

Because of the poorly keratinized *stratum corneum* that provides minimal resistance to the diffusion of water, the preterm infant is at risk for TEWL through the skin, and heat loss via evaporation. Characteristic skin factors that predispose premature infants to excessive water loss include reduced skin barrier function from fewer layers of *stratum corneum* and thinner epidermis, larger surface area in relation to body weight, increased water content, increased permeability, and increased blood supply closer to the skin surface. Mature keratin, a major component of the tough, nonliving outer layer of the epidermis, is relatively water-impermeable. Because keratin formation is directly related to gestational age, the premature infant less than 30 weeks' gestation is at increased risk for increased TEWL and evaporative heat loss.

Premature infants of 23 to 25 weeks' gestation have TEWL that is 10 times higher than full-term newborns (Agren et al., 1998; Visscher et al., 2015). Mature barrier function—at one time thought to advance rapidly over a 2-week period in premature infants less than 30 weeks' gestation—has been shown to take longer in extremely premature infants of 23 to 24 weeks' gestation and occurs when the infant reaches approximately 30 to 31 weeks postconception age (Kalia et al., 1998).

In the delivery room, premature infants less than 28 weeks' gestation are placed in a polyethylene bag or wrap without drying the skin, in an effort to reduce the degree of evaporative heat loss and hypothermia/cold stress during initial stabilization (Bissinger & Annibale, 2010; Knobel, Wimmer, & Holbert, 2005; Vohra, Roberts, Zhang, Janes, & Schmidt, 2004). This technique is so effective that studies have reported hyperthermia in some infants; thus, careful monitoring of temperature is needed.

High humidity, a relative humidity (RH) greater than 70%, added to an incubator has been shown to effectively reduce evaporative heat loss and TEWL; the rate of TEWL has been shown to decrease by half when the RH increases from 20% to 60% (Hammarlund & Sedin, 1979; Harpin & Rutter, 1983). The use of humidified "hybrid" incubators in premature infants less than 1,000 g are capable of providing high humidity in a convectively heated incubator and also radiant heat for procedures and emergencies. A study reported positive effects on fluid balance, electrolyte stability, and growth velocity after the hybrid humidity devices were implemented, compared to a historical control group (Kim, Lee, Chen, & Ringer, 2010). This study utilized high levels of humidity (70%–80%) for the first week, with reduced humidity levels to 50% to 60% for the second week until the infant reached 30 to 32 weeks postconception age (Kim et al., 2010). The rationale for reducing the humidity level in this fashion was based on an earlier RCT that demonstrated improved skin barrier function and maturity when humidity levels were reduced to 50% compared to 75% in the second week of life (Agren et al., 2006).

FIGURE 12.8 Silicone-based adhesives developed for use in wound care products are now available as silicone tapes and have been shown to improve adherence to wounds and reduce discomfort when removed.

Application of petrolatum-based emollients every 6 to 12 hours also reduces TEWL and can be used on infants on radiant warmers or under phototherapy without temperature increases or burns (Nopper et al., 1996). A novel use of a protective barrier film was also shown to reduce TEWL compared to petrolatum ointment in premature infants less than 33 weeks' gestation (Brandon et al., 2010). However, due to the concerns raised in a large RCT of infants less than 1,000 g regarding increased coagulase negative staphylococcus infections with prophylactic use of this petrolatum ointment. These approaches are not recommended without further study.

Because of the numerous benefits of skin-to-skin holding (kangaroo care), a study was undertaken to measure evaporative loss while out of the high humidity environment. Five premature infants of 22 to 26 weeks' gestation were held skin-to-skin by their mothers at 3 to 9 days of age; covering with a single layer of cotton fabric resulted in decreased evaporative heat loss (Kjällström, Sedin, & Ågren, 2011).

Thus, addressing the important area of reducing excessive heat loss and TEWL is necessary in the care of the extremely premature neonates to maintain adequate hydration without excessive fluid intake. The goal of maintaining hydration and normal serum sodium levels on an intake of less than 150 mL/kg/day is optimal and achievable using preventive strategies.

MANAGEMENT OF SKIN CARE PROBLEMS

The *stratum corneum* can be traumatized by a variety of insults, including epidermal stripping from removal of adhesives; chemical burns from disinfectants; pressure injuries, especially from medical devices; infection; nutritional inadequacies, such as zinc and essential fatty acid deficiency; extravasation of intravenous fluids; and diaper dermatitis. The goal of all skin care for neonates should be the maintenance of skin integrity; however, even with meticulous care, skin breakdown can occur.

Skin Assessment

A thorough examination of all skin surfaces on a daily basis will reveal the state of skin integrity in critically ill or extremely premature infants in the NICU. Early signs of skin abrasions or small excoriations may call for either diagnostic or treatment procedures. A skin assessment tool such as the Neonatal Skin Condition Score (NSCS; Box 12.1; Figure 12.9), used in the AWHONN/National Association of Neonatal Nurses (NANN) research-based practice project, may be beneficial when assessing skin conditions (Lund et al., 2001). The NSCS was found to have both interrater and intrarater reliability, and validity was confirmed by the relationship of the skin scores with birth weight, number of observations over time, and prevalence of infection (Lund & Osborne, 2004). Identifying risk factors for skin injury in individual patients may include gestational age less than 32 weeks, use of paralytic medications and vasopressors, multiple tubes and lines, numerous monitors and probes, surgical wounds, ostomies, and technologies that limit patient

Box 12.1

NEONATAL SKIN CONDITION SCORE

Dryness

1 = Normal, no sign of dry skin
2 = Dry skin, visible scaling
3 = Very dry skin, cracking/fissures

Erythema

1 = No evidence of erythema
2 = Visible erythema over <50% of the body's surface
3 = Visible erythema on >50% of the body's surface

Breakdown/Excoriation

1 = None evident
2 = Small localized areas
3 = Extensive

Note: Perfect score = 3; worst score = 9

movement such as high-frequency ventilation and extracorporeal membrane oxygenation.

Other scoring tools such as the Braden Q and Starkid Scale that assess risk for pressure sores have been suggested (Curley, Razmus, Roberts, & Wypij, 2003; Suddaby, Barnett, & Facteau, 2005). However, in these studies the number of neonates is not indicated, patients from ages 0 to 12 months are evaluated as a single group, and no premature infants were included so the applicability of these tools to a NICU population has not been demonstrated.

The Braden QD was developed to predict hospital-acquired pressure injuries (HAPI) in pediatric patients, including those caused by both immobility and medical devices. Their study involved 625 patients, with 17% less than 1 month of age. The overall HAPI rate was lower than expected, with 86 HAPI found in 49 patients; 75% were device-related (Curley et al., 2018).

The Braden QD evaluates for intensity and duration of pressure in terms of the patient's mobility and sensory perception. It also evaluates skin tolerance in terms of friction, shear, nutrition, tissue perfusion, and oxygenation. In addition, the number of medical devices is quantified as well as the ability to reposition devices and sensors. However, there is no scoring for prematurity or gestational age, both important aspects of skin tolerance in NICU patients, so how helpful the use of the Braden QD in NICU patients is remains questionable. It is also important to recognize that risk assessment is not the same as skin assessment and careful observation and documentation of the skin condition are essential components of skin care in NICU patients.

Skin Injuries

Although little clinical research is available to guide selection of topical agents and products to treat skin injuries in neonates, there are several principles to help inform practitioners. These include the concept of moist wound healing, gentle cleansing, and understanding the proper application of appropriate dressings (Cousins, 2014; M. D. Fox, 2011). In addition, although the injury may be due to mechanical trauma, the role of microorganisms can further complicate the management of skin injury, especially in the very low birth weight premature infant. In these cases, a skin culture may be helpful.

If the culture is positive for a candidiasis species, antifungal ointment and systemic treatment with fluconazole or amphotericin may prevent devastating, disseminated disease (Benjamin et al., 2010; Darmstadt, Dinulos, & Miller, 2000). Although fungal causes are sometimes suspected, other microorganisms such as *S. aureus* species, *Escherichia coli,* and other gram-negative bacteria have also been cultured in extremely premature infants. The knowledge of their skin colonization may be very useful in guiding systemic treatment should their clinical condition worsen, suggesting systemic disease, including sepsis.

Ointments are sometimes used on skin injuries not only because of their antibacterial or antifungal properties but also because covering the wound with a semi-occlusive layer promotes healing by facilitating the migration of epithelial cells across the surface. Petrolatum-based emollients and ointments are used to cover wounds and provide a semi-occlusive layer that facilitates the migration of epithelial cells across the surface and may actually become part of the *stratum corneum* layer during the healing process. Antibacterial ointments such as Polysporin, Bacitracin, or Bactroban are useful to treat gram-positive colonized surfaces but also actually promote the growth of gram-negative organisms (Smack et al., 1996). Many dermatologists recommend against the use of Neosporin because of the potential for developing later sensitization to this ointment, although sensitization to Bacitracin is being reported with increasing frequency (Marks et al., 1995). If fungal infection is suspected, nystatin ointment is used and can also be applied to surrounding intact skin to prevent extension of the infection. In general, ointments are preferable to creams in this application because of better adherence and healing properties.

Gentle cleansing of the skin injury or wound can remove debris and exudate and promote a clean wound bed. These materials and other necrotic tissue impede wound healing and the removal reduces the level of bacterial contamination (Cousins, 2014). Wound cleansing is best accomplished by gentle irrigation with normal saline, either diluted or undiluted, using a 20 to 60 mL syringe and a blunt intravenous catheter (AWHONN, 2018). Antiseptic solutions and cleansers are to be avoided as these can cause further injury to delicate healing tissue and may delay healing (Lineaweaver et al., 1985; Rolstad & Ovington, 2007; Wilson, Mills, Prather, & Dimitrijevich, 2005).

Dressings for wound care and for treating skin injury should be occlusive and nonadherent in order to promote moist healing to facilitate the migration of epithelial cells. These include silicone dressings, hydrocolloid dressings, hydrogel dressings, transparent dressings, and dressings made of foam or other composite materials. In addition, some may be impregnated with silver ions, with potential benefit due to anti-infective properties (M. D. Fox, 2011). Although use of silver-containing creams and dressings were initially avoided due to concerns with toxicity, more recent articles demonstrate safe uses of silver-containing agents in neonates (August, Ireland, & Benton, 2015; Tenenhaus, Greenberg, & Potenza, 2014).

Medical grade honey, either as an ointment or in a dressing, has also been described for use in neonates and may also be used to facilitate debridement (Amaya, 2015). Benefits include anti-infective properties and facilitating moist healing cascade (Alvarez-Suarez, Gasparini, Forbes-Hernández, Mazzoni, & Giempieri, 2014). There are several case studies that report positive results using medical grade honey in premature infants (Boyar, Handa, Clemens, & Shimborske, 2014; Esser, 2017; Mohr, Reyna, & Amaya, 2014).

Intravenous Extravasations

The extravasation of intravenous fluids and medications can result in skin injury and, in some cases, deep-tissue injury to muscle and nerves (Figure 12.10). Neonates are at high risk for developing extravasation injuries because of their immature skin, lack of subcutaneous tissue, and the small size of their blood vessels (Amjad, Murphy, Nylander-Housholder, & Ranft, 2011; Casanova,

FIGURE 12.10 Intravenous extravasation injury with swelling, discoloration, and leaking of fluid.

Bardot, & Magalon, 2001). The most serious extravasation injuries are iatrogenic complications that can lead to pain, prolonged hospitalization, and increased morbidity, such as infection. Extravasation injuries can also result in increased hospital costs and the potential for legal action.

Nursing actions such as the monitoring of intravenous sites and other preventive strategies as well as immediate interventions that reduce the extent of tissue injury are important considerations for all nurseries that care for newborns with intravenous devices for fluid administration and medications. Some of the risk factors for tissue injury from intravenous extravasations in NICU patients are listed in Box 12.2.

Hourly assessments of insertion site, with more frequent assessments during administration of certain medications, is recommended, as well as not relying on the infusion pump to detect infiltration of fluid into the tissue (Amjad et al., 2011; Simona, 2012; Tofani et al., 2012). Quality improvement efforts involving standardizing assessment strategies have been described and are beneficial, such as "Touch, Look, Compare" and "Assess, Compare, Touch" (Tofani et al., 2012; Wilder, Kuehn, & Moore, 2014). One center included these aspects of assessment, along with review of factors such as catheter type, securement method, and daily review of catheter necessity; these efforts resulted in a reduction in infiltration rates over a 6-month period (Watterson et al., 2018).

Prevention of skin injury after infiltration is an important consideration. Strategies include ensuring that the insertion site is clearly visible by using transparent adhesive dressing or clear tape to secure the device and observing the site with appropriate documentation every hour. In addition, the tape should be carefully placed on the extremity to avoid obstruction of venous return. Tape placed loosely over a bony prominence, such as the knee or elbow, permits extravasated fluids and medications to disperse over a larger surface area and thus reduce the risk of injury, compared with extravasation limited to a small surface area. Avoiding extremities with poor perfusion in favor of better-perfused scalp veins (except, of course, those on the forehead) may also be prudent; in some cases, the wiser choice may be the placement of central venous lines for access.

The fluid that is being infused is a known factor that can lead to greater risk of extravasation. The risk is related to the fluid's chemical properties, osmolality, and pH (Gorski et al., 2017). Normal serum osmolality is 280 to 295 mOsm/kg and solutions that exceed this are considered hypertonic. Solutions that are infusing through a peripheral vein in a neonate should stay within this range (Thigpen, 2007). Glucose concentrations that are higher than 12.5% are at risk for extravasation injury (Weinstein, 2007).

Medications can be both hyperosmolar and irritating due to pH extremes. Particularly irritating medications and solutions, called vesicants, should be either avoided or carefully watched during infusion. A chart showing various degrees of vesicants can be a helpful guide for neonatal patients and may also identify patients who would benefit from central venous access (Gorski et al., 2017).

Once an intravenous extravasation has been identified, immediate measures to reduce injury are instituted (Thigpen, 2007). The device should be carefully removed and the extremity elevated (if it is an arm or leg). Treatment with heat or moisture is not recommended because the delicate tissue could be further injured by a burn or the effects of maceration. Making multiple puncture holes over the area of greatest swelling and squeezing to allow the fluid to leak out of the tissue releases the infiltrated fluid and can potentially prevent skin injury (Chandavasu, Garrow, Valda, Alsheikh, & Dela Vega, 1986; Sawatzky-Dickson & Bodnaryk, 2006). Saline washout has also been described (Casanova et al., 2001; Davies, Gault, & Buchdahl, 1994; Kostogloudis et al., 2015), although no randomized trial has been published to compare efficacy (Gopalakrishnan, Goel, & Banerjee, 2017).

Hyaluronidase is an enzyme that facilitates diffusion of the extravasated fluids by temporarily dissolving the normal interstitial barriers, reducing tissue damage, and has been reported to reduce tissue injury following extravasation in neonates (Banta & Noerr, 1992; Laurie, Wilson, Kernahan, Bauer, & Vistnes, 1984; Raszka, Kueser, Smith, & Bass, 1990). A dose of 15 to 20 U is administered in five subcutaneous injections around the periphery of the extravasation (Treadwell, 2012), and this dose may be repeated. The addition of multiple punctures may also facilitate flow of fluid from the tissues, as well as keeping the site moist for several hours using hydrogel products or moist compresses.

If tissue damage results despite the immediate care measures, the use of topical wound care treatments is necessary. In the most severe cases of deep-tissue necrosis after extravasation injury, a surgical or plastic surgery consultation may be necessary (Figure 12.11).

Diaper Dermatitis

A common skin disruption that occurs in neonates and infants is diaper dermatitis (diaper rash). This term encompasses a range of processes that affect the perineum, groin, thighs, buttocks, and anal area of infants who are incontinent and wear some covering to collect urine and feces. Diaper dermatitis can be caused by

Box 12.2

RISKS FOR TISSUE INJURY FROM INTRAVENOUS EXTRAVASATIONS

Some of the factors known to increase the risk of tissue injury include:

- The length of exposure after extravasation occurs, especially when the patients are unable to verbalize the discomfort of pain or pressure
- The nature of the drug or solution; hypertonic solutions with high concentrations of calcium, potassium, glucose, or amino acids; and medications such as nafcillin have been identified as high risk for causing injury
- The mechanical compression caused by electronic infusion pumps

FIGURE 12.11 This intravenous extravasation injury will require plastic surgery.

many different mechanisms, but the condition of the skin has a direct role in the progression of skin injury. Review articles provide an excellent background for current evidence-based care in the prevention and treatment for diaper dermatitis (Adam, 2008; Heimall, Storey, Stellar, & Davis, 2012).

The pathogenesis of diaper dermatitis is partly related to the degree of wetness of the skin. Skin that is moist and macerated becomes more permeable and susceptible to injury because wetness increases friction. In addition, moisture-laden skin is more likely to contain microorganisms than dry skin.

Another component in the process of skin injury from diaper dermatitis is the effect of an alkaline pH. The normal skin pH is acidic—ranging between 4.0 and 5.5—but can become alkaline when it is diapered (Visscher, Chatterjee, Ebel, LaRuffa, & Hoath, 2002; Visscher, Chatterjee, Munson, Pickens, & Hoath, 2000). It is the resulting increased pH of the skin that increases its vulnerability to injury and penetration by microorganisms. Another problem associated with increased pH of the skin is that it stimulates fecal enzyme activity. Specifically, both protease and lipase, which are found in stools, can injure the skin, which is made up of protein and fat components. These enzymes can cause significant injury to the epidermis fairly quickly and are responsible for the contact irritant diaper dermatitis that is commonly seen.

Once the epidermis has been impaired or becomes a less efficient barrier because of one of the aforementioned mechanisms, invasion by bacteria or fungus can occur. Thus, a contact irritant diaper dermatitis can turn into a staphylococcal or fungal rash if this progression occurs. *S. aureus* can be found in large numbers on the skin surface, especially if it is inflamed or impaired, and can result in secondary infection. The classic presentation for *S. aureus* is pustule formation at the site of hair follicles, although the overall incidence of *S. aureus*-complicated diaper dermatitis is quite low.

Fungal rashes, primarily those caused by *C. albicans*, may have different mechanisms of invasion. Many researchers have identified *C. albicans* as a secondary invader of skin that has been injured by other mechanisms, whereas others suggest that *C. albicans* is a primary causative factor in diaper dermatitis. This theory is based on the ability of *C. albicans* to penetrate the *stratum corneum*, especially in a warm and moist environment, such as that found under an occlusive diaper. The resulting intense inflammation is significant and appears as brightly erythematous, sharply marginated dermatitis that involves the inguinal folds as well as the buttocks, thighs, abdomen, and genitalia, characteristically with satellite lesions that may extend the rash over the trunk (Figure 12.12). The gastrointestinal tract is often the reservoir for *C. albicans*, and it can frequently be recovered in stools. Oral therapy may be indicated, especially if evidence of oral infection, such as thrush, is apparent.

Diaper dermatitis can be the result of a primary dermatological condition, such as psoriasis, eczema, and seborrheic dermatitis. Significant family history of these skin conditions may identify infants who are especially vulnerable to developing severe reactions to inflammation in the diaper area. The role of allergens has also been implicated in some cases of diaper dermatitis and should be considered when treatment strategies fail (Smith & Jacob, 2009).

Management

Prevention is the first goal of intervention and is paramount in breaking the cycle of diaper dermatitis. Frequent diaper changes result in skin that is drier with a more normal pH and a more normal functional barrier of the skin. Strategies to keep the skin dry also include the use of highly absorbent gelled diapers that act to "wick" moisture away from the skin. Use of baby powders is discouraged because of the risk of inhalation of particles into the respiratory tract.

The use of commercially available diaper wipes, although in widespread use, has variable support in the literature with reports of contact allergens and concerns with product ingredients (Ehretsmann, Schaefer, & Adam, 2001; Fields, Nelson, & Powell, 2006; Smith & Jacob, 2009). A carefully controlled study of one brand of wipes compared to cloth and water for skin cleansing in the diaper area of premature infants showed improved skin pH and TEWL with the diaper wipe (Visscher, Odio, et al., 2009). An RCT comparing using diaper wipes to cotton balls and warm water found no difference in skin barrier function and changes in skin pH between the two techniques (Lavender et al., 2013). However, these findings are not generalizable to other products with different formulations.

Once diaper dermatitis occurs—and it is not completely avoidable in most infants—protection of injured skin during healing is the primary goal. Use of a generous layer of protective skin barriers that contain petrolatum ointment and/or zinc oxide prevents further trauma and allows impaired skin to heal (Figure 12.13). Although various amounts of zinc are found in different products, there is no evidence that one is better than another (Stamatas & Tierney, 2014). Other ingredients that have been reportedly as beneficial include products with carboxymethylcellulose that adhere extremely well to excoriated skin (Esser, 2016). The ingredient cyanoacrylate, found in "liquid bandages," is now found in some products for incontinence-associated dermatitis in adults and hold

FIGURE 12.12 Candida diaper dermatitis involving labia and inguinal folds with characteristic satellite lesions.

FIGURE 12.13 Use of thick layer of a skin barrier such as zinc oxide or pectin paste will prevent reinjury of skin damage in diaper dermatitis.

promise for the most severe cases of diaper dermatitis in infants and children (Brennan, Milne, Agrell-Kahn, & Ekholm, 2017).

Opening the skin to light and air is not effective if the fecal contents are allowed to have direct contact with already injured areas. Because protective skin barriers tend to adhere well to the skin, it is neither necessary nor desirable to completely remove them during diaper changes before more cream is applied because the friction that is generated will injure healing tissue. It is best to generously apply more cream to the site to protect the area from further injury.

Multiple products are used in the care of diaper dermatitis—including topical emollients, diaper rash balms, and wipes—but product selection is often affected by myth and tradition rather than science. A damp diaper covered with a plastic coating enhances the risk of irritation and percutaneous absorption. The risk of absorption is even greater in newborns and premature infants because of their large surface area to body weight ratio and immature skin. The various compounds and numerous chemicals used have been described extensively (Gilliam & Williams, 2008; Siegfried & Shah, 1999), with concerns raised about potential toxicity, irritancy, and later sensitization. Simple, inexpensive products such as zinc oxide ointment are recommended over more complex compounds.

Treatment of diaper dermatitis that is solely due to invasion with *C. albicans* requires the use of antifungal creams or ointments. Some of the antifungal preparations include nystatin, miconazole, and clotrimazole. If the diaper dermatitis involves both fungus and a contact irritant component, alternating applications of the topical creams or ointments is effective.

Severe diaper dermatitis with deep excoriations can be seen in infants with malabsorption syndrome, secondary to intestinal resection or mucosal injury. In these cases, the stool is extremely caustic and contains a higher level of enzyme activity, a lower pH as the result of rapid transit through the intestine, and significant amounts of undigested carbohydrates. In the case of opiate withdrawal, stool frequency is often greatly increased. Other infants at risk for severe diaper dermatitis include those with spina bifida, exstrophy of the bladder, and infants with decreased anal sphincter tone due to early pull-through procedures for Hirschsprung's disease. In cases of loss of sphincter tone, fecal material constantly dribbles to the perianal area.

Although skin disruption frequently becomes the focus of nursing interventions, this symptom may be a significant indication of more serious physiological concerns. These infants' stools should be carefully monitored by documentation of number and volume. The infants must be observed for the dehydration caused by extensive water losses in diarrhea. Once dietary manipulations and hydration have stabilized the general physiologic status, a program of skin protection is imperative because some level of chronic diarrhea may be ongoing for many weeks or months. Products such as pectin-based powders or pectin-containing pastes without alcohol may be better barriers to the caustic, constant fecal irritation if traditional zinc oxide creams do not work adequately. If yeast is present, antifungal creams may be applied in conjunction with protective barriers.

EVIDENCE-BASED SKIN CARE GUIDELINE

Many intensive care and newborn nurseries have written protocols for various aspects of neonatal skin care. The AWHONN and the NANN collaborated in the development of a comprehensive, evidence-based neonatal skin care guideline. An extensive review of the scientific basis for neonatal skin care was undertaken by a team, including advanced practice nurses and a pediatric dermatologist (Lund, Kuller, Lane, Lott, & Raines, 1999), and a neonatal skin guideline was written to address 13 aspects of skin care (Box 12.3). An evaluation project involving 51 nurseries was undertaken to evaluate the effect of using this guideline. The project involved identifying coordinators at each site who were willing to collect baseline information about the skin condition of infants in their units, implement the practice guideline in their respective units, and then collect skin condition information again once the guideline had been introduced. Issues of safety and feasibility were important, as was the evaluation of the impact of evidence-based practice on skin condition.

More than 11,000 skin observations using the NSCS were performed on 2,820 newborns of varying gestational ages and weights. An improvement in skin condition was observed after implementation of the guideline, as evidenced by overall lower scores on the NSCS during the observation period. Initial scores were similar in both the pre-guideline and post-guideline groups but improved more rapidly after the guideline had been implemented. The results were more dramatic in low birth weight infants, but improvement was seen in the "well-baby" sample as well.

The Neonatal Skin Care Guideline was revised in 2007, with the addition of a section on *vernix caseosa* due to the availability of numerous studies published on this topic. A third revision was released in 2013 and a fourth in 2018.

Box 12.3

ELEMENTS OF THE AWHONN/NANN EVIDENCE-BASED PRACTICE GUIDELINE: NEONATAL SKIN CARE

1. Newborn skin assessment
2. Neonatal skin injury
3. Bathing
4. Vernix caseosa
5. Umbilical cord care
6. Diaper dermatitis and diaper wipes
7. Circumcision care
8. Emollient use for dry skin and atopic dermatitis
9. Skin disinfectants
10. Medical adhesives
11. Intravenous extravasation
12. Transepidermal water loss in premature infants
13. Parent education

SUMMARY

Neonatal skin management is a complex problem that requires a collaborative approach. Some research has been conducted in this area but a lot remains to be done regarding the use of routine NICU equipment and its impact on neonatal skin, the use of skin barriers for protection, and the effect of a consistent approach to skin care on the integrity of neonatal skin. This chapter has outlined the development and structure of the skin. It has addressed differences in the skin based on gestational age variations. Normal physiological as well as common dermatological abnormalities have been presented. Evidence-based neonatal skin care is recommended and has proven to be feasible and safe and to result in improvement in skin condition for newborns.

CASE STUDY

■ **Identification of the Problem.** This extremely premature infant was admitted to the NICU 3 days ago with respiratory distress syndrome; birth weight 650 g, gestational age 24 0/7 weeks. He has an endotracheal tube and is receiving assisted ventilation; catheters are inserted in both the umbilical artery and vein for blood sampling, blood pressure monitoring, and administration of IV fluids. An area of skin breakdown is noted on the abdomen where a temperature probe had been placed and removed on the first day of life. By day 3, the area is erythematous and oozing a yellow-tinged fluid. Surrounding areas are also quite red.

■ **Assessment: History and Physical Examination.** The infant, a baby boy, was born via vaginal delivery to a 30-year-old G1 P1 mother. The pregnancy was complicated by preterm labor starting at 20 weeks, and a cervical cerclage was performed. A month later the mother was again hospitalized with prolonged rupture of membrane (PROM) and preterm labor. This time the efforts to stop labor were unsuccessful, and the infant was delivered vaginally 48 hours after a single course of betamethasone was administered.

The infant's Apgar scores were 4 and 7. The infant was intubated in the delivery room due to poor respiratory effort, and an initial dose of surfactant was administered. The infant was placed immediately into a polyurethane bag for reduction of evaporative heat and fluid loss in the delivery room. Upon arrival in the NICU, the infant was placed on a combination radiant warmer/incubator table for insertion of umbilical catheters. The skin was prepared with a disinfectant (2% chlorhexidine in 70% isopropyl alcohol) prior to placing umbilical catheters. After catheters were placed and position was confirmed with a radiograph, the disinfectant was wiped away using normal saline. At this time, the top of the heating device was lowered and converted to a convectively heated incubator with RH set at 80%.

The infant's skin was very moist and fragile in appearance. After placement of the umbilical catheters, although the periumbilical skin was cleansed with sterile water to remove the skin disinfectant, the skin was noted to be more erythematous than prior to insertion. A temperature probe was attached to the abdomen with a hydrogel electrode, which promptly slid off as a result of the high humidity in the environment. An adhesive-backed foil probe cover was used to secure the catheter.

■ **Differential Diagnosis.** The chief differential diagnoses for an extremely premature infant with skin breakdown include trauma from adhesive removal, chemical burn from disinfectant used for periumbilical skin preparation, and infection. Although the original problem may be trauma, the wound can also be infected by microorganisms on the skin surface.

■ **Diagnostic Tests.** A skin culture with Gram stain and KOH prep is obtained from the area of breakdown. A CBC is obtained, as well as a blood culture. Although a catheter urine culture is requested, this is not obtained due to the extremely small size of the infant's penis and urethra; a "clean" bag specimen is collected instead.

■ **Working Diagnosis.** The Gram stain and KOH prep show budding yeast within 24 hours. The skin culture later shows a heavy growth of *C. albicans*. The blood and urine show no growth of microorganisms after 72 hours. The white blood cell remains unchanged from the first sample sent on the day of admission, but the platelet count has dropped from 100,000 to 60,000.

■ **Development of Management Plan.** After the Gram stain and KOH prep report, the area of breakdown appeared more extensive and the skin over the abdomen erythematous. The excoriated skin was gently debrided using a 30 mL syringe with warmed, one-half normal saline gently squirted through a 20-gauge Teflon catheter. Antifungal ointment, rather than cream or powder, was selected for topical treatment because of the potential healing benefits of ointments.

Because of the proximity of the excoriation to the umbilical catheter insertions, a decision was made to place a percutaneously inserted central line and peripheral arterial line so that the umbilical catheters could be discontinued.

■ **Implementation and Evaluation of Effectiveness.** After receiving the preliminary culture report and noting the drop in platelet count, it was determined that further evaluation for systemic illness would be necessary. A subsequent platelet count was 45,000, and this, coupled with the need for dopamine infusion for hypotension, prompted the medical decision to initiate systemic antifungal treatment. Fluconazole infusion was begun and a platelet transfusion was also administered.

After a second platelet transfusion, the platelet count had stabilized at 90,000 by the fifth day of treatment with fluconazole.

Despite having no growth of *C. albicans* from blood or urine samples, fungal infections in extremely premature infants can initially be cutaneous infections. If not treated early, this can quickly progress to disseminated *Candida* infections involving the blood, urinary tract, cerebrospinal fluid, or other organs.

Factors associated with cutaneous fungal infections in the first week of life are instrumentation procedures, such as cerclage placement, and PROMs. The infant can be colonized from maternal fungal or bacterial flora. Additional risk factors are skin breakdown from trauma or irritation and glucosuria. Several authors recommend early, aggressive management of cutaneous manifestations of fungal infection to prevent further dissemination and systemic complications.

CHAPTER 13

Hematologic System

Gail A. Bagwell and Deborah K. Steward

INTRODUCTION

The hematologic system is probably one of the least understood body systems of the neonate by the neonatal nurse. To provide the utmost care to the neonate, a thorough and complete understanding of the hematologic system and its components is necessary. The knowledge of how the blood cells develop and function as well as how the hemostatic system functions is essential in understanding the diseases of the newborn that affect the hematologic system. Without this knowledge the nurse will miss many of the subtle signs and symptoms that indicate that a problem has arisen. This chapter discusses the hematologic and hemostatic systems, as well as the most common hematologic diseases of the newborn period.

OVERVIEW OF THE HEMATOLOGIC SYSTEM

Hematopoiesis

The hematopoietic system is characterized by the presence of pluripotent stem cells that differentiate into the three types of circulating blood cells: red blood cells (RBCs), white blood cells (WBCs), and thrombocytes (platelets). The formation, production, and maintenance of blood cells are referred to as hematopoiesis. Hematopoiesis is a continuous process that involves cell maturation and destruction concurrent with new cell production. Gestational age and postnatal age influence maturation and govern individual cell components, the level of activity, and the site of production.

The liver becomes the main site for hematopoiesis beginning at approximately 5 to 6 weeks' gestation. The production peaks at 4 to 5 months of age, then slowly regresses, with the bone marrow predominating from 22 weeks' gestation on. Also helping with hematopoiesis during the fetal period are extramedullary sites of the spleen, lymph nodes, thymus, and kidneys while the long bones are small (Yoshimoto & Yoder, 2017).

Red Blood Cells

Erythropoiesis, the production of RBCs, begins at approximately 3 to 4 weeks' gestation. The RBCs are initially primitive megaloblasts, but when the liver becomes the primary site of hematopoiesis, a definitive line of RBCs is formed from the normoblasts, which progress through several phases of refinement and accrue hemoglobin before reaching maturation. When the hemoglobin concentration of the normoblast reaches 34%, the nucleus is extruded and the cell becomes a reticulocyte. Approximately 1 to 2 days later, the reticulocyte becomes a mature RBC and is released into the bloodstream. The development of the RBC is identical in the bone marrow when it becomes the primary site of erythrocyte production.

The role of the RBC is to exchange oxygen and carbon dioxide between the lungs and tissues. Tissue oxygenation occurs by hemoglobin transport, whereas carbon dioxide removal is a reaction with carbonic anhydrase. RBCs also serve as a buffer to maintain acid–base balance.

The life span of fetal and newborn RBCs is much shorter than the adult RBC life span of 120 days. The term newborn's erythrocyte can last 60 to 90 days, and that of a preterm infant, 35 to 50 days. One theoretical reason for this is the diminished deformability of the neonatal erythrocyte. Because of its larger size and cylindrical shape, the neonatal erythrocyte is more prone to destruction in the narrow sinusoids of the spleen (Gallagher, 2015; Ohls, 2017).

The mean RBC count in the term newborn is in the range of 5.8 million/mL, with an elevated reticulocyte count of 3% to 7% during the first 24 to 48 hours of life. Mean RBC counts in the premature infant range from 4.6 to 5.3 million/mL, with a greater number of circulating immature RBCs reflected in a higher reticulocyte count of 6% to 12% (Gallagher, 2015). In both groups of infants, the reticulocyte count falls abruptly to about 0% to 1% and the erythropoietin level drops to low, often undetectable, levels by the first week of life (Gallagher, 2015).

Hemoglobin

At 10 weeks' gestation, hemoglobin synthesis changes from the embryonic to the fetal form (hemoglobin F). This event coincides with the transition of the site of erythropoiesis from the yolk sac to the fetal liver. The mechanism by which stem cells and progenitor cells perform this is controlled by chromosome 11 in the beta-globin gene cluster where they are controlled by the beta-globin locus control region (LCR). The LCR controls the transcription factors to regulate the development of embryonic to fetal to adult hemoglobin (Antoniani, Romano, & Miccio, 2017). Although low levels of a third form of hemoglobin, adult hemoglobin (hemoglobin A), are detectable at this time, hemoglobin F remains the predominant form during fetal development. At 30 weeks' gestation, 90% to 100% of hemoglobin is the fetal form; the remainder is hemoglobin A. Between 30 and 32 weeks,

the percentage of hemoglobin F starts to decline. At 40 weeks, 50% to 75% of RBCs contain fetal hemoglobin; at 6 months of age, 5% to 8%; and at 1 year of age, 1%.

Each type of hemoglobin has properties that make it valuable at the time of its synthesis. Each has a different affinity for oxygen that varies its uptake and release to the tissue (Figure 13.1). Fetal hemoglobin has a high affinity for oxygen, binding it more readily at the intervillous spaces in the placenta when the fetal partial pressure of oxygen (Po_2) averages between 25 and 35 mmHg. Adult hemoglobin has a decreased affinity for oxygen, which allows easier release of oxygen to the tissues when metabolic needs are high and the lungs are functional.

Erythropoietin

The single most important factor in regulating RBC production is tissue oxygenation. The main stimulus for RBC production at times of low oxygen is the hormone erythropoietin. This circulating glycoprotein hormone, the gene of which is located on the seventh chromosome, is an obligate growth factor that stimulates stem cells to become committed progenitors of the erythrocyte (Figure 13.2). In adults, the kidneys produce 90% to 95% of erythropoietin, but in the fetus the liver is considered the predominant site of production throughout most of gestation.

The major stimulus for erythropoietin release is diminished tissue oxygenation. In the absence of erythropoietin, hypoxia has no effect on the production of RBCs. However, if erythropoietin production is intact, hypoxia stimulates a rapid increase in erythropoietin levels, which remain elevated until hypoxia no longer exists. Although the liver is less responsive to hypoxia than the kidneys, production of erythropoietin in the fetus and newborn increases within minutes to hours after a precipitating event such as hypoxia. Erythropoietin acts by directly stimulating the RBC precursors, accelerating their passage through the various maturational stages. Although erythropoietin levels increase rapidly, no change in the number of erythrocytes is noted for approximately 5 days after a hypoxic stress. When erythropoietin stimulates production of excess RBCs, the RBCs are released into the circulation before they have reached maturity (i.e., as reticulocytes); this is reflected in an elevated reticulocyte count.

Factors besides hypoxia that increase erythropoietin production in the newborn are maternal hypoxemia, smallness for gestational age, and poor placental function. Erythropoietin levels are also increased by testosterone, estrogen, thyroid hormone, prostaglandins, and lipoproteins. Cord-blood levels are normally elevated compared with adult values but drop dramatically to almost undetectable levels in the newborn. The healthy newborn, therefore, produces few RBCs in the first few weeks of life because the hypoxic stimuli of low fetal Po_2 levels are no longer present. Erythropoietin levels do not increase in the term infant until 8 to 10 weeks of age, when tissue hypoxia caused by anemia is sensed by the kidneys.

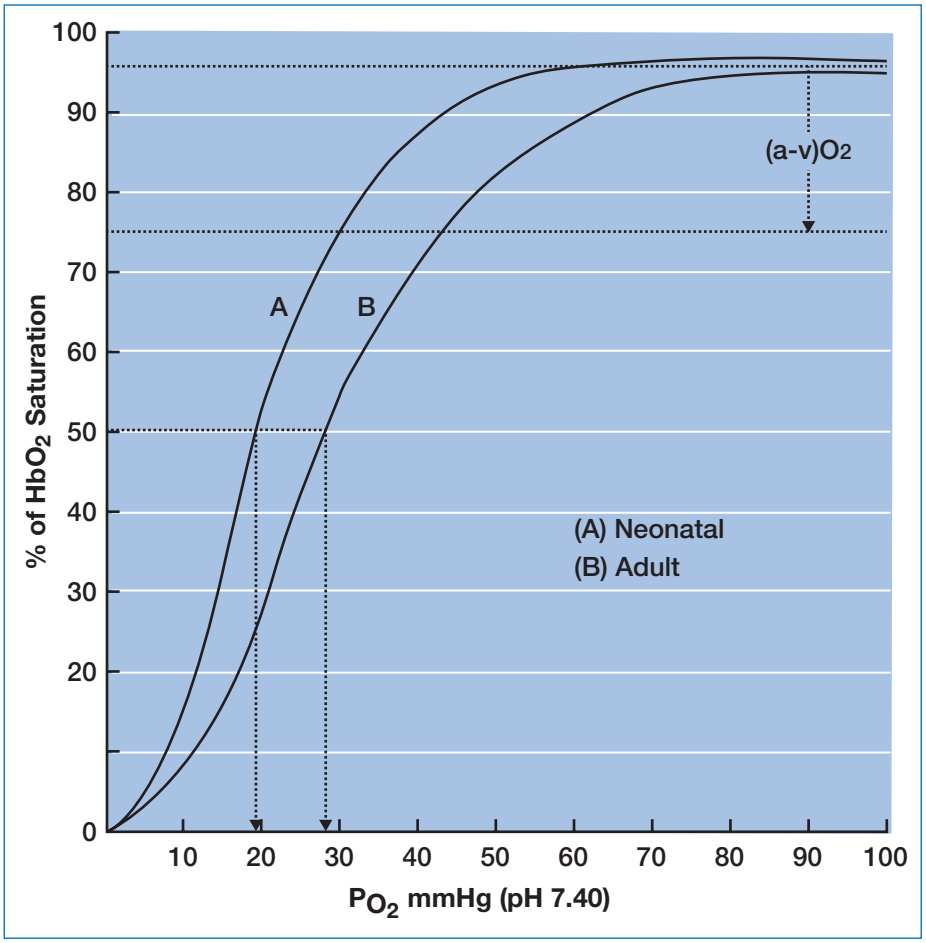

FIGURE 13.1 The affinity for oxygen (i.e., the ability of the hemoglobin molecule to bind and hold the oxygen molecule) is markedly different between fetal and adult hemoglobin. Fetal hemoglobin has a greater affinity for oxygen. It is able to bind to oxygen more readily at the intervillous spaces of the placenta, a property that is useful in the low partial pressure of oxygen (Po_2) environment of the fetus. Adult hemoglobin has a diminished affinity for oxygen, which allows easier release of oxygen to the tissue when metabolic needs are higher than those that arise in the fetus.

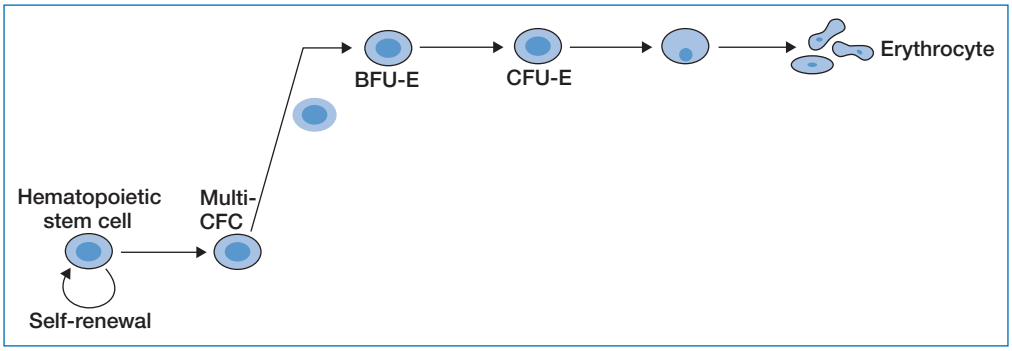

FIGURE 13.2 Hematopoietic stem cells stimulated to become erythrocytes initially develop into multipotent colony-forming cells (multi-CFC). A portion of the multi-CFC become erythroid progenitor cells, the early and late erythroid burst-forming units (BFU-E), which eventually differentiate into erythroid colony-forming units (CFU-E). These progenitor cells progress to form the normoblast, the erythrocyte precursor. Multiple divisions and alterations of the normoblast lead to the development of the reticulocyte. When the reticulocyte extrudes its nucleus, it normally moves out of the predominant production sites (i.e., the liver or bone marrow) and into the blood.

Source: Adapted from Diab, Y., & Luchtman-Jones, L. (2015). Hematologic and oncologic problems in the fetus and neonate. In R. J. Martin, A. A. Fanaroff, & M. C. Walsh (Eds.), *Fanaroff and Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (10th ed., pp. 1294–1343). Philadelphia, PA: Elsevier.

The characteristics of the neonatal erythrocyte predispose both preterm and term infants to problems associated with hemolysis and immature hepatic response to erythrocyte destruction, as well as to the effects of shortened erythrocyte life span (as is seen in physiologic neonatal anemia and anemia of the premature infant). In addition to maturational influences, preexisting maternal diseases and intrauterine abnormalities can impair RBC function and production, resulting in increased oxygen and nutritional requirements for the growing fetus (Ohls, 2017).

White Blood Cells

The formation of the WBCs begins in the liver at approximately 5 to 7 weeks' gestation and then in the lymph nodes at 12 weeks' gestation, with the number of circulating WBCs increasing dramatically during the third trimester. The purpose of the WBC is to work against foreign proteins found in the body. The production and function of WBCs are also affected by gestational age; this subject is covered in more detail in Chapter 11, Immune System.

Platelets

The production of platelets and clotting factors is also a function of gestational age. Although some factors are deficient at birth, several clotting factors and platelets are present in concentrations similar to adult levels. However, many of these components are functionally different from those of adults, possibly because of impaired activity or limited ability to respond to heightened needs. Coagulation dysfunction in the newborn may also be the result of genetic abnormalities (e.g., X-linked hemophilia), preexisting maternal illness (e.g., immune thrombocytopenic purpura), or infection (e.g., disseminated intravascular coagulation [DIC]).

Platelet counts in the newborn do not vary much in relation to gestational age. Counts are similar from 27 to 40 weeks' gestation, with the range of normal falling between 215,000 and 378,000/mm^3. At 32 weeks' gestation, platelet levels are comparable to those of an adult, but platelet function is not. Platelet counts under 150,000/mm^3 are considered thrombocytopenic.

Blood Volume

Normal blood values found shortly after birth reflect a time of maximum change. Blood values at birth depend on (a) the timing of cord clamping, (b) the infant's gestational age, (c) the blood sampling site, and (d) the technique used to obtain adequate blood flow.

The timing of cord clamping and the positional differences between the infant and the placenta can significantly influence newborn blood volume. Complete emptying of placental vessels before clamping can increase blood volume by 61%; one quarter of the placental transfusion occurs within the first 15 seconds, and half of the transfusion is complete by 1 minute. In previous editions of this text, delayed cord clamping (DCC) was considered controversial due to some perceived negative effect on the neonate, but over time randomized controlled trial studies have been done in both term and preterm neonates to dispel those thoughts. The results of the studies on DCC for greater than 30 seconds in vigorous term and preterm newborns that have an intact placental circulation have been shown to be advantageous to the newborn, both preterm and term. Preterm newborns who had DCC for 30 to 60 seconds had higher blood pressure, higher blood volume resulting in higher hematocrits (Hct), decreased need for blood transfusion, higher ferritin levels resulting in lower incidence of iron deficiency, lower incidence of neonatal anemia, and decreased incidence of intraventricular hemorrhages and necrotizing enterocolitis (American Academy of Pediatrics [AAP], 2017; American College of Obstetricians and Gynecologists [ACOG] Committee on Obstetric Practice, 2017). For the term neonate, the advantages are increased hemoglobin levels at birth and improved iron stores, which may lead to less incidence of iron deficiency anemia. The one concern with DCC is that it may also increase the amount and severity of jaundice in term neonates, so it is essential to ensure that the neonate is observed for signs of jaundice and has adequate follow-up (AAP, 2017; AAP & ACOG, 2017; ACOG Committee on Obstetric Practice, 2017). For these reasons both ACOG (Committee on Obstetric Practice, 2017) and AAP (2017) recommend DCC for all neonates that are vigorous at birth for 30 to 60 seconds, when the mother is hemodynamically stable.

Umbilical cord milking (UCM) is another manner to increase blood volume in neonates, but UCM has not been studied as rigorously as DCC. UCM can be done in 10 to 15 seconds versus the 30 to 60 seconds required for DCC and could be beneficial in cases when there is a need for immediate resuscitation. While the studies done on DCC show similar results, those on UCM show varied results, making it hard to generalize the results. At this point there is not strong enough evidence to recommend UCM in either term or preterm neonates (Al-Wassia & Shah, 2015).

TABLE 13.1

AGE-SPECIFIC NORMAL BLOOD CELL VALUES IN FETAL SAMPLES (26–30 WEEKS' GESTATION) AND NEONATAL SAMPLES (28–44 WEEKS' GESTATION)

Age	Hb (g/dL)[a]	Hct (%)[a]	MCV (fL)[a]	MCHC (g/dL RBC)[a]	Reticulocytes	WBCs ($\times 10^3$/mL)[b]	Platelets (10^3/mL)[b]
26–30 weeks' gestation[c]	13.4 (11)	41.5 (34.9)	118.2 (106.7)	37.9 (30.6)	–	4.4 (2.7)	254 (180–327)
28 weeks	14.5	45	120	31.0	(5–10)	–	275
32 weeks	15.0	47	118	32.0	(3–10)	–	290
Term[d] (cord)	16.5 (13.5)	51 (42)	108 (98)	33.0 (30.0)	(3–7)	18.1(9–30)[d]	290
1–3 days	18.5 (14.5)	56 (45)	108 (95)	33.0 (29.0)	(1.8–4.6)	18.9 (9.4–34)	192
2 weeks	16.6 (13.4)	53 (41)	105 (88)	31.4 (28.1)	–	11.4 (5–20)	252
1 month	13.9 (10.7)	44 (33)	101 (91)	31.8 (28.1)	(0.1–1.7)	10.8 (4–19.5)	–

[a] Data are mean (number in parenthesis is −2 standard deviations [SD]).

[b] Data are mean (number in parenthesis is −2 SD).

[c] In infants younger than 1 month, capillary Hb exceeds venous Hb: at 1 hour old, the difference is 3.6 g; at 5 days, 2.2 g; at 3 weeks, 1.1 g.

[d] Mean (95% confidence limits).

Hb, Hemoglobin; Hct, hematocrit; MCV, mean corpuscular volume; MCHC, mean corpuscular hemoglobin concentration; WBCs, white blood cells.

Source: Modified from Costa, K. (2018). Hematology. In *The Harriet Lane handbook* (pp. 364–394). Philadelphia, PA: Elsevier.

The average blood volume of the neonate without DCC is approximately 85 mL/kg of body weight in the term infant, though it can be as high as 90 to 105 mL/kg in the preterm infant. As stated earlier, DCC can increase the blood volume by 61%, thus making term infant blood volume as high as 136 mL/kg and the preterm infant blood volume as high as 150 mL/kg. The younger the infant's gestational age, the greater the blood volume will be per kilogram of body weight as a result of a higher plasma volume.

The hemoglobin concentration and Hct are also functions of gestational age, especially in infants born before 32 weeks' gestation. The average mean hemoglobin concentration at 26 to 30 weeks is 13.4 g/dL, with an average mean Hct of 41.5%. In the term infant, mean hemoglobin values range from 16 to 17 g/dL, with mean Hct values between 51% and 60% (Gallagher, 2015). Mean hemoglobin values in postmature infants are higher than in the term infant, possibly as a result of progressive placental dysfunction and oxygen deficit, which stimulates the release of erythropoietin. Table 13.1 summarizes the differences in hematologic values as a function of increasing gestational and postnatal age.

It is important to consider the sampling site and the quality of blood flow when interpreting laboratory values. The hemoglobin levels of capillary blood are 10% to 20% higher than those of venous and arterial blood. This discrepancy can be minimized by warming the extremity before drawing blood to enhance peripheral perfusion, allowing better spontaneous blood flow. Discarding the first few drops obtained on a capillary draw also improves the accuracy of the sample. Sampling by the venous route also requires care; poor blood flow through small-bore needles increases the chance of hemolysis, which can lead to sampling errors. Greater accuracy can be obtained by using the largest possible bore needle and removing the needle from the syringe before placing the sample in the specimen container. Gestational age also affects the discrepancy between reported capillary and venous results: the younger the gestational age, the larger the discrepancy. The key to accuracy in hematology laboratory values lies in the use of a consistent sampling site.

Blood Group Type

The RBCs have antigens located on the surface of the cell membranes that can cause antigen–antibody reactions. Blood is classified by groups and types based on the antigens that are found on the RBC. The four major blood types are A, B, O, and AB. The most common blood types in the population are O at 47% and A at 41% (Hall, 2016). Antibodies to the antigens of different blood types occur naturally in the plasma (Table 13.2). For example, type A blood has A antigens on the cell surface but has circulating anti-B antibodies in the plasma. Type B blood has just the opposite, B antigens on the cell surface and anti-A antibodies in the plasma. Type AB blood has A and B antigens on the cell surface and neither antibody in the plasma, and type O blood has neither antigen on the cell surface and both anti-A and anti-B antibodies in the plasma. Antigens are usually polypeptides and complex proteins; antibodies are immunoglobulins (mostly IgG and IgM).

The other type of antigen is Rh antigens. Chromosome 1 stores the genetic material governing Rh antigens, and in most individuals two genes, *CD240CE* and *CD240D*, determine the Rh blood group (Liley, Gardner, Lopriore, & Smits-Wintjens, 2015). There are three presumed Rh gene loci with the capability of producing five recognized antigens in the Rh complex: C, D, E, c, d, and e. Each individual has a paired set of these factors, having inherited a single set of C or c, D or d, and E or e from each parent. A predilection exists toward three particular combinations, two Rh positive (CDe and cDE) and one Rh negative (cde). Of these six factors, the two involved in Rh determination are D and d. The D antigen is most prevalent; its presence on the RBC indicates an Rh-positive cell, whereas its absence indicates an Rh-negative cell. Approximately 85% of Caucasians are Rh positive and 15% Rh negative. African Americans are approximately 95% Rh positive, and Africans are virtually 100% Rh positive (Hall, 2016). Because of single-set inheritance from each parent, the potential exists for three different combinations of paired antigens: one pair being both d (Rh negative, homozygous), another pair being both D (Rh positive, homozygous), and the third pair being a combination of d and D (Rh positive, heterozygous). The end product is the production or absence of Rh antigen positioned on the surface of the RBC. The Rh antigen can be detected as early as 38 days' gestation on the fetal RBC and attains complete development during fetal life. This antigen is necessary for normal function of the RBC membrane, and, unlike A and B antigens, which can be found in other tissues, it is confined exclusively to the RBC. Antibodies never occur naturally in the Rh system; exposure to the antigen is necessary to produce antibodies.

TABLE 13.2

BLOOD GROUPS AND THEIR ANTIGENS AND ANTIBODIES

Blood Group Type	Antigens	Antibodies
O	None	Anti-A, Anti-B
A	A	Anti-B
B	B	Anti-A
AB	A and B	None

Hemostatic System

The components involved in blood coagulation and fibrinolysis (dissolution of a formed clot) are produced in the liver, vascular wall, and tissue during early fetal life. Many of the clotting factors (procoagulants) and anticoagulants (inhibitors) can be identified during the 8th to 12th week of gestation. However, procoagulants, anticoagulants, and the substances responsible for dissolution of a clot, fibrinolytics, do not increase in number and function or reach adult levels simultaneously (Tables 13.3–13.5). Some components increase with increasing gestational age, whereas others achieve normal adult levels several weeks to months before the fetus reaches term. Still other components do not achieve normal adult levels until several weeks to months after birth. Although the function of coagulation factors and anticoagulants in the fetus is not identical to that in an older child or adult, initial vascular response to injury by release of tissue thromboplastin is functional in the fetus as early as 8 weeks.

Hemostasis consists of a delicate and dynamic balance between factors that prevent exsanguination and those that keep the blood in a fluid form. The balanced interrelationship among four distinct components ensures orderly hemostasis and fibrinolysis when vascular integrity is destroyed or interrupted. The four constituents are vascular spasm, platelets and their activating substances, coagulation or plasma factors, and the fibrinolytic pathway.

TABLE 13.3

NORMAL COAGULATION TEST RESULTS AND BLOOD LEVELS OF COAGULATION FACTORS IN THE FETUS (19–27 WEEKS' GESTATION) AND NEWBORN (28 WEEKS' GESTATION TO TERM)

Test/Factor	19–27 Weeks Mean ± SD	28–31 Weeks Mean (boundary)	30–36 Weeks, Day 1 Mean (boundary)	30–36 Weeks, Day 5 Mean (boundary)	Full Term, Day 1 Mean (boundary)	Full Term, Day 5 Mean (boundary)

INITIAL STEPS IN HEMOSTASIS

Vascular Spasm

Initial hemostasis in a ruptured blood vessel consists of vascular spasm, which is a consequence of multiple mediator interactions, nervous reflexes, and localized muscle spasm. Although nervous reflexes are a response to pain, most of the vascular spasm is due to muscle contraction in the vessel wall secondary to direct injury. This vascular response to injury is present in an 8-week fetus and at term is the equivalent of adult norms in regard to capillary fragility and bleeding time. This component is dependent on gestational age, as is evident in the increased capillary fragility shown by the preterm infant.

Platelet Plug Formation

The second mechanism of hemostasis after vascular injury is the formation of the platelet plug. Platelets coming into contact with an injured vascular wall adhere to the wall and form a platelet plug. This hemostatic plug is the primary means of closing small vascular holes at the capillary and small-vessel level. The platelets' ability to adhere on contact to a denuded vascular wall requires a glycoprotein, von Willebrand factor (vWF), which is synthesized by vascular endothelial cells and megakaryocyte vWF

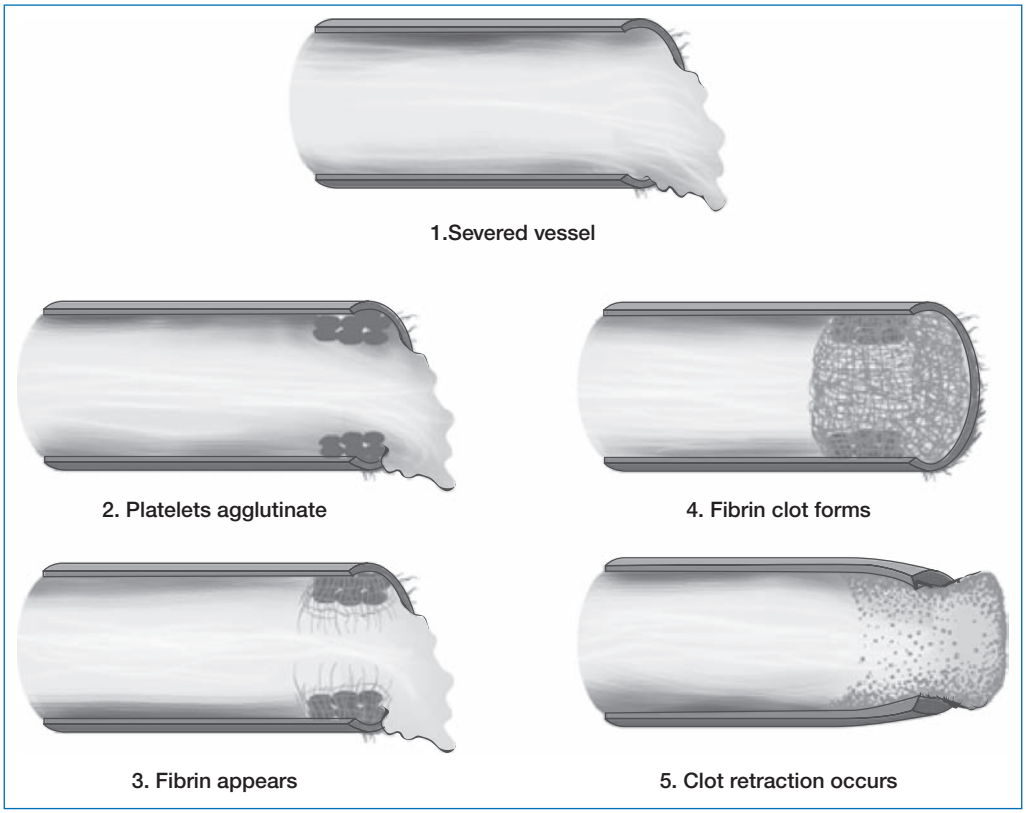

FIGURE 13.3 When vessel wall injury occurs, the initial clotting process begins with the formation of a platelet plug. Platelet activation stimulates fibrinogen receptors found on the surface of the platelets, which enhance their aggregation with other platelets and fibrinogen. The fibrin clot that forms retracts and occludes the damaged vascular wall.

complexes with Factor VIII (antihemophilic factor) and both circulate jointly.

Platelets also have the ability to aggregate (stick to other platelets), forming large clumps. Aggregation is made possible by the platelet's ability to modify its shape and to secrete many biochemical substances (platelet release reaction) that enhance cohesion. When platelets and associated glycoproteins are activated by excess release of these biochemical substances during times of stress, fibrinogen receptors appear on the surface of the platelet. These receptors enhance the platelets' ability to bind fibrinogen, which in turn cross-links the platelets, allowing them to aggregate. This provides a tight mesh or clot around an injured vessel that controls bleeding (Figure 13.3). After 32 weeks' gestation, average platelet counts are comparable to those of term infants and adults, but the ability of platelets to aggregate is relatively diminished.

Coagulation

When bleeding cannot be controlled with merely a platelet plug, circulating plasma coagulation factors are triggered to form a network of fibrin that turns the existing plug into a hemostatic seal, which in turn completes hemostasis. Fibrin threads, necessary for clot formation, can develop within 15 to 20 seconds in the presence of normal coagulation factors. Within 3 to 6 minutes after vascular rupture, the entire opening is occluded by clot; within 30 to 60 minutes, the clot begins to retract, pulling the injured vascular portions together and further sealing the vascular end. This coagulation reaction involves several plasma proteins and three distinct phases. The first phase involves the formation of prothrombin activator, followed by the activation of prothrombin to thrombin (formation of thrombin), and then concludes with the conversion of soluble fibrinogen to fibrin (fibrin clot formation; Hall, 2016).

Phase I: Formation of Prothrombin Activator. According to the earliest theories on coagulation (cascade theory), prothrombin activator can be generated by two separate pathways, the intrinsic and extrinsic pathways. The intrinsic pathway is triggered by trauma or damage that occurs inside the vessel or to the blood itself and the extrinsic pathway is triggered by the production of tissue thromboplastin that is generated by vessel wall damage. This bimodal pathway can be interrupted or negated by a deficiency in platelets or any of the plasma coagulation factors or by the presence of inhibitors (anticoagulants) in the plasma. Selective activation of one of these pathways depends on the site and severity of injury.

Activation of the intrinsic pathway is slower because it lacks the major stimulus of the extrinsic pathway, tissue thromboplastin generated by vessel wall damage. The intrinsic pathway relies on blood trauma or injury within the vessel to alter platelets and plasma proteins and to convert dormant factors (zymogens), naturally found in circulating blood, into active proteolytic enzymes (Figure 13.4). Each activated enzyme subsequently reacts with the succeeding factor, changing it into its activated form. The steps of intrinsic activation of coagulation are as follows:

1. An activator (blood trauma, injury within the vessel, or contact with collagen) activates Factor XII, converting it to Factor XIIa, while simultaneously damaging platelets, which causes a release of platelet phospholipids.
2. Factor XIIa, in conjunction with prekallikrein and high-molecular-weight kininogen, activates Factor XI, converting it to Factor XIa.

3. Factor XIa activates Factor IX, converting it to Factor IXa.
4. Factor IXa, platelet phospholipid, and Factor VIII combine to activate Factor X, converting it to Factor Xa.
5. Factor Xa combines with Factor V and platelet phospholipids to form prothrombin activator (prothrombinase), which releases thrombin from prothrombin. Calcium is required for this and the preceding two steps.

The extrinsic pathway can generate thrombin in a matter of seconds when injury occurs outside the vascular space (Figure 13.5). Tissue thromboplastin (tissue factor), composed of glycoproteins and phospholipids, is produced when tissue is injured. When plasma comes in contact with this substance, the initial intrinsic phases are bypassed and the following responses occur:

1. Tissue thromboplastin or tissue factor (Factor III) activates Factor VII to Factor VIIa. These two factors form a complex with glycoprotein in the presence of ionized calcium (tissue factor–Factor VIIa complex) that activates Factor X, converting it to Factor Xa.
2. In the presence of calcium, Factor Xa forms complexes with phospholipids and Factor V to form prothrombin activator.

From this point on, the intrinsic and extrinsic pathways are identical, with both proceeding to phase II.

Phase II: Formation of Thrombin. Prothrombin activator from either of the two pathways continues the clotting cascade by further influencing the breakdown of the unstable plasma protein prothrombin. Prothrombin (Factor II) is synthesized by the liver under the influence of vitamin K, along with the other factors that form the prothrombin complex (Factors VII, IX, and X). When acted on by prothrombin activator, prothrombin forms the potent coagulant thrombin. The newly formed thrombin stimulates completion of the third and final phase of coagulation.

Phase III: Fibrin Clot Formation

Procoagulants. Thrombin promotes the conversion of fibrinogen (Factor I), a protein produced by the liver, into fibrin by splitting off two peptides from the soluble fibrinogen molecule. This exposes two sites, to which other split fibrin molecules can cross-link, forming an insoluble fibrin chain. Fibrin stabilizing factor (Factor XIII) further strengthens the tight bond of this developing fibrin mesh. Fibrin stabilizing factor is naturally found in the plasma and is also secreted by entrapped platelets. The forming fibrin clot begins to contract and retract with the help of platelets that have actin-myosin action, the same action by which a muscle works. Extension of the clot into the surrounding circulating blood promotes further thrombosis. Thrombin from the clot has the ability to cleave prothrombin into more thrombin and enhances the production of prothrombin activator, thus acting as a potent biofeedback system for perpetuation of the clotting cascade.

Anticoagulants. Throughout the entire coagulation pathway, the action of the activated enzymes is modulated at each stage by multiple and specific inhibitors (anticoagulants). Consequently, coagulation is a process of balance between coagulation factors and naturally occurring inhibitors. Some of these anticoagulants are endothelial surface factors that prevent coagulation until the vessel's endothelial wall is damaged. One such factor is the smoothness of the wall, which prevents any adherence and subsequent activation; another is the monomolecular layer of protein covering the wall, which repels plasma clotting factors and platelets.

Two inhibitors, alpha-1-antitrypsin and C1 esterase inhibitor, interfere with the coagulation factors involved in the initial activation of the intrinsic pathway, as does Factor Xa despite its role in cleaving prothrombin into thrombin. Factor Xa rapidly binds with a tissue factor pathway inhibitor (TFPI) found in the plasma. This complex, TFPI–Factor Xa, joins with the tissue factor–Factor

VIIa complex to form a quaternary complex that inhibits further activation of Factor X by tissue factor.

Thrombin also acts as its own inhibitor by stimulating activation of protein C, which inactivates Factors V and VIII in the presence of another vitamin K–dependent inhibitor, protein S. A deficiency of these two proteins has been implicated in cases of neonatal thrombosis.

Other inhibitors of thrombin formation are: (a) fibrin threads created during clot formation, which absorb thrombin, thus removing it from circulation and eliminating its potential for further coagulation; (b) thrombomodulin, found on the endothelial surfaces of the body and in the plasma complexes with thrombin, which eliminates thrombin's ability to cleave fibrinogen; (c) alpha-2-macroglobulin, which inhibits proteases, including thrombin; (d) antithrombin III, which combines with thrombin, blocking the conversion of fibrinogen into fibrin; and (e) heparin cofactor II, which removes several activated procoagulants. Both antithrombin III and heparin are produced in the precapillary connective tissue of the lungs and liver.

Fibrinolysis. Once a clot develops, it can be invaded by fibroblasts that lay down connective tissue throughout the clot or it can be dissolved. The process of dissolution occurs by activation of naturally occurring factors that lyse the clot. Fibrinolysis is activated simultaneously with stimulation of the coagulation system, with powerful but inactivated anticoagulants built right into the clot. One of these anticoagulants, plasminogen, is manufactured by the liver, kidneys, and eosinophils. Under the influence of thrombin, activated Factor XII, tissue plasminogen activator (t-PA; located on the vascular endothelium), and urokinase plasminogen activator (u-PA; found in the urine), plasminogen is converted into plasmin, a proteolytic enzyme that breaks down fibrin into fibrin split products. Plasmin not only digests the fibrin chains but also deactivates fibrinogen; Factors V, VII, and XII; and prothrombin. Plasmin can be inactivated by its inhibitor, alpha-2-antiplasmin; t-PA can be inactivated by its inhibitor, plasminogen activator inhibitor-1.

In summary, both term and preterm newborns have the ability to create a balance between transitory deficiencies in the amount and function of a variety of clotting factors, platelets, and anticoagulant factors. The homeostasis between clotting factors and anticoagulants places the newborn in a mildly hypercoagulable state at birth. Compared with older children and adults, therefore, the newborn has no greater tendency to bleed but does have several differences in regard to coagulation components and reserves, including (a) gestational age-dependent variations in the concentrations of coagulation factors, anticoagulants, and fibrinolytics; (b) a faster turnover rate of components; (c) a slower rate of synthesis of components; and (d) limited ability to supply necessary components during times of increased need (Cantor, 2015).

ASSESSMENT OF HEMATOLOGIC FUNCTION

Because infants respond to a variety of problems in a similar manner, many clinical findings (e.g., hypoglycemia, hypocalcemia, hypothermia, apnea, bradycardia, cyanosis, lethargy, poor feeding) warrant at least a complete blood count (CBC) to determine if a hematologic reason exists for these symptoms. With active bleeding, platelet counts, clotting studies, fibrinogen levels, and measurements of products of fibrinolysis (e.g., D-dimer, fibrin split products, or fibrin degradation products) can shed light on the type of blood dyscrasia present and can direct the caregiver to the appropriate therapeutic response. These studies also provide a way to monitor and evaluate treatments. However, laboratory data are most helpful when they are used in conjunction with astute observation and physical assessment skills.

Several physical findings can help determine the well-being and homeostasis of the hematologic system (Box 13.1). Cutaneous abnormalities such as hematomas, abrasions, petechiae, and bleeding should alert the nurse to the possibility of a hematologic abnormality. Hepatosplenomegaly also can indicate abnormal breakdown of RBCs. Hepatosplenomegaly concurrent with hyperbilirubinemia and hemolysis can signal alloimmune problems (e.g., Rh and ABO incompatibilities) or acquired, congenital, or postnatal infection (e.g., cytomegalovirus [CMV], toxoplasmosis, herpes simplex infection, or hepatitis).

COMMON HEMATOLOGIC DISORDERS

Blood Group Incompatibilities

Blood group incompatibilities were first recognized in the 1940s with the discovery of the Rh grouping and the first test for detection of antibody-coated RBCs, devised by Coombs in 1946. Before the introduction of Rh immune globulin (i.e., RhIgG, RhIG, RhoGAM, Rhophylac) in 1964 and its release for general use in 1968, Rh incompatibility accounted for one third of all blood group incompatibilities. With the use of RhIgG, the frequency of Rh incompatibility has dropped significantly, and ABO has become the main blood group incompatibility, with sensitization occurring in 3% of all infants. Both incompatibilities involve maternal antibody response to fetal antigen, leading to fetal RBC destruction by hemolysis. Rh antibody response is elicited on exposure to antigen and does not exist spontaneously, whereas anti-A and anti-B antibodies occur naturally. These entities also differ in the severity of the effect on the fetus and newborn and in the method of treatment.

Box 13.1

- Plethora

Other minor blood groupings (e.g., Kell, C, E, Duffy, and Kidd) may also be involved in incompatibilities that result in hyperbilirubinemia, but Rh and ABO incompatibilities are the most common, accounting for 98% of all cases. There are 400 known RBC antigens that can induce antibody production. Some of these antibodies are induced after transfusion therapy with incompatible blood; others occur in response to the transfer of incompatible fetal blood cells into the maternal circulation during pregnancy. The Rh system alone has 40 discrete antigens, but only six (C, D, E, c, d, and e) are important.

ABO Incompatibility

As discussed earlier in this chapter, the four major blood types are A, B, O, and AB, with the antibodies to the antigens of different blood types occurring naturally in the plasma (Table 13.2). Antigens or agglutinogens present on the fetal RBC surface of each blood type react with antibodies or agglutinins found in the maternal plasma of opposing blood types. Of the 30 common antigens involved in antigen–antibody reactions, the ABO antigens are one of two groups most likely to be a problem, the other being the Rh group (Hall, 2016).

With antigen and antibody in harmony, no RBC destruction occurs, but when a conflicting antibody is introduced into the circulation, RBC destruction may occur. RBCs have multiple binding sites to which opposing antibodies can attach. An antibody is capable of simultaneously attaching to several RBCs, thus creating a clump of cells. This clumping of cells, known as agglutination, can cause occlusion of small vessels and impair local circulation and tissue oxygenation. Fetal RBCs coated with antibodies attract phagocytes and macrophages that eventually destroy these agglutinated RBCs, usually through hemolysis by the reticuloendothelial cells in the spleen. Hemolysis can occur without preliminary agglutination, but it is a more delayed process because the body must first activate its complement system. High antibody titers (hemolysins) are required to stimulate this system, which causes the release of proteolytic enzymes that rupture the cell membrane.

In a transfusion reaction, when opposing blood types are mixed, the donor's RBCs are agglutinated, and the recipient's blood cells tend to be protected. The plasma portion of donor blood that contains antibodies becomes diluted by the recipient's blood volume, thus reducing donor antibody titers in the recipient's circulation. However, recipient antibody titers are adequate to destroy the donor RBCs by agglutination and hemolysis or by hemolysis alone. This is the situation in ABO incompatibility. In such cases, the maternal blood type usually is O, containing anti-A and anti-B antibodies in the serum, whereas the fetus or newborn is type A or B. Although incompatibility can occur between A and B types, it is not seen as frequently as AO or BO because of the globulin composition of the antibodies. In the O-type mother, the antibodies are usually IgG and can cross the placenta, whereas the antibodies of the type A or B mother are frequently IgM, which are too large to cross the placenta.

When transplacental hemorrhage (TPH) occurs between an ABO-incompatible mother and fetus, fetal blood entering the maternal circulation undergoes agglutination and hemolysis by maternal antibodies. This rapid response prevents the development of antibodies to other antigens present on fetal RBCs, because a time lapse is required for activation of the immune system. Consequently, fetal RBCs that are Rh positive in addition to being type A or type B are destroyed by naturally occurring anti-A or anti-B antibodies before any maternal antibodies to Rh factor (anti-D) can be produced. This naturally occurring phenomenon is the basis for the use of RhIgG, in which extrinsic anti-D destroys fetal cells before the maternal immune system can be activated to produce antibodies.

Despite this destruction of fetal RBCs, maternal anti-A or anti-B antibodies of the IgG form can freely cross the placenta and adhere to RBCs in the fetal circulation. For this reason, ABO incompatibility can occur in the first pregnancy (40%–50% of total occurrences involve primigravidas) because TPH and inoculation of the mother with fetal blood are not necessary for the development of these naturally occurring antibodies. Since the A and B antigens on the fetal and neonatal RBCs are not well developed, only a small amount of maternal antibody actually attaches to the antigen. Other body tissues and secretions also have antigen sites to which some of the circulating antibodies can adhere, thereby decreasing the potential for RBC destruction. The resulting small amounts of IgG in the plasma do not stimulate activation of the complement system; therefore, hemolysis is minimal. This lack of stimulation of the complement system and the previous factors may explain why only a small subset of the 15% of infants who are ABO incompatible with their mothers become symptomatic (Watchko, 2015).

Erythrocyte antibodies are not usually present in the circulating blood until 2 to 8 months of postnatal age, which prevents maternal inoculation with fetal anti-A or anti-B antibodies. Antibody production then increases, reaching a maximum titer at 8 to 10 years of age (Hall, 2016). The newborn becomes inoculated with A and B antigens after birth through ingestion of food and the resulting bacterial colonization. This initiates production of anti-A or anti-B antibodies that circulate in the plasma, depending on the antigens present on the RBCs.

Clinical Manifestations. The chief symptom of ABO incompatibility is jaundice within the first 24 hours of life; 90% of all affected infants are female. Blood typing and a direct Coombs test are performed (Watchko, 2015). The direct Coombs test is a measurement of the presence of antibody on the RBC surface; the indirect Coombs test is a measurement of antibody in the serum. ABO incompatibility can also be identified by the performance of an eluate test, which involves washing the RBCs of the newborn and testing the wash for anti-A or anti-B antibodies. In addition, hemolysis and anemia are minimal, although signs of a mildly compensated hemolytic state are reflected in certain CBC values. There may be an elevated reticulocyte count and the peripheral blood smear may show evidence of spherocytes, or RBCs lacking the normal central pallor and biconcave, disklike shape of the normal RBC. Because they are smaller than normal RBCs, spherocytes appear thicker. These physical characteristics result in abnormal fragility under osmotic stress. Spherocytes are not distensible or compressible because they lack the normal amount of loose cell membrane, making them more susceptible to destruction in the splenic sinusoids.

On physical examination, hepatosplenomegaly can be observed, a reflection of extramedullary erythropoiesis generated by the fetus in response to significant hemolysis. In an effort to compensate for increased cell destruction, the liver and spleen manufacture RBCs for a longer period than is usually seen in the fetus and newborn. Engorgement of the splenic sinusoids by hemolyzed RBCs contributes to splenomegaly.

Treatment. Since the antibodies involved in ABO incompatibility occur naturally, elimination of this type of incompatibility is virtually impossible. However, its effects on the fetus and newborn are much less dramatic and life threatening than those of Rh incompatibility; therefore, amniocentesis and monitoring of amniotic fluid bilirubin levels, intrauterine transfusions, and early delivery are usually not necessary. Nevertheless, problems associated with postnatal bilirubin clearance do arise, and phototherapy and possible exchange transfusion become part of the repertoire of care. These two treatment methods are discussed in further detail later in the chapter.

Rh Incompatibility

Incompatibilities involving the Rh system are the second most common alloimmune problem, but the severity of complications far surpasses that of ABO incompatibility. Antibodies never occur naturally in the Rh system; exposure to the antigen is necessary to produce antibodies. Such exposure is thought to occur through maternal inoculation with fetal RBCs by TPH or through undetectable hemorrhage during labor, abortion, ectopic pregnancy, amniocentesis, chorionic villus sampling, or percutaneous fetal procedures. **Emergency Alert: A thorough prenatal history may identify risk factors for the development of ABO or Rh incompatibility that have gone undetected.**

Spontaneous TPH occurs in 50% to 75% of all pregnancies, with the greatest and most severe occurrence at the time of delivery. Fetal RBCs can be found in 3% of all pregnancies during the first trimester, 12% in the second trimester, and 45% in the third trimester (Blackburn, 2017). Spontaneous TPH allows fetal RBCs to pass into the maternal circulation, where antibodies develop in response to any foreign RBC antigen the mother does not possess. The risk of immunization depends on the ABO status of both mother and fetus and the size of the hemorrhage. On the basis of blood type, the risk for maternal Rh immunization in an ABO-compatible Rh-negative mother and Rh-positive fetus is 16%, whereas an ABO-incompatible pregnancy with an Rh-negative mother and Rh-positive fetus runs a 1.5% to 2% risk with each pregnancy. If the volume of TPH is less than 0.1 mL RBCs, the overall risk for immunization is 3%; if the hemorrhage is greater than 5 mL, the risk increases to 50% to 65%.

The maternal Rh antibody is slow to develop and initially may consist exclusively of IgM, which cannot cross the placenta because of its molecular size. This is followed by the production of IgG, which can cross the placenta into the fetal circulation. The maximum concentration of the IgG form of antibody occurs within 2 to 4 months after termination of the first sensitizing pregnancy (Hall, 2016). If initial immunization occurs shortly before or at the time of delivery, the first Rh-positive infant born to such a mother may trigger the initial antibody response, but the infant will not be affected. However, subsequent exposure to RBCs of Rh-positive fetuses produces a rapid antibody response that consists mostly of IgG. This response results in antibody attachment to antigen sites on the fetal RBCs of these fetuses. The antibody coating of the RBCs forms the basis for a positive result on the direct Coombs test. The affected RBCs undergo agglutination, phagocytosis, and eventually extravascular hemolysis in the spleen. The by-products of hemolysis, especially bilirubin, pass through the placenta into the maternal circulation to be metabolized and conjugated by the maternal liver. The rate of destruction of fetal RBCs depends on the amount of anti-D antibodies on the cells, the effectiveness of anti-D antibodies in promoting phagocytosis, and the capability of the spleen's reticuloendothelial system to remove antibody-coated cells.

Erythroblastosis Fetalis

Hemolysis in the fetus caused by Rh incompatibility results in the disease known as erythroblastosis fetalis (EBF); the major consequences are anemia and hyperbilirubinemia. The name is derived from the presence of immature circulating RBCs (erythroblasts), which are forced into the circulation of affected fetuses to compensate for rapid destruction of fetal blood cells. The severity of the disease depends on the degree of hemolysis and the ability of

the fetus's erythropoietic system to counteract the ensuing anemia. In an attempt to compensate for rapid destruction, the fetus continues to use extramedullary organs, such as the liver and spleen, which normally would have ceased RBC production after the seventh month of gestation.

Clinical Manifestations. The clinical manifestations of EBF are similar to those of ABO incompatibility but often are more intense (see Table 13.6). Jaundice results from an exaggerated rise in bilirubin, with the premature infant exhibiting an earlier rise and a more prolonged period of elevation. Hepatosplenomegaly may be found on physical examination, along with varying degrees of hydrops. Hydrops fetalis, a late sign, is a severe, total body edema often accompanied by ascites and pleural effusions. This is only seen in approximately 25% of infants affected. Although the pathogenesis is unclear, it is thought to be the result of congestive heart failure and intrauterine hypoxia from severe anemia, portal and umbilical venous hypertension caused by hepatic hematopoiesis, and low plasma colloid osmotic pressure induced by hypoalbuminemia. Low serum albumin levels are a consequence of altered hepatic synthesis, which may be due to local cellular necrosis and compromised intrahepatic circulation.

TABLE 13.6

CONTRAST BETWEEN RH AND ABO INCOMPATIBILITY

	Rh Incompatibility	ABO Incompatibility
Rh-negative mom	Yes	No
First pregnancy affected	Rarely	Often
Cord bilirubin elevated	Yes	Sometimes
Early anemia prominent	Yes	No
Jaundice in first 24 hours	Yes	Yes
Hepatosplenomegaly	Yes	Sometimes
Nucleated red blood cells	Very common	Quite common
Spherocytes	No	Yes
Reticulocytosis	Yes	Yes
Maternal antibodies	Yes	Not always
Direct Coombs test	Positive	Positive or negative
Indirect Coombs test	Negative	Positive

Source: Modified from Ohls, R. (2015). Anemia. In R. Polin & M. Yoder (Eds.), *Workbook in practical neonatology* (5th ed., pp. 107–136). Philadelphia, PA: Elsevier.

All these factors can lead to portal and venous hypertension and edema. The severity of the anemia and hypoalbuminemia affects the degree of extravasation of fluid into the tissue.

Altered hepatic synthesis can impair production of vitamin K and vitamin K–dependent clotting factors, which can lead to hemorrhage in these infants. Petechiae and prolonged bleeding from cord and blood sampling sites may be initial signs of clotting abnormalities. Transient hypoglycemia that occurs secondary to hyperplasia of the pancreatic islet cells is also associated with moderate to severe EBF. Products of RBC hemolysis are thought to inactivate circulating insulin, promoting increased insulin release and subsequent pancreatic beta-cell hyperplasia. Another theory suggests that potassium or amino acids released from hemolyzed cells may directly stimulate insulin production or indirectly produce this effect by increasing glucagon secretion. Approximately one third of surviving erythroblastotic infants have low blood glucose levels and elevated plasma insulin levels.

Antenatal Therapy. Adequate antenatal care is important in safeguarding the fetus that may be affected by EBF. Proper screening of any pregnant woman at her first prenatal visit is essential and should include blood type and Rh factor. If the mother is Rh negative, the father's blood type should also be ascertained. If the father is Rh positive, it is essential to determine Rh immunization of the mother by Coombs testing, specifically the indirect Coombs test. In addition to blood typing, a concise obstetrical history regarding any previous spontaneous or therapeutic abortions or delivery of an affected infant is important to ensure appropriate management of the current pregnancy.

Women who are sensitized require more surveillance throughout the pregnancy than their unsensitized counterparts, and women who have previously given birth to affected infants require the greatest degree of care. Serial maternal anti-D antibodies are monitored. If the titers reach a critical threshold (≥1:16) then the fetus is monitored closely for the development of fetal anemia. Monitoring includes Doppler studies of the middle cerebral artery and fetal imaging for signs of an enlarged placenta, hepatomegaly, and hydrops fetalis (Castro & Hobel, 2016). Evidence of fetal anemia will result in percutaneous umbilical blood sampling to assess fetal hemoglobin and Hct. Further management can include intrauterine or intraperitoneal transfusions, steroids to promote fetal lung maturity, monitoring of fetal well-being and growth, and assessing the need for an early delivery (Castro & Hobel, 2016).

Unsensitized Rh-negative mothers can benefit from antenatal and postpartum administration of RhIgG. Prophylactic RhIgG should be administered to all unsensitized Rh-negative mothers at 28 weeks' gestation. Mothers should receive a second dose of RhIgG within 72 hours following delivery if it is determined that the infant is Rh positive. The approach to RhIgG is based on the documented presence of fetal RBCs. The erythrocyte rosette screen detects the presence of fetal whole blood in the maternal circulation. A Kleihauer–Betke test should be performed following a positive rosette screen to determine the percentage of fetal RBCs present (ACOG Committee on Practice Bulletins—Obstetrics, 2017). With the use of RhIgG after delivery, the incidence of Rh immunization was dramatically reduced to 1% to 1.8%. Because sensitization was known to occur without evidence of TPH at the time of delivery, the question was raised whether antenatal sensitization occurred in response to frequent, small, and undetectable hemorrhage before or during labor. For this reason, antenatal administration of RhIgG was initiated to eliminate such cases of alloimmunization. Antenatal administration has further reduced the incidence to as low as 0.2% (ACOG Committee on Practice Bulletins—Obstetrics, 2017). However, sensitization during pregnancy may still occur in Rh-negative mothers. Reasons for this

can include ineffective dose of RhIgG or failure to provide RhIgG within 72 hours of a sensitizing event during pregnancy, failure to administer a prophylactic dose of RhIgG during the third trimester, or unrecognized, spontaneous TPH (Fyfe et al., 2014).

The manner in which RhIgG works to prevent sensitization of the D antigen is not fully understood. Two known effects of the anti-D antibody are that it prevents antigen-induced B lymphocyte antibody production in the mother, and it adheres to the D-antigen sites on the RBCs in the fetus that could cross the placenta and enter the maternal circulation, which then interferes with the immune response to the D antigen. Agglutination, hemolysis, and removal of these foreign RBCs occur before the maternal immune system can recognize the invasion and develop antibodies that would transplacentally cross into the fetus (Hall, 2016).

Potential obstetrical conditions occurring during the first or second trimester, which may require RhIgG prophylaxis because they can increase the risk of sensitization by increasing the chances of TPH, are as follows:

- Therapeutic or spontaneous abortion of any type; the incidence of TPH is higher with therapeutic abortion (three in 30 women may be sensitized)
- Any procedure that could cause TPH such as an amniocentesis, chorionic villus sampling, or percutaneous umbilical sampling (risk is low when performed by an experienced professional [Meleti et al., 2013])
- Ectopic pregnancies or hydatidiform moles
- Abdominal trauma
- Antepartum bleeding, as with placental abruption or placenta previa

Failure to administer RhIgG after such occurrences may leave these women at risk for sensitization. The ACOG (Committee on Practice Bulletins—Obstetrics, 2017) recommends a dose of 50 mcg for high-risk situations that arise before 12 weeks' gestation and 300 mcg after 12 weeks' gestation, with the 300-mcg dose repeated at 28 weeks' gestation. RhIgG has a half-life of 23 to 26 days and is effective for approximately 2 weeks after antigen exposure. It is essential to maintain an adequate level of anti-D antibodies throughout pregnancy to maintain protection, so if it is given prior to 28 weeks' gestation, it is advised to repeat it every 12 weeks until delivery (Mintz, 2010).

The timing of the dose after delivery is important; administration within 72 hours of delivery is recommended. The dose after delivery allows a maximum estimated fetal transfusion of 30 mL of whole blood or 15 mL of packed RBCs, which leaves 1% of postpartum mothers without full coverage. If massive TPH is suspected, the dose of RhIgG may need to be increased to provide adequate amounts of anti-D antibodies. After administration of RhIgG, the Kleihauer–Betke test can be performed on the mother's blood to check for RBCs with fetal hemoglobin and to help determine the need for additional RhIgG.

By reducing the incidence of EBF, there was at one time a fear of having a reduced supply of RhIgG, as there would be a reduced number of available immunized donors. While there are still women who have had their children and ask to be sensitized to help others, the majority of donors now are male who have been DNA typed to the RBCs that are used to sensitize them. DNA typing prevents the donors from developing anti-C, Kell, and other antibodies. A monoclonal antibody was developed, but it did not have the same success rates as the polyclonal antibodies in the market.

Treatment. On delivery of an infant with EBF, assessment of the newborn's cardiorespiratory status is of utmost importance. Because of ascites, pleural effusions, and circulatory collapse, these infants often require stabilization of the airway by intubation and mechanical ventilation. If peritoneal or pleural fluid prevents adequate chest excursion, paracentesis may be required to remove fluid from the abdominal cavity, or thoracentesis may be needed to drain excess pleural fluid.

Delivery of an infant shortly after intraperitoneal transfusion may not allow adequate time for absorption of blood from the peritoneal cavity because the rate of absorption is variable, especially if the infant is hydropic (Castro & Hobel, 2016). The unabsorbed portion could lead to diminished lung expansion, resulting in respiratory failure or restricted mechanical ventilation. Such infants may require paracentesis for removal of blood from the peritoneal cavity.

After initiation of respiratory support, the infant should be assessed for adequacy of circulating blood volume. If the infant is severely hydropic, the inevitable anemia must be corrected with transfusions of packed RBCs, since an exchange transfusion may not be tolerated until the intravascular RBC volume is replenished. Transfusion is accomplished with O-negative or type-specific Rh-negative blood cross-matched against maternal blood. Initial use of a single-volume or partial exchange may offer a degree of cardiovascular stability before a double-volume exchange is attempted. Congestive heart failure, not present at the time of intravascular volume depletion, may become apparent as the infant is transfused. At times, a severely affected infant, while often normovolemic, may benefit from inotropic support and diuretic therapy to improve cardiac output.

Prenatal damage to the liver can adversely affect the production of coagulation factors in such infants, making them prone to bleeding disorders. Hepatic damage can intensify any hyperbilirubinemia present, because the hepatic substances required for conjugation may also be impaired. Laboratory evaluation of the infant affected by EBF should consist of liver function studies, Hct determinations, and evaluation of coagulation status.

Nursing care of the infant affected by EBF involves scrupulous attention to the infant's cardiorespiratory status and vital signs. The infant needs to be positioned so as to reduce abdominal pressure on the diaphragm which will permit better chest expansion. Maintaining a normal Pao_2 and avoiding overventilation may prevent barotrauma to lungs already compromised by pleural effusions. The lungs may be hypoplastic if their growth has been sufficiently compromised by hydrops in-utero, making ventilation difficult and predisposing the infant to extraventilatory air. Vital signs are usually assessed every hour until the infant's condition has stabilized. Hct and bilirubin levels should be checked frequently during the first few hours and days of life to maintain adequate circulating blood volumes and to prevent toxic levels of bilirubin by timely initiation of therapy. If the cord bilirubin levels are significantly elevated, exchange transfusion may be necessary shortly after birth. A newer therapy that has been proven to be safe and effective is the administration of intravenous immunoglobulin (IVIG) to the neonate with hemolytic disease that has a rapidly rising serum bilirubin level despite intense phototherapy (Maisels et al., 2004). **Emergency Alert: Bilirubin neurotoxicity and, ultimately, kernicterus remain a serious complication of hyperbilirubinemia. It is critical that neonatal nurses remain hypervigilant in their assessment of an infant with elevated bilirubin, especially when the total serum bilirubin (TSB) is greater than 20 mg/dL.**

If bilirubin levels do not require immediate exchange, blood levels should be checked every 4 to 8 hours, depending on the initial cord-blood levels and subsequent rate of rise. In Rh incompatibility, exchange is imminent if the rate of rise exceeds 1 mg/hour for the first 6 hours of life. The interval of blood sampling for bilirubin may be increased to 6 to 12 hours after the first 48 hours of life.

The major therapies used to control excessive unconjugated bilirubin levels are similar for all problems resulting in elevated unconjugated bilirubin levels. Phototherapy and exchange transfusion, the most frequently used therapies, are discussed later in the chapter.

Analysis of Laboratory Data. The following laboratory data can be helpful in the diagnosis and treatment of EBF.

- The mother's and infant's blood and Rh types
- Coombs reactivity: The infant's RBCs are coated with anti-D antibodies, resulting in a positive direct Coombs test result; on occasion, the heavy coating of neonatal RBCs with antibody can lead to a false Rh typing (Rh negative); if the direct Coombs test result is positive, the infant should be considered Rh positive.
- The infant's Hct, reticulocyte count, and RBC morphologic characteristics: The presence of immature cells or spherocytes helps distinguish Rh incompatibility from ABO incompatibility.
- Plasma bilirubin levels: The initial cord-blood bilirubin level and the rate of rise determine the appropriate timing of any exchange transfusion needed to control bilirubin levels. Cord bilirubin levels are closely associated with the severity of the disease and the mortality rate.

BILIRUBIN METABOLISM AND HYPERBILIRUBINEMIA

Bilirubin production begins as early as 12 weeks' gestation. It is the primary degradation product of hemoglobin, although 20% to 30% is derived from nonerythroid sources such as tissue heme. Bilirubin is produced after completion of the natural life span of the RBC, but ineffective erythropoiesis or premature destruction of blood cells can increase its production. In RBC destruction, the aging or hemolyzed RBC membrane ruptures, releasing hemoglobin that is phagocytized by macrophages. The hemoglobin molecule then splits into a heme portion and a globin portion. Bilirubin is derived from the degradation of the heme ring in the heme portion that is catalyzed by heme oxygenase. The ferric heme breaks down to the ferrous form and then is cleaved to form carbon monoxide and biliverdin. Biliverdin is further reduced by the enzyme biliverdin reductase to form bilirubin, and carbon monoxide joins with heme to form carboxyhemoglobin.

The four forms of circulating bilirubin are (1) conjugated (water-soluble) bilirubin (which is excretable through the kidneys and intestines), (2) conjugated covalently bound bilirubin (which is attached to serum albumin and not found in neonates younger than 2 weeks of age), (3) unconjugated (insoluble in water) bilirubin (which is reversibly bound to albumin), and (4) free bilirubin (which is unconjugated and unbound). The measurement of conjugated (direct) bilirubin identifies the amount of bilirubin that reacts directly with van den Bergh's reagent. The portion of bilirubin reversibly bound to albumin is lipid soluble. It does not react with van den Bergh's reagent until it is combined with alcohol, hence the term *unconjugated (indirect) bilirubin*. Free bilirubin is not attached to albumin and can easily cross the blood–brain barrier, causing the damage seen in kernicterus. Measurements of conjugated and unconjugated bilirubin are important in the evaluation of the hyperbilirubinemic infant and provide valuable information for the diagnosis and method of treatment (Downs & Gourley, 2015).

Although bilirubin is found in stool and amniotic fluid, the major route of elimination in the fetus is through the placenta. For this reason, bilirubin must be retained in the unconjugated form to allow its passage into the maternal circulation. Consequently, the enzyme systems found in the fetus enhance the retention of bilirubin in the unconjugated form. Persistence of some of these fetal mechanisms during the newborn period can contribute to jaundice. Plasma concentrations of bilirubin are usually low in the fetus, except in cases of severe hemolytic disease. All bilirubin in the cord blood of the fetus is the unconjugated variety, which is effectively metabolized, conjugated, and excreted by the maternal liver and gallbladder. The mean cord-blood bilirubin concentration in an infant unaffected by hemolytic disease is 1.8 mg/dL, regardless of the infant's gestational age or weight.

In the newborn, the major routes of bilirubin excretion are through the intestine and the kidneys. As the production of bilirubin exceeds the newborn liver's capacity to conjugate and eliminate it, plasma levels begin to rise rapidly. Jaundice becomes noticeable when the serum concentration reaches three times the amount normally present in the serum. The conjunctivae become visibly jaundiced at serum levels exceeding 2.5 mg/dL. In the full-term infant, jaundice usually becomes apparent within 2 to 4 days after birth and lasts until the sixth day, reaching a peak concentration of 6 to 7 mg/dL. Although infants born at 37 weeks' gestation or later are considered term, they are more likely to reach or exceed serum bilirubin levels of 13 mg/dL or higher than are infants born at 40 weeks' gestation. The preterm infant has cord-blood bilirubin levels similar to those of the term infant, but peak levels are higher, jaundice lasts longer, and levels peak later, at 5 to 7 days. Among preterm infants, 63% reach levels of 10 to 19 mg/dL, and 22% reach levels above 15 mg/dL.

Although the neonatal liver's conjugating mechanisms are reduced during the first few days of life, the liver is able to metabolize and excrete two thirds to three quarters of the bilirubin circulating throughout the body. Initially, bilirubin is transported in the plasma, bound to albumin at two sites—a primary binding site that has a strong bond and a secondary site that has a weak bond. When available albumin binding sites are saturated, bilirubin circulates freely in the plasma. It is this portion of unconjugated bilirubin that can migrate into brain cells, causing damage known as kernicterus. The occurrence of kernicterus is related to the amount of diffusible, loosely bound bilirubin, and the availability of albumin binding sites (Downs & Gourley, 2015).

When bilirubin reaches the liver, it is transferred from plasma albumin, across the cell membrane of the liver, and into the liver cell. Two proteins, Y and Z, also called ligands, affect bilirubin transfer from plasma to the liver. Here the bilirubin is either stored in the cell cytoplasm or removed from the ligands and conjugated in the hepatic endoplasmic reticulum. Conjugation is essential for the excretion of bilirubin into bile. Eighty percent of bilirubin is conjugated with glucuronic acid, becoming bilirubin glucuronide. Glucuronosyltransferase is the important hepatic enzyme required for the production of bilirubin glucuronide. Ninety-five percent of bilirubin glucuronide is excreted into bile and subsequently into the intestine.

Effective excretion of bilirubin from the intestine depends on the length of time needed for the passage of stool and on the presence of substances that break down conjugated bilirubin. The newborn may have diminished bowel motility and delayed meconium passage, which allow longer exposure of stool to bilirubin glucuronidase, the enzyme responsible for breaking down conjugated bilirubin. The action of this enzyme, in conjunction with the newborn's lack of the intestinal flora required to reduce bilirubin to urobilinogen, converts the conjugated form to the unconjugated form, which is then reabsorbed by the intestine and enters the enterohepatic circulation where it returns to the liver for conjugation (Downs & Gourley, 2015).

Kernicterus

Kernicterus is a chronic and preventable form of acute bilirubin encephalopathy. The exact incidence of kernicterus is unknown. It is estimated to occur in 0.4 to 2.7 cases per 100,000 live births (Watchko & Tiribelli, 2013). There are conflicting reports as to whether there is a resurgence in the occurrence of kernicterus (Kaplan, Bromiker, & Hammerman, 2011). Kernicterus continues to occur and remains a serious complication of hyperbilirubinemia. Potential causes include a lack of systematic bilirubin screening and adherence to recommended guidelines especially for early discharges, home births and births at a non-hospital birthing center, breastfeeding, unrecognized hemolysis, and genetic influences (Christensen et al., 2012). The guidelines from the AAP Provisional Committee for Quality Improvement & Subcommittee on Hyperbilirubinemia (Maisels et al., 2004), updated in 2009 (Maisels et al., 2009), clearly state that newborn infants should have their bilirubin levels screened and assessment of risk factors done prior to hospital discharge and again within 48 to 72 hours after discharge. Systematic screening guidelines have been found to significantly decrease the incidence of kernicterus (Christensen et al., 2012).

Kernicterus occurs when the albumin binding sites are filled, allowing increased amounts of free bilirubin to pass into the central nervous system (CNS). Free bilirubin easily crosses the blood–brain barrier and is transferred into the brain cells, causing obvious yellow staining of the brain tissue (kernicterus) that is similar to the effect on the skin. The areas of the brain usually affected by the staining are the basal ganglia, hippocampus, dentate nucleus, substantia nigra, cerebellum, and nuclei of the floor of the fourth ventricle (Downs & Gourley, 2015). Kernicterus is associated with varying degrees of neurologic damage, but a direct correlation cannot be drawn between serum total bilirubin levels and the severity of involvement. While numerous risk factors play a role, the risk for kernicterus increases as serum total bilirubin rises above 20 mg/dL, with the highest risk associated with serum levels above 30 mg/dL. The development of kernicterus and the subsequent neurologic sequelae may be a reflection of the imbalance among rate of bilirubin production, binding, conjugation, and elimination (Kaplan, Wong, Sibley, & Stevenson, 2015; Shapiro, 2012). The available evidence suggests that measuring unbound bilirubin, bilirubin–albumin binding capacity, and bilirubin–albumin ratios, rather than serum total bilirubin concentrations, are better correlated with the appearance of subsequent CNS abnormalities. However, prospective studies are needed to include these measures as a part of standard clinical practice (Hulzebos & Dijk, 2014; Kaplan et al., 2015; Morioka, Iwatani, Koda, Iijima, & Nakamura, 2015).

Many factors can influence bilirubin binding to albumin and increase the risk of kernicterus at lower bilirubin levels, including the following:

- The total amount of available serum albumin: Premature infants normally experience a relative hypoproteinemia and have fewer albumin binding sites available for free bilirubin.
- The presence of other substances competing for available binding sites: Certain drugs (e.g., sulfonamides, cephalosporins, penicillins, salicylates, sodium benzoate) compete with bilirubin for binding sites or displace bilirubin loosely attached to binding sites. Of note, ibuprofen was found to displace bilirubin, raising unbound levels during in-vitro studies. However, ibuprofen was not found to increase unbound bilirubin levels during in-vivo studies (Morioka et al., 2015).
- Acidosis and hypoxia: Increased production of hydrogen ions and implementation of anaerobic metabolism can impede bilirubin binding. Albumin's ability to bind bilirubin drops to half its potential at a serum pH of 7.1, with free fatty acids produced during anaerobic metabolism competing for albumin binding sites. The simultaneous presence of acidosis and hypoxia, which can open the blood–brain barrier, can expose a sick infant to the development of kernicterus at much lower serum bilirubin levels.

Clinical Manifestations. Kernicterus initially presents during the first few days of life as acute bilirubin encephalopathy. Signs of acute encephalopathy include lethargy or irritability and poor eating. As the encephalopathy progresses, alterations in muscle tone may manifest as hypertonia and hypotonia, a high-pitched cry develops, and further signs include paralysis of upward gaze, opisthotonic posturing, and spasticity. In its chronic and irreversible form, permanent signs of kernicterus include auditory processing disturbance with or without deafness, continued paralysis of upward gaze, choreoathetoid cerebral palsy, and tooth enamel abnormalities (Kaplan et al., 2011). Preventing elevated levels of free bilirubin is the primary means of eliminating kernicterus. Prevention may require phototherapy for slowly rising levels but almost certainly demands exchange transfusion if the rise is rapid and marked.

Nonimmune Causes of Hyperbilirubinemia

The presence of jaundice during the first 24 hours of life or bilirubin levels that are excessive based on the infant's age are not considered physiologic and require further investigation (Kaplan et al., 2015). Many conditions other than blood group incompatibilities can cause jaundice in the newborn. Most of the commonly seen disorders result in elevated levels of unconjugated rather than conjugated bilirubin. These pathologic conditions can be classified as (a) those that cause increased breakdown of RBCs (e.g., sepsis, drug reactions, and extravascular blood); (b) those that interfere with bilirubin conjugation (e.g., breast milk jaundice, drug interactions, hypothyroidism, acidosis, and hypoxia); and (c) those that cause abnormal bilirubin excretion (e.g., hypoxia or asphyxia, bowel obstruction, ileus, and congestive heart failure). The single factor most implicated in hyperbilirubinemia is prematurity, with the severity of jaundice directly correlated to declining gestational age. The premature infant is thought to be subject to a combination of increased RBC breakdown secondary to reduced RBC life span and impaired bilirubin conjugation as a result of liver immaturity (Blackburn, 2017).

Increased Red Blood Cell Breakdown

Several problems that arise in the perinatal period are associated with excessive and premature destruction of the RBCs by hemolysis. Neonatal bacterial and viral infections and intrauterine viral infections, especially those of the TORCH complex (toxoplasmosis, other agents, rubella, CMV, and herpes simplex), have been implicated in the hemolytic destruction of RBCs. Certain medications, such as the synthetic analogues of vitamin K or large doses of natural vitamin K, also induce RBC destruction. Other conditions prevalent in the premature and term newborn can result in the extravasation of large amounts of blood (e.g., cephalohematoma and pulmonary or intracerebral hemorrhages). These extravascular collections of blood cells must undergo hemolysis to be reabsorbed by the body. Significant hemolysis, regardless of the cause, increases the bilirubin load on a metabolically immature neonatal liver. This increased load often results in hyperbilirubinemia in the newborn.

Interference With Bilirubin Conjugation

Breast Milk Jaundice. Breast milk jaundice affects a small percentage of all breastfed babies and can be divided into two types, breastfeeding jaundice and breast milk jaundice, each with a different time of onset and a different underlying cause. However, overlap may occur between the two types. In breastfeeding jaundice, the infant is affected within the first few days of life. The etiology of this condition is not fully understood, but is thought to be due to a combination of maternal and infant factors that lead to diminished fluid intake and dehydration in the infant. Predisposing maternal factors include limited maternal milk supply, engorgement, cracked nipples, poor feeding technique, and maternal illness or fatigue. Neonatal factors include poor suck, illness, lethargy that accompanies hyperbilirubinemia, and dehydration. Poor intake leads to poor stool output and increased enterohepatic resorption of unconjugated bilirubin. The recommended treatment is phototherapy and alleviation of dehydration. Frequent breastfeeding with avoidance of supplementation, lactation counseling, and monitoring of weight gain and stool output are advised.
