The Center for Behavioral Health Statistics and Quality (CBHSQ) estimated that in 2015, 27 million people were abusing illicit or prescription drugs. As in previous opiate epidemics, women of childbearing age were not immune to the problem. For women of childbearing age (ages 15–44), the CBHSQ (2016) reported that heroin use increased by 31% from 2011–2012 to 2013–2014 and that there was a 5.3% increase in the number of women who reported OxyContin misuse during the same time periods.

HISTORY AND EPIDEMIOLOGY OF NEONATAL ABSTINENCE SYNDROME

A consequence of the opiate epidemic is the exposure of the fetus in-utero to opiates, which results in neonates withdrawing from the substance after birth. This is referred to as neonatal abstinence syndrome or NAS, which is not a new phenomenon. The term NAS was first coined by Dr. Loretta Finnegan and her colleagues in the early 1970s to describe neonates they were caring for who were withdrawing from heroin and other opiates, but the term now includes neonates withdrawing from other substances as well. However, this was not the first description in medical literature of neonates withdrawing from substances.

The first descriptions of this phenomenon appeared in medical publications as early as 1875 under the term *congenital morphinism* (Perlstein, 1947). With the morphine epidemic described earlier, there were documented cases of neonates dying several days after birth, even though they appeared normal at birth. The case reports described neonates displaying the signs of what we today call NAS.

As the opioid epidemic increased in the early 2000s, NICUs and special care units (SCNs) began to see an explosion of neonates being admitted for NAS. In a first-of-its-kind article on the epidemic of NAS, Patrick et al. (2012) did a retrospective, cross-sectional analysis of data from the Centers for Medicare and Medicaid (CMS) of neonates diagnosed with NAS from 2000 to 2009 in the United States, to determine the prevalence of NAS. The investigators found that the number of neonates experiencing NAS increased from approximately 1.3 per 1,000 births in 2000 to approximately 3.4 per 1,000 births in 2009. The number of neonates tripled in 9 years from approximately 4,000 to approximately 13,539 neonates or approximately one neonate being born every hour with NAS (Patrick et al., 2012).

A follow-up study by Patrick, Davis, Lehmann, and Cooper (2015) revealed that the numbers of babies being diagnosed with NAS continued to increase from 2009 to 2012. In the 2015 study, the investigators also looked at the regional prevalence of NAS and found that it varied from 2.6 per 1,000 births to 16.2 per 1,000 births based on geographical location. The overall incidence of NAS in 2012 was 5.8 per 1,000 births, equivalent to 21,732 births or one baby born every 25 minutes. Most recently, Winkelman, Villapiano, Kozhimannil, Davis, and Patrick (2018) reported that in 2014 the overall incidence of NAS in the United States was 14.4 per 1,000 births or one baby being born every 15 minutes.

As the number of babies being diagnosed with NAS increased, mother/baby units were not equipped to care for the withdrawing infant, so the majority of the neonates affected were transferred to NICUs and SCNs to be observed and treated. Tolia et al. (2015) reported that the number of NICU admissions increased from seven per 1,000 admissions in 2004 to 27 per 1,000 admissions in 2013, putting a strain on NICUs and SCNs around the country by taking up valuable bed space and utilizing resources designed for ill neonates, neonates with congenital defects, and premature infants.

The increasing numbers of neonates with NAS that are being born in the United States has put a strain not only on hospitals, but also on the healthcare system. In 2014, approximately 82% of all neonates with NAS were covered by Medicaid, up from 73.7% a decade earlier in 2004. Neonates with an NAS diagnosis that were Medicaid recipients had longer hospital stays than neonates with NAS that were covered by private insurance and neonates covered by Medicaid who did not have NAS. As a result of the increasing number of Medicaid-covered neonates, hospital costs increased from $65.4 million to $462 million during the 10-year period from 2004 to 2014, putting a strain on many systems (Winkelman et al., 2018).

DIAGNOSIS

Diagnosis of NAS begins with a thorough checking of maternal history of any substance usage during the pregnancy. A policy of universal screening for all pregnant women should be in place in physician offices, hospitals, and birthing centers, as substance abuse occurs across all socio-economic classes. Many confuse screening with testing pregnant women for a substance abuse problem and believe the terms are interchangeable, which they are not. Screening is different from testing, as it consists of interviewing pregnant women for use of both legal and illicit substances, while testing involves checking for presence or absence of substances in biological fluids.

Maternal Screening

When screening the pregnant woman, the interview should be done in a nonjudgmental manner and in a private setting, away from family members and friends. This is done as many family members and friends may be unaware of a woman's substance usage or may not want the woman to divulge this information for fear of consequences. The interview questions should include the use of five types of substances: (1) prescription drugs; (2) over-the-counter drugs; (3) nutritional supplements, including herbal medications; (4) legal substances, such as alcohol, nicotine, and caffeine; and (5) illicit/illegal drugs. In addition to the type of substance/drug used, the length of use, the amount used, the method of use, the context of use, and any history of drug treatment is essential. For women who do not admit to drug use, a history of drug habits of family members and friends should be obtained, as often a woman may admit to a family member's use/abuse, but not to her own abuse.

There are many tools available to assist with screening patients with substance use disorders such as the Alcohol Use Disorders Intervention Test-C, (AUDIT-C), National Institute on Drug Abuse (NIDA) Drug Use Screening Tool and Quick Screen, Opioid Risk Tool, Screening to Brief Intervention (S2BI), Brief Screener for Alcohol, Tobacco, and other Drugs (BSTAD), CAGE, and the Car, Relax, Forget, Friends, Trouble (CRAFFT). The BSTAD, CRAFFT, and S2BI are designed specifically for adolescents and the remaining tools are designed for adults, though the NIDA test does have an adaptation for adolescents (NIDA, 2018). The choice of the correct tool is based on the age of the clientele and what the clinician needs to assess. Regardless of the tool chosen, it is important to use an evidence-based and validated tool, which all of the previously noted items are, and to ask the questions in a nonjudgmental manner and environment.

One method to assist with obtaining information from a client is motivational interviewing (MI). MI was developed in the 1980s by Miller and Rollnick based on the work by Carl Rogers as a way to elicit information from a client and to begin the change process (Substance Abuse and Mental Health Services Administration-Health Resources and Services Administration [SAMHSA-HRSA] Center for Integrated Health Solutions, n.d.). MI utilizes the four principles of expressing empathy and avoiding arguing, developing discrepancy, rolling with resistance, and supporting self-efficacy. For the interviewer to be successful in using the MI technique he or she must listen more than talk, be sensitive and open to the person's issue, invite the person to be open and to discuss and explore ideas of change, encourage the person to discuss reasons not to change, ask for permission to give his or her feedback, reassure the mother that ambivalence to change is normal, help the mother identify successes and challenges, seek to understand the person, summarize what he or she is hearing, value the person's opinion, and remind oneself that the person is capable of making her own choices (SAMHSA-HRSA Center for Integrated Health Solutions, n.d.).

Maternal Testing

Urine drug testing can be ordered to help with the detection of a substance abuse disorder. Maternal urine toxicology is easy to obtain, but is not always accurate. Women with substance use disorder have a fear of losing their babies and will go to great lengths to hide their substance use. The half-life of substances of abuse varies, so depending on the timing of the urine drug test, the urine may or may not be positive. Women with substance abuse disorder also know methods to ensure that the urine drug test has a false negative. A quick search online will show novel ways to pass a urine drug test, ranging from devices that could be used,

information on how long substances are detectable, and how to clear the urine of substances. For these reasons, the maternal urine drug test could be negative, even though there is a substance abuse disorder. In addition, it is important to remember that maternal drug testing has legal implications if not all pregnant women admitted to a hospital or in a medical practice are tested, as it could be considered profiling. Because of the legal issues to testing only certain individuals, many medical practices and hospitals are adopting universal drug testing protocols for all pregnant women.

Neonatal Testing

When a baby is symptomatic of NAS or there are indicators that the mother is abusing substances, laboratory tests can be ordered to help with diagnosis of NAS. Toxicology tests can be performed on neonatal urine, hair, meconium, or the umbilical cord. Each of these tests has their pros and cons related to their use, as well as legal implications. Neonatal urine toxicology is the easiest to obtain, but is not always accurate. Neonatal urine has several limitations, some of which are: (1) only recent drug use can be detected, so if the first urine is not caught, the test may be negative, (2) if the mother is an infrequent user, the drug test may be negative, or (3) if the mother has not used in the week prior to delivery of the infant, the test may be negative depending on the drug abused and its half-life (Hudak & Tan, 2012; Kocherlakota, 2014; Kwong & Ryan, 1997; Ostrea, Chavez, & Strauss, 1976; Sutter, Leeman, & Hsi, 2014). If the urine drug test is positive, it is important to review the mother's medication record during delivery, as narcotics given to the mother during labor will show up in the neonate's urine.

Hair testing for drug use is more accurate than urine drug testing as it can detect in-utero drug usage for the last 3 to 4 months of pregnancy (Kwong & Ryan, 1997; Ostrea et al., 1976; Vinner et al., 2003). Hair testing is rarely used in the neonatal population as most newborns do not have the quantity of hair needed to perform the test and for those who do, the mothers object to their newborns' hair being shaved (Kwong & Ryan, 1997).

Meconium analysis is the most common form of drug testing in the neonate and is considered the gold standard. Meconium analysis detects in-utero drug usage for the last two trimesters of pregnancy (Kocherlakota, 2014; Ostrea et al., 1976). Unfortunately meconium is not always properly collected and stored in many units, leading to false negative results. For meconium to be accurate, the entire column of meconium must be collected and stored in a specimen cup. Substance metabolites in meconium are stable for 2 weeks at room temperature but storing it in a refrigerator is preferable. When adding meconium to the specimen cup, the new meconium sample needs to be mixed with the existing sample to ensure that the metabolites are well distributed when the lab takes only one small sample for testing. **Quality and Safety: When the entire column of meconium has been passed and collected, the specimen is sent to the lab to be tested. The lab will only take a small sample (2–5 g) to be tested, which is why it is important to mix all the meconium as it is added to the specimen cup.** While meconium is more accurate, it has its limitations. As stated before, if it is not collected correctly, false negatives will occur. Second, if the baby is not suspected of being exposed in-utero, not all of the meconium will be able to be collected. Thirdly, a specimen can be negative even if the mother abused drugs during pregnancy, depending on when and how often the mother abused drugs (Kocherlakota, 2014). Finally, in the case of babies that room-in with their mothers, meconium samples can be missed as the parents will throw the diapers away.

Umbilical cord testing for drug exposure in-utero is a newer method of testing for maternal drug usage. Like hair and meconium, the umbilical cord test is highly reliable and can detect the last 4 to 5 months of maternal drug usage (United States Drug Testing Laboratories [USDTL], n.d.). The advantage of the use of the umbilical cord is the initial availability and ease of collection. A 6-inch segment of cord is obtained at birth, drained of blood, cleansed per company protocol, labeled, sealed, and stored. The cord can be stored for a week at room temperature, refrigerated for up to 3 months, or frozen for up to 1 year (USDTL, n.d.), so if a baby starts to show signs of withdrawal, the cord can be sent at that time. The disadvantage is that if the cord is not obtained at the time of birth, then it cannot be used.

Quality and Safety: It is important to remember that no matter what type of specimen testing is done on a neonate, the appropriate chain of custody is maintained during the collection, labeling, and transport of the specimen from the unit to the laboratory. This is important for legal purposes.

Signs of NAS

Of neonates exposed to substances in-utero, approximately 55% to 96% will display signs of withdrawal (Hudak & Tan, 2012). For the majority of neonates, the onset of the acute signs of NAS can range from 12 to 96 hours after birth, though there are some cases reported of neonates beginning withdrawal only 7 days after birth. The wide range of time for withdrawal is related to the substance used, the timing of the last dose, maternal metabolism, the placental transport of the medication, as well as the neonatal gestation, metabolism, and excretion. The central and autonomic nervous systems, the gastrointestinal system, and/or the respiratory system can be involved in the withdrawal process (Finnegan & MacNew, 1974; Hudak & Tan, 2012). Table 30.1 outlines the most commonly seen signs of withdrawal in the neonate.

Not every neonate exposed to substances in-utero will show signs of withdrawal. It has been well established that term neonates experience more significant withdrawal than preterm neonates, likely due to less exposure and a more immature nervous system (Hudak & Tan, 2012; Liu, Jones, Murray, Cook, & Nanan, 2010). But other differences in withdrawal have been noted between males and females, between the type of substance exposure in-utero, and more recently the finding of genetic polymorphisms. Studies are just beginning to be published on these differences. In a recent retrospective cohort study published in 2017, Charles et al. demonstrated that male neonates were more likely than female

TABLE 30.1

WITHDRAWAL SIGNS OF NEONATAL ABSTINENCE SYNDROME

Central nervous system	High-pitched continuous crying, irritability, tremors, hyperactive Moro reflex, sleep disturbances, increased muscle tone, skin excoriation, myoclonic jerking, and seizures
Autonomic nervous system	Fever, diaphoresis, mottling, sweating, and yawning
Gastrointestinal system	Excessive sucking, poor feeding, regurgitation, vomiting, and loose or watery stools
Respiratory system	Tachypnea with or without retractions, sneezing, nasal flaring, nasal stuffiness

neonates to be diagnosed with NAS and require treatment, though the severity of NAS was not affected by gender. Huybrechts et al. (2017) found in an observational cohort study that neonates exposed to antidepressants, benzodiazepines, and gabapentin had a 30% to 60% increase of NAS when compared to those infants that were not exposed.

A newer area of study in both addiction medicine and the study of NAS is the role of genetics. In adults, single nucleotide polymorphism (SNP) in the mu-opioid receptor (*OPRM1*), catechol-*o*-methyltransferase (*COMT*), and multidrug resistance (*ABCB1*) genes are associated with the risk of addiction (Wachman, Hayes, & Brown, 2013). The authors did a multicenter prospective cohort study looking at DNA samples for variants in the SNPs of the *OPRM1*, *COMT*, and *ABCB1* genes of babies diagnosed with NAS. The results were that neonates with variants in the SNP of the *OPRM1* and *COMT* genes had significantly shorter lengths of hospital stay and a decreased need for medication therapy than those infants without. The *ABCB1* SNP did not make a difference in the length of stay or medication therapy (Wachman et al., 2013). In another study, Mactier, McLaughlin, Gillis, and Osseton (2017) looked for variations in neonate genotype of the *OPRM1*, *ABCB1*, *COMT*, *CYP2B6*, and *CYP2D6* genes as an explanation for the variation in the presentation of neonates whose mothers were maintained on methadone during pregnancy. The authors demonstrated that neonates treated for NAS were more likely to carry the homozygous allele of the *CYP2B6* gene. This new information on how genes can influence NAS could lead to more tailored approaches in caring for the NAS neonate in the near future.

With the increasing incidences of NAS, it is easy to forget that the signs of NAS are somewhat generalized and that other disease processes have similar signs. **Emergency Alert: Sepsis, hypoglycemia, and hypocalcemia have similar signs in newborns, so it is of utmost importance to rule these out before assuming that a neonate has NAS.**

Tools for Assessing Signs of NAS

Several tools have been designed over the years to help quantify the onset and progression of signs of NAS, as well as to judge the effectiveness of both nonpharmacological and pharmacological treatment. The most commonly used tool is the Finnegan Neonatal Abstinence Scoring System (FNASS), more commonly referred to as the Finnegan (Bagley, Wachman, Holland, & Brogly, 2014; Gomez-Pomar & Finnegan, 2018). The development of multiple tools over the years demonstrates the lack of agreement on how to best assess NAS. The majority of tools have been validated for interrater reliability and sensitivity to diagnosing NAS. Due to the subjective nature of the tools, especially the FNASS, it is essential for nurses to be trained on how to properly use a tool. One method for maintaining reliability in a nurse's assessment is to have nurses do dual scoring of an infant at least two times per day, which helps to maintain interrater reliability.

The tools range from the FNASS, which assesses for 21 different neurological, autonomic, gastrointestinal, respiratory, and other signs to determine if a neonate is withdrawing, to a relatively simple newer tool called ESC that looks at three items to determine treatment for withdrawal—Is the baby eating at least 1 oz or breastfeeding well? Is the baby sleeping greater than or equal to 1 hour and can the baby be consoled within 10 minutes? (Finnegan, Cron, Connaughton, & Emich, 1975; Grossman, Lipshaw, Osborn, & Berkwitt, 2018). Table 30.2 compares the published tools for assessing NAS. Studies looking at novel ways such as maternal vagal tone, fetal heart rate, skin conductance of the neonate, and brain-derived neurotropic factor levels within 48 hours of NICU admission have been done to assess and diagnose NAS, but at this point these are not widely used (Wachman, Schiff, & Silverstein, 2018).

MANAGEMENT

Once the infant is diagnosed with NAS, management focuses on the prevention or worsening of withdrawal signs and the provision of comfort for the neonate. Both nonpharmacological and pharmacological treatment options are available to manage the neonate with NAS. As more research becomes available on the detrimental effects of opioids and other medications on the developing newborn brain, the trend for treatment of babies with NAS is to do as much nonpharmacological treatment as possible before beginning pharmacological treatment.

Nonpharmacological

Initially nonpharmacological interventions such as low lighting and noise levels, skin-to-skin care by the mother, as well as swaddling and holding the baby are utilized to help control the symptoms and provide comfort to the infant experiencing NAS. Studies on nonpharmacological interventions have been done, and many of the interventions such as breastfeeding and rooming-in demonstrate a decreased length of hospital stay and symptoms of NAS, but it is important to remember that the studies are usually small with low-quality evidence (Wachman et al., 2018). Box 30.1 has a list of nonpharmacological interventions that have been published that are currently being used to help the NAS neonate.

The method of feeding and type of feeding that the neonate receives has been shown to help alleviate the symptoms of NAS and is considered a nonpharmacological intervention. Research has demonstrated that breastfeeding can decrease the severity of symptoms of NAS and shorten the length of pharmacological treatment and hospital stay. Breastfeeding, which is the optimal source of nutrition for all newborns, is recommended by the American Academy of Pediatrics (AAP) for newborns of mothers in methadone or buprenorphine treatment programs (Hudak & Tan, 2012). Studies have shown that breastfeeding increases maternal attachment and compliance in drug treatment programs, while it decreases the symptoms of NAS and the length of hospital stay for infants with NAS (McQueen, Murphy-Oikonen, Gerlach, & Montelpare, 2011; Pritham, Paul, & Hayes, 2012; Short, Gannon, & Abatemarco, 2016). However, breastfeeding rates among this group of women are low. Wachman, Byun, and Philipp (2010) found that of the 68% of women in a methadone treatment program who qualified for breastfeeding, only 24% breastfed their infants to some extent during hospitalization and 60% discontinued in an average of 5.88 days. Reasons given for less breastfeeding among women in methadone treatment programs include: (1) the lack of clear, consistent guidelines for breastfeeding mothers, (2) inconsistent advice from healthcare providers, (3) infant feeding problems due to drug withdrawal, (4) separation of the mother–infant dyad because of hospitalization, (5) mother's low self-esteem, lack of knowledge, feelings of guilt, and (6) inadequate support from healthcare providers (Jansson, Choo, Velez, Lowe, & Huestis, 2008; McQueen et al., 2011). Another factor that can affect a woman with a substance abuse disorder and her ability to breastfeed is her past history with sexual abuse. While breastfeeding is often perceived as a pleasurable experience for women, for those with a history of sexual abuse as a child, an adult, or during the pregnancy, negative feelings and reflections of the past abuse can arise and deter breastfeeding (Jansson, Velez, & Butz, 2017).

The advantages of breastfeeding (i.e., better mother–infant bonding, fewer withdrawal symptoms, and a shorter length of

TABLE 30.2

COMPARISON OF NEONATAL ABSTINENCE SCORING TOOLS

Name of Tool	Author	Year Published	Items Scored	Range of Scores	Treatment Score
FNASS	Finnegan et al.	1975	21	Severity ranges from 0 to 5	Three continuous scores ≥8 or two continuous scores ≥12
Narcotic Withdrawal Score	Lipsitz	1975	11	0–3	≥4
Neonatal Narcotic Withdrawal Index	Green & Suffett	1981	7, with seventh item being "other," which consists of 12 items	0–2	5 or greater
Ostrea	Ostrea	1976	6	Ranking of symptoms	
Neonatal Withdraw Inventory	Zahorodny et al.	1998	8	0–4	Three continuous scores ≥8 or two continuous scores ≥12
MOTHER NAS Scale	Jones et al.	2010	19	0–8	Two continuous scores ≥9 or one score ≥13
FNASS—Short Form	Maguire, Cline, Parnell, & Tai	2013	7	0–5	Three continuous scores ≥8 or two continuous scores ≥12
sFNASS	Gomez-Pomar et al.	2017	10	0–5	Three continuous scores ≥6 or two continuous scores ≥10
ESC	Grossman et al.	2018	3	Yes or no to questions	Algorithm to determine treatment based on answers

hospital stay) fuel the recommendation of the AAP, the Academy of Breastfeeding Medicine (ABM), and the American College of Obstetricians and Gynecologists (ACOG) to encourage breastfeeding among mothers who are free of other drugs in methadone and buprenorphine treatment programs and are HIV negative (ACOG, 2017; Chantry, Eglash, & Labbok, 2015; Hudak & Tan, 2012).

For those who are unable to breastfeed or choose not to breastfeed their babies, the choice of the formula that is offered to the infant, in terms of its calorie and lactose content, has generated some discussion among those treating such infants. While no randomized controlled trial studies have been done on this topic, observational studies, expert opinion, and quality improvement projects have been published. The Ohio Children's Hospital Consortium noted through observation that babies who were fed 22 calorie, low-lactose formula did better than those babies who were fed regular-lactose, 19 calorie formula (Hall et al., 2014, 2015).

In an orchestrated testing quality improvement project done by the Ohio Perinatal Quality Collaborative (OPQC), a 22 calorie/oz formula has been found to help with the alleviation of NAS symptoms, regardless of lactose content. The orchestrated testing comprised of putting the 54 hospitals participating in the quality improvement project into four types of feeding groups. The groups were low lactose 19 calorie, regular lactose 19 calorie, low lactose 22 calorie, and regular lactose 22 calorie. The neonates that had the 22 calorie formula regardless of lactose concentration had a decreased length of hospital stay and shorter medication treatment when compared to neonates in the 19 calorie groups (Kaplan et al., 2017). The higher concentration formula is needed to meet the higher metabolic demands of a baby going through active withdrawal and helps to decrease the weight loss seen in babies diagnosed with NAS. The higher calorie formula is only needed for the first week of life during the initial withdrawal period (Walsh et al., 2018).

Box 30.1

NONPHARMACOLOGICAL INTERVENTIONS FOR NAS

Swaddling—in a flexed position with hands midline against chest and legs loosely swaddled in lumbar flexion to decrease sensory stimulation

Minimize environmental and physical stimulation—low lighting and noise levels—do not use TV or mobiles

Avoidance of abrupt changes in infant's environment—handling neonate gently and keeping neonate close to the body to increase sense of security

Skin-to-skin care with the mother or other family members

Gentle rocking—vertical rocking preferred over horizontal rocking

Slow approach with a soft voice and gentle touching to awaken baby and prepare for cares

Limit all stimulation at first signs of distress

Pacifiers for nonnutritive sucking

Hand containment during cares—involve the mother with this when she is present

Use of soft shushing, singing, or humming

Offer firm input to feet for bracing during feeds, your hand on the infant's chest to offer firm support and maintain flexion, which will increase organization for sucking, and apply firm pressure to palate to increase and improve quality of sucking

Frequent, small feedings for infants with feeding difficulties or gavage feeds may be needed

Avoid talking to the infant while feeding or rocking

Clustering care with extended rest periods

Encourage mother to room-in with neonate

Prone sleeping until stable, then transition to back sleeping for safe sleep at home

Relaxation baths

Acupuncture

Massage therapy

Aromatherapy using mother's scent

Pharmacological

When nonpharmacological treatments do not work, medication-assisted treatment will be needed to help alleviate the signs of withdrawal in the neonate. The recommendation of the AAP is to use the same medication class of the drug the neonate was exposed to in-utero (Kocherlakota, 2014). For narcotics and heroin, oral morphine and methadone are the most commonly used medications to help alleviate the withdrawal symptoms, though paregoric and tincture of opium continue to be used despite recommendations against these drugs. Several studies have been done comparing morphine to methadone for treatment in the neonate withdrawing from opiates, but to date there is no consensus on which one is better. One of the issues when looking at the studies is that there is no national standard on how to prescribe or when to start the medication therapy (Sanlorenzo, Stark, & Patrick, 2018). Buprenorphine, which is a mainstay in treating pregnant women with opiate-use disorder, has been recently studied in neonates as an alternative to morphine and methadone. In a small, single site, randomized double-blinded, double-dummy trial, buprenorphine was compared to morphine. The results of this study showed that buprenorphine-treated neonates had a significantly decreased length of hospital stay and a decreased length of treatment than neonates treated with morphine (Kraft et al., 2017).

For babies born to mothers who are polysubstance abusers with drugs such as barbiturates, benzodiazepines, antidepressants, and/or antipsychotics and sedatives or hypnotics, phenobarbital and clonidine can be used in conjunction with the narcotic replacement medications (Kocherlakota, 2014). Table 30.3 lists the most commonly used medications in NAS treatment with the route of administration and dosage.

No matter what pharmacological agent is used, the standardization of a medication protocol has been shown to be beneficial in decreasing the length of treatment and the hospital stay. The Ohio Children's Hospital Consortium from 2012 to 2014 did a multicenter retrospective cohort study with 981 neonates on the implementation of a standardized NAS weaning protocol. Prior to forming the consortium, each of the six children's hospitals treated NAS neonates in a different manner. Approximately halfway through the study, all the hospitals adopted a strict weaning protocol for either morphine or methadone. The adoption of the weaning protocol resulted in a shorter hospital stay, shorter duration

TABLE 30.3

COMMONLY USED MEDICATIONS TO CONTROL NEONATAL ABSTINENCE SYNDROME SYMPTOMS

Medication	Route	Dose Range
Morphine	PO	0.05–0.2 mg/kg/dose q3–4h; increase by 0.05 mg/kg Maximum dose: 1.3 mg/kg/day
Methadone	PO	0.05–0.1 mg/kg/dose q12h, increase by 0.05 mg/kg q48h Maximum dose: 1 mg/kg/day
Buprenorphine	Sublingual	4–5 mcg/kg/dose q8h Maximum dose: 60 mcg/kg/day
Phenobarbital	PO	Loading dose: 16 mg/kg Maintenance dose: 1–4 mg/kg/dose q12h
Clonidine	PO	Initial dose: 0.5–1 mcg/kg, followed by 0.5–1.25 mcg/kg/dose q4–6h

PO, by mouth.

of opioid treatment, and less need for adjunct therapy in the three centers that did not previously have a protocol (Hall et al., 2015).

DEVELOPMENTAL OUTCOMES

While the acute signs of withdrawal can be ameliorated in days to weeks, subacute signs may last as long as 6 months, which can affect the development of the neonate (Hudak & Tan, 2012). Studies have been published and are currently being done on the long-term outcomes of neonates diagnosed with NAS, but the true effects are not totally known as it is difficult to determine the actual cause of developmental delays. Neonates diagnosed with NAS usually have had exposure to more than one substance in-utero and many are raised in unstable home environments, shifting from one caretaker to another. Confounding factors such as low socio-economic class, poor nutrition, lack of parenting skills due to use of multiple drugs and/or psychiatric issues, and poor prenatal care, to name a few, are known to affect the development of a neonate. Furthermore, apart from NAS, most neonates are healthy, so long-term follow-up is often difficult as the parents don't see the need for developmental follow-up of their child if they appear to be hitting their developmental milestones (Oei, 2018).

Outcomes explored in studies are the effects of chronic drug exposure in-utero on vision and motor function; cognitive function and neurodevelopment; risk of addiction; emotional, behavioral, and social adjustment; resilience; physical health; academic outcomes; and potential criminal activity in adulthood, but all of them are contaminated by multiple drug exposures and adverse lifestyles, all of which cannot be discussed in this chapter.

Recent studies have been published on visual disturbances being observed in neonates exposed to opiates. Visual disturbances range from strabismus, nystagmus, reduced visual acuity, refractive errors, and cerebral visual impairment (Hamilton et al., 2010; Spiteri-Cornish, Hrabovsky, Scott, Myerscough, & Reddy, 2013). These disturbances are being noticed in the preschool to kindergarten age group and at this point it is undetermined if this will continue as the child grows and develops.

For cognitive function and neurobehavioral function, a study on the effects of prenatal cannabis on adults was done in Canada. The study followed children until they were 22 years of age. Early concerns regarding behavioral issues had resolved by adulthood and the adults performed similarly to non–cannabis-exposed adults on cognitive testing. But a functional magnetic resonance imaging demonstrated significantly different blood flow response to the posterior left brain, a side effect of the prenatal exposure (Smith et al., 2016; World Health Organization, n.d.).

A study on opioid exposure demonstrated that those exposed had decreased cognitive and fine motor function when compared to non-exposed adults in both the early childhood period and adulthood. Again, confounding factors such as being in an adverse home situation with parents who lack parenting skills, poverty, and chaos at home affect developmental outcomes, which many of these subjects had been exposed to (Nygaard, Slinning, Moe, & Walhovd, 2017; Ornoy, 2001; Ornoy, Segal, Bar-Hamburger, & Greenbaum, 2001).

The risk of future addition problems is of concern for neonates exposed in-utero. It is now well-known that there is a genetic component to addiction as well as environmental factors. **Quality and Safety: When comparing children of parents without addiction problems to children of parents who are addicts, the latter is two times more likely to develop an addiction disorder to substances such as alcohol and/or drugs** (Chasin, Pitts, & DeLucia, 1999). A study on prenatal cannabis exposure demonstrated that the endo-cannabinoid system that modulates and influences neurodevelopment into adulthood is affected. This leads to an increased risk of poor social outcomes, criminal activity, higher failure rates in school, having children out of wedlock, unemployment, and psychiatric issues (Goldschmidt, Richardson, Cornelius, & Day, 2004; Leech, Larkby, Day, & Day, 2006; Sonon, Richardson, Cornelius, Kim, & Day, 2016).

NONJUDGMENTAL NURSING CARE OF THE MOTHER–INFANT DYAD

When caring for the baby diagnosed with NAS it is important to remember that you are not only caring for the neonate, but also for the mother. Unfortunately many healthcare providers view the mothers with substance abuse disorder through a judgmental lens. Frequent comments from healthcare providers are: "The mother shouldn't have gotten pregnant," "What a horrible thing she did to her baby!", "If she loved her baby she would have just quit," or "She should be put in jail for what she did to her baby." These statements or thoughts are often heard by the mother or she will feel the judgment of the provider by his or her actions and attitude. When caring for the mother–infant dyad it is important to remember that up to 40% or more of women with substance use disorder are victims of child abuse, sexual abuse, or both (Konkolÿ-Thege et al., 2017). So, it is important when caring for the mother–infant dyad that you confront your feelings about the fact that the infants were exposed to substances in-utero. Remind yourself that addiction is a chronic disease similar to diabetes and hypertension, and that the woman did not decide to have a substance use disorder after becoming pregnant. The mother of the NAS neonate deserves to be treated with the same respect as any patient's mother you care for. In order to deal with mothers with substance abuse disorder, seeking education on trauma-informed care will help to care for them and their infants without judgment.

Quality and Safety: Nursing care of the neonate requires doing careful ongoing physical assessments, always being mindful of any potential seizure activity. Documentation of the baby's tolerance to stimuli is important as is monitoring the baby's fluid and electrolyte balance and daily weights. When caring for a baby requiring medication-assisted treatment, it is important to give the medication as ordered and on time.

When caring for the baby, you will also be interacting with the mother, so it is essential that you develop a therapeutic relationship with the mother and show her respect. This will encourage the mother to be more open to teaching and interventions. The mother is part of the caregiving team and needs to be taught how to provide supportive care to her infant. You can help her bond with her baby by providing skin-to-skin care opportunities for the mother, encouraging her to room-in with her infant, and by providing positive feedback for all attempts to comfort her infant. Explaining to the mother that the infant's behavior is not a reflection of her but a result of the drugs the baby was exposed to in-utero, and intervening early when the infant is fussy, will also help her bond with her infant.

When providing information to the mothers, always provide clear, concise, and specific guidelines for expected behaviors. The education should be goal-directed and the educational materials need to be presented in a nonjudgmental manner and at an appropriate reading level.

Caring for infants diagnosed with NAS and their mothers can be a difficult and tiring assignment. It is important to acknowledge to yourself that the mothers and infants require flexibility in schedules, energy, patience, and a nonjudgmental attitude. While it is good to provide consistent caregivers for these mother–infant dyads, it is also important to take breaks in order to prevent burnout.

When the infant is ready for discharge, it is important to make the appropriate referrals, if not done prior to discharge. A home health referral should be made as well as a referral to an early intervention or Help Me Grow program. If the mom is not already in a drug rehabilitation program, then a referral to a program should be done as this is a period where treatment can be most successful.

SUMMARY

Maternal opiate addiction in the United States has become a national epidemic. NAS is a result of this epidemic and has increased in prevalence. Maternal substance abuse disorder and NAS is costing hospitals and the government millions of dollars each year in treatment costs. Improving the care of infants with NAS and decreasing the length of stay in the hospital are two of the main issues facing hospitals and healthcare providers today. This chapter has attempted to discuss the many issues related to NAS as we currently understand them. There are still many unanswered questions related to the care of the infant with NAS regarding the best treatment strategy, the long-term outcomes, as well as why some infants do not show signs of withdrawal, even though there is known exposure in-utero.

EVIDENCE-BASED PRACTICE BOX

In the past decade or so there has been a dramatic shift in thinking regarding breastfeeding recommendations for mothers taking methadone. Prior to 2001, the AAP only recommended breastfeeding for mothers on methadone doses of 20 mg/day or less, because methadone is a small molecular-sized drug that is water-soluble with a weak base, and drugs that meet these criteria are known to readily transfer into human milk (Kreek, 1979; Kreek et al., 1974). However, studies on methadone in human milk between the 1970s and the 1990s demonstrated that mothers on methadone doses greater than 20 mg/day had very little methadone transfer through human milk to the neonate (Geraghty, Graham, Logan, & Weiss, 1997; Kreek et al., 1974; Pond, Kreek, Tong, Raghunath, & Benowitz, 1985; Wojnar-Horton et al., 1997). The data from these studies convinced the AAP Committee on Drugs to change their recommendations. The dose restriction was removed and methadone at all doses is now considered safe for the neonate (Hudak & Tan, 2012).

Studies in the 2000s continued to demonstrate only low amounts of methadone transfer into human milk, with minimal amounts measured in neonate and infant plasma. Methadone given in the United States contains both *R* and *S*-methadone and both substances are metabolized at different rates. Bogen et al. (2011) examined the levels of *R* and *S*-methadone in human milk on days 1 to 6 in postpartum women ($n = 20$) who were taking between 40 and 200 mg/day of methadone. The study looked at *R* and *S*-methadone levels in the breast milk as well as maternal plasma levels. The breast milk and maternal plasma levels were drawn when methadone levels were highest, to estimate maximum infant plasma levels. The study showed that *R*-methadone is found in higher concentrations than *S*-methadone. However, estimated levels of *R* and *S*-methadone in infant plasma were relatively low, even at the highest maternal methadone dose.

Jansson, Choo, Velez, Harrow, et al. (2008) studied the amount of methadone in breast milk in the first month of life. The maternal participants ($n = 8$) had both foremilk and hindmilk collected as well as blood drawn to assess maternal plasma levels of methadone. Additionally, the neonates had blood and urine collected to assess methadone levels. The study found that in the neonatal period—the initial 28 days of life—the amount of methadone found in the breast milk was low and unrelated to the mother's methadone dose. Methadone concentration in the breast milk did increase over the period of the study (30 days), but this did not increase the level of methadone in the neonate's plasma.

In a similar study, Jansson, Choo, Velez, Lowe, and Huestis (2008) studied methadone in breast milk in long-term lactation up to 6 months postpartum. Four of the five mothers who were followed up to 6 months postpartum had levels of methadone in breast milk that remained low.

In the past 10 years, buprenorphine has become the drug of choice for treating pregnant women with substance abuse problems. Similar studies done with methadone to determine the amount of drug in the breast milk have now been done in mothers who are receiving buprenorphine. Ilett, Hackett, Gower, Doherty, and Hamilton (2012) studied the amount of buprenorphine and norbuprenorphine a breastfed infant would receive during maternal maintenance treatment. The authors found that the norbuprenorphine concentration in the breast milk was 1.94 mcg/kg/day with an absolute infant dose of 0.29 mcg/kg/day, which was approximately half of the buprenorphine concentration of 3.65 mcg/kg/day and absolute infant dose of 0.55 mcg/kg/day (Ilett et al., 2012). Both the buprenorphine doses and norbuprenorphine doses were considered low and unlikely to cause problems in infants (Ilett et al., 2012).

In another study by Lindemalm, Nydert, Svenson, Stahle, and Sarman (2009), infant urine as well as the breast milk, urine, and blood of mothers who received buprenorphine in a treatment program and breastfed their babies were examined. The authors found that the levels of buprenorphine and its active metabolite norbuprenorphine were low, at less than 1% (Lindemalm et al., 2009). Finally Gower et al. (2014) looked at the long-term effect of buprenorphine on the infant. The authors examined infants at 4 weeks of age who had received breast milk from their mothers who were in buprenorphine treatment programs and found that there were no adverse side effects to the infants up to 4 weeks postnatally (Gower et al., 2014). Like the studies on methadone, the amount of drug transferred from the mother to the infant is low, thus supporting the recommendation by the AAP, ACOG, and ABM for breastfeeding with buprenorphine or methadone usage in a treatment program.

CASE STUDY

Identification of Problem. Baby girl Jones, a 1-day-old, is admitted to the NICU from an outside referring hospital for high pitched crying, increasing irritability, tremors/jitteriness, increased muscle tone, poor feeding, emesis, and tachypnea requiring O_2 per nasal cannula.

Assessment: History and Physical. The baby girl was born at 39 1/7 weeks gestation at 3.2 kg to a 28-year-old gravida 4 para 4 AB 0, hepatitis B and C and HIV negative Caucasian mother. The pregnancy was complicated by no prenatal care and a history of Graves' disease, with the mother not compliant with medication therapy, unknown Group B bacterial streptococcal status, and opiate use. The baby was born by spontaneous vaginal delivery with clear amniotic fluid. The baby was vigorous at birth with Apgar scores of 8 and 8 and no resuscitation required. The mother's blood type was unknown and the baby's blood type was A positive. The infant was taken to the newborn nursery for tachypnea and O_2 administration and to be observed for signs of withdrawal. The infant was bottle-fed but had emesis with each feed. The course at the referring hospital was unremarkable except for increasing tachypnea with retractions, increasing irritability, poor feeding with emesis, tremors/jitteriness, and the requirement for continued O_2.

On admission to the NICU, the infant was noted to be alert and well-hydrated. The infant was on a nasal cannula at 0.1 L/minute for tachypnea with O_2 saturation at 99%. Her vital signs were within normal limits with an axillary temperature of 98.5°F, a heart rate of 150 beats/minute, a respiratory rate of 55 breaths/minute, and blood pressure of 60/36 mmHg with a mean of 48 mmHg. Her weight on admission was noted to be 2.88 kg, a 10% loss in 1 day. Her examination was nonremarkable, except for increased muscle tone. Finnegan scoring on the infant revealed a score of 8.

Differential Diagnosis. Several conditions in the neonate can cause the symptoms described in this infant. The most common are hypoglycemia, hypocalcemia, hypomagnesium, neurological insult, sepsis, and NAS. With the mother's history of being noncompliant with medication for Graves' disease, neonatal Graves' disease must also be considered.

Diagnostic Tests. To determine the exact cause of the signs, a glucose, calcium, and a complete blood count (CBC) differential should be ordered as well as a T_4 and TSH. The collection of meconium could be obtained from any remaining meconium that the infant passes and sent for toxicology. A call to the referring hospital to inquire if they collect umbilical cords at birth can also be made. If the cord was saved, then sending the cord for toxicology should be ordered.

Working Diagnosis. The baby's CBC and differential were normal, the glucose was 60, and the calcium normal at 9.0. The T_4/TSH was normal at 2.3 and 3.14. The baby continued to be irritable and a poor feeder, with jitteriness and increased muscle tone, as well as tachypnea. The baby started to develop excoriation on her cheeks from frequent rubbing on the mattress. Urine toxicology returned from the referral hospital was positive for opiates. The working diagnosis for the infant is NAS secondary to in-utero exposure to opiates.

Development of Management Plan. The goal for the neonate with NAS is to alleviate signs of withdrawal through nonpharmacological and pharmacological management. Wean infant to room air (RA) from nasal cannula oxygen. Maintain O_2 saturation at 95% to 96%. Continue scoring the infant every 3 hours with the Finnegan Scoring Tool. Ensure the neonate is swaddled with hands midline and legs flexed and placed in a dark, quiet environment to decrease stimulation. Encourage the mother to do skin-to-skin care or to hold the baby as much as possible. Feed infant 22 calorie formula q3h, PO ad lib, since the mother is not yet in a treatment program. When the baby has three scores greater than 8 or two scores greater than 12, begin pharmacological therapy of morphine at 0.05 mg/kg q3h and increase as needed based on scores.

Implementation and Evaluation of Effectiveness. The infant was weaned to RA over the next 2 hours, maintaining O_2 saturation between 95% and 96%. Infant Finnegan scores began to escalate over the next 12 hours to three consecutive scores of 10, 12, and 14, respectively, despite maximizing nonpharmacological interventions. The infant was started on morphine at 0.05 mg/kg/dose PO at 36 hours of age. Symptoms continued to escalate and the dose was increased to 0.07 mg/kg/dose PO by 48 hours of age. On day of life (DOL) 4 the baby had been stable on the morphine dose for 48 hours with Finnegan scores less than 8 and weaning of the morphine began. By DOL 10, the infant had been weaned off the morphine but Finnegan scoring continued for an additional 48 hours to ensure that the infant did not start to display signs of withdrawal after the discontinuation of the morphine. The infant did not display any signs of withdrawal, so this was discontinued on DOL 12. The infant was discharged home on DOL 13 on full PO feeds of 19 calorie formula with a weight of 3.2 kg. The infant was discharged to the care of a foster family and, after completing all discharge, newborn testing and education was completed with the foster family. A referral was made to Help Me Grow and the NAS clinic at the regional referral center.

QUALITY AND SAFETY

Scoring

All NAS scores have a degree of subjectivity to them, making interrater reliability among staff of utmost importance when caring for neonates with NAS. Inconsistency in scoring from one nurse to another makes it difficult for the practitioner to manage the patient. Doing dual scoring at least two times per day helps to increase interrater reliability between nurses and increases confidence in the practitioners that the neonate is actually scoring the number that has been assigned.

Pharmacological Treatment

When multiple practitioners care for a neonate with NAS, differences in management of the patient is a common occurrence. Practice differences in administering either morphine or methadone, as well as when and how to wean the neonate, can lead to increased days on medication therapy and in the hospital. Establishing a medication protocol that all practitioners can agree on, and adhering to the protocol, has been shown to improve outcomes by decreasing the length of time on medication and the number of days in the hospital.

General Management of NAS Patients

Quality improvement is now part of all NICUs and SCNs. NAS babies can have long length of stays. A quality improvement project to decrease the length of stays has been shown to work. A multidisciplinary team will be needed to develop a specific aim, determining key drivers that affect the aim and then designing interventions to achieve the aim through a series of Plan-Do-Study-Act cycles. When creating your team, be sure to include a former patient mother to help, as parents have many great ideas on what can and cannot work!

Breastfeeding NAS Babies

One of the many reasons for poor breastfeeding rates in mothers of babies diagnosed with NAS is the fear by healthcare providers that substances will transfer into the maternal breast milk, thus harming the baby. This fear by the healthcare provider is usually due to a lack of understanding of the pharmacokinetics of medications in breast milk. An education program to increase the healthcare knowledge on the subject can help increase breastfeeding as the providers are more likely to assist and support the breastfeeding mother.

Unit VI: Environmental Health and Family-Centered Care in the NICU and Beyond

CHAPTER 31

Neurobehavioral Development

Leslie B. Altimier and Diane Holditch-Davis

INTRODUCTION

The care of high-risk infants, both those born prematurely and those with medical, surgical, or developmental problems, has long been a major focus of nursing and healthcare. Advances in neonatal care have increasingly focused on the impact of the neonatal intensive care unit (NICU) environment on the infant's physiologic and neurobehavioral functioning, the provision of sensory input geared to meet the individual infant's needs and current level of developmental function, and mediating the effects of stress and overstimulation. Care in the NICU focuses on meeting the physiologic, neurobehavioral, and developmental needs of these infants, with attention to the social interactive consequences of the NICU environment. This chapter focuses on the improved understanding of these factors and of the pathophysiologic problems encountered by infants in the NICU, along with the development of new management strategies, technologies, and caregiving approaches that have markedly improved the outcome of high-risk infants.

CONSEQUENCES OF PREMATURITY

Birth at extremely low gestational ages presents a significant threat to an infant's survival, health, development, and future well-being. Although comprising just 1% to 2% of all births, extremely preterm infants (delivered at 22–28 weeks' gestation) pose the greatest challenge to neonatal medicine, healthcare, education, and social services in providing continued support for survivors who often have significant ongoing needs. Among infants born at 22, 23, and 24 weeks, survival to 1 year of age was 6%, 27%, and 60%, respectively, and increased for each 1-week increase in gestational age (GA) from 78% at 25 weeks to 94% at 28 weeks (Anderson et al., 2016). Survival depends highly on the place of birth. Hospitals with larger neonatal services and more experience in the care of extremely low birth weight (ELBW, <1,000 g birth weight) infants have higher rates of survival (Marlow et al., 2014). The prevalence of major neonatal morbidities common to this gestational age group—chronic lung disease (CLD) or bronchopulmonary dysplasia (BPD), periventricular leukomalacia (PVL), intraventricular hemorrhage (IVH), cerebral palsy (CP), necrotizing enterocolitis (NEC), retinopathy of prematurity (ROP), severe visual and hearing impairment, and sepsis—is essentially unchanged, despite continually evolving less invasive strategies (Costeloe, Hennessy, Haider, Stacey, & Marlow, 2012).

Premature infants also remain at high risk for a variety of neurodevelopmental, cognitive, behavioral, motoric, visual, hearing, attentional, social, emotional, and educational problems (Adam-Chapman et al., 2018; Anderson et al., 2016; Ditzenberger, Blackburn, Brown, & Altimier, 2016; Marlow et al., 2014; Moore et al., 2018; Neil & Inder, 2018; Symes, 2016). Infants born very preterm (before 32 weeks' GA) are three times more likely than full-term born infants to develop psychiatric disorders (Johnson & Marlow, 2011), and are at higher risk for a wide range of sociocognitive impairments (Blencowe et al., 2013; Spittle, 2016; Synnes & Hicks, 2018).

It is well documented that parents of NICU babies have significantly higher rates of postpartum depression (PPD), posttraumatic stress disorder (PTSD), and anxiety disorders (M. M. Greene et al., 2015). The psychosocial needs of parents who are enduring the unexpected and extreme stress of having a hospitalized preterm or sick newborn have been long neglected, and most NICU staff (medical, nursing, and therapy) have not been trained to recognize the psychosocial needs of NICU parents. While much support can readily be given by compassionate, caring, trained NICU staff, some parents will require referral to mental health professionals. Since neurodevelopment outcomes of NICU babies are directly linked to secure attachments with their parents, supporting NICU parents in developing bonds of attachment with their babies can be considered neuroprotective care (Altimier & Phillips, 2018).

Although survival rates for ELBW premature infants have improved, there has only been a modest improvement in the proportion of surviving infants without neurologic impairment, no change in the proportion with severe disability, and an overall increase in the total number of children with neurodisability (Anderson, 2018; Holsti, Serenius, & Farooqi, 2018). Infants born at 25 weeks' GA have predicted survival rates exceeding 70%; however, along with improved survival rates, the risk of neurodevelopmental impairment increases with the degree of prematurity, reaching rates as high as 80% at 23 weeks' GA (Glass et al., 2015).

Executive functions, a set of inter-related cognitive processes that allow individuals to respond flexibly to the environment and to engage in purposeful, goal-directed behavior, often include,

but are not limited to, inhibition, planning, shifting or cognitive flexibility, working memory, and verbal fluency (Anderson, 2014; Burnett, Cheong, & Doyle, 2018; Farooqi, Hägglöf, Sedin, & Serenius, 2011; Samuelsson et al., 2017). Deficits in these executive functions have been reported in very preterm and very low birthweight (VLBW, <1,500 g birth weight) infants, with a greater deficit noted in infants born less than 26 weeks' gestation, which appear to persist over time into adolescence (Burnett et al., 2018; Holsti et al., 2018).

Authors have reported that 21% to 41% of extremely preterm children screen positive for the risk for autism spectrum disorders (ASD) at 2 years corrected age (Agrawal, Rao, Bulsara, & Patole, 2018). It is also thought that these may be core cognitive deficits that underlie much of the psychiatric morbidity and learning difficulties in this population (Patra & Greene, 2018).

Healthcare utilization is extremely high among preterm infants in recent years and significantly associated with worse neurodevelopmental outcomes (Patra & Greene, 2018). Prematurity of any degree affects the cognitive performance of children born preterm and the poor neurodevelopment persists at various ages of follow-up (Allotey et al., 2018).

Extremely preterm children are less likely to complete basic school education and are more likely to have poorer academic attainment than both their term-born peers and their more mature preterm counterparts. They also experience significantly increased rates of learning difficulties. Consequently, 39% to 62% of extremely preterm children are reported to have special educational needs (ElHassan et al., 2018; Litt et al., 2012); therefore, it is not surprising that after care in the NICU, the greatest costs associated with support for extremely preterm children lie in education (Dmowska, Andrews, Schreiber, & Msall, 2016; Hall & Greenberg, 2016; Mangham, Petrou, Doyle, Draper, & Marlow, 2009; Petrou, Johnson, Wolke, & Marlow, 2013). An innovative methodology to calculate community-level costs associated with preterm birth was performed by Hall and Greenberg (2016). Costs included initial direct hospital expenditures from the perspective of delivery hospitals and insurers, as well as indirect costs incurred through decreased educational attainment and lost earnings from the perspective of adults who were born preterm. The total initial hospital cost for all births within each GA category was calculated. Maternal costs were calculated a single time for each singleton delivery or set of gestation deliveries. To determine the excess cost attributed to prematurity, the initial hospital costs of full-term care for an equivalent number of infants were subtracted from the totals. Next, cost savings were calculated, which could be potentially realized by prolonging each preterm pregnancy by a single week of gestation.

Next, the impact of preterm birth on local educational attainment and annual income using measures obtained from the American Communities Survey (ACS) were estimated. An adjusted number of degrees that would have been expected had the preterm population earned degrees in the same proportion as the full-term population were then calculated (estimating the difference between earned degrees and adjusted degrees as the number of "lost" degrees attributable to preterm birth). Next, the impact of preterm birth on earnings (mean annual incomes associated with three income levels) among working adults was calculated.

Then, an adjusted income that would have been expected had the preterm population earned income in the same proportion as the full-term population was calculated (estimating the difference between actual earnings and adjusted earnings as "lost" earnings attributable to preterm birth). Lastly, the difference in both lost degrees and lost earnings if the rate of adults who were born preterm shifted from 10% to 9% was calculated. The preterm population represented 13.2% of the population, but 74.1% of the $131.7 million total initial hospital costs.

The annual initial hospital cost associated with 1,444 preterm infants was estimated at $93 million. In addition, over 9,000 fewer college degrees and over $300 million in lost annual earnings were attributed to local adults who were born preterm. Prolonging each preterm birth by 1 week could potentially reduce initial hospital expenditures by over $25 million. Additional potential savings could be realized as healthier infants attain higher levels of education and earnings as adults. The generalizable methods developed for estimating the economic impact of preterm birth at the community level can serve to rally support for local stakeholder investments in developing strategies for preterm birth intervention leading to improved pregnancy outcomes (Hall & Greenberg, 2016).

Immature infants differ in two important ways from healthy full-term infants. First, these infants are born early and therefore must adapt to the extrauterine environment with bodily systems, including a central nervous system (CNS), that are not yet mature. Second, this interruption of intrauterine life significantly modifies the environment of the infant. Thus, the preterm infant spends the last weeks or months of gestation in an environment—the NICU—that is very different from that of the uterus or the home of a healthy full-term infant. The NICU environment has similar implications for the more mature, although still vulnerable, ill full-term infant. For these infants, this environment is also abnormal and quite different from that experienced by healthy infants who go home with their parents soon after birth.

Neonatal nurses are very familiar with interpreting the physiologic status of infants and basing their interventions on physiologic changes. In recent years, nurses have placed increased emphasis on the importance of understanding the behaviors of infants under their care because behavior is the way infants communicate their needs and their responses to nursing interventions. However, two factors make this understanding difficult. First, newborn infants have limited behavioral repertoires. The same behavior may have different meanings in different situations, but busy neonatal nurses may not have the time necessary to correctly interpret infants' behaviors by comprehensively assessing both the infants' actions and the environmental stimulation. Second, the behaviors of critically ill infants are sometimes even more difficult to interpret, because they lack the energy to display characteristic behavioral responses. Thus, neonatal nurses can never rely totally on infants' behaviors to determine their needs, but in combination with physiologic parameters, understanding infant behavior enriches both nursing assessment and the evaluation of nursing interventions. In considering the vulnerabilities of ill and immature infants, it is useful to examine the implications of the state of CNS and sensory system development, neonatal neurobehavioral development, and sleeping and waking states—and their relevance for neonatal nursing.

FETAL AND NEONATAL CENTRAL NERVOUS SYSTEM DEVELOPMENT

The brain grows and develops most rapidly during the fetal period and the first years of life. Total brain volume measured 2 to 4 weeks after birth is approximately 36% of that of an average adult brain. The brain increases in size by 101% during the first year and by another 15% during the second year, reaching over 80% of adult brain volume. During this rapid development, multiple interacting mechanisms such as myelination of white matter (WM) and functional specialization of brain areas is happening simultaneously (Dubois, Dehaene-Lambertz, Kulikova, Poupon, & Hu, 2014).

As noted in Chapter 15, Neurologic System, the development of the CNS can be divided into six overlapping stages (Table 15.1). These stages are important to consider in examining neurobehavioral development and the effects of the NICU environment, because the stage of development influences the effect of any insult. In addition, several areas of the CNS, including predominantly organizational processes, continue to undergo significant changes during the period when preterm infants are in the NICU, increasing their vulnerability to insult. Vulnerabilities include decreased inhibitory potential, slower nerve conduction and synaptic potential, inability to sustain high firing rates, incomplete cell differentiation, and decreased synaptogenesis and dendritic arborization. The stage of development is also reflected by the behavioral characteristic of immature infants such as altered state regulation, increased and decreased tone, alterations in primitive reflexes, increased irritability, immature inhibition, jerky movements, lower arousal, lesser ability to sustain alert states, poorer coordination, altered autonomic regulation, and asymmetrical, uncoordinated posture and movement (Blackburn, 2018; du Plessis & Volpe, 2018; Gressens & Huppi, 2015; K. L. Moore, Persaud, & Torchia, 2015; Yuskaitis & Pomeroy, 2017).

The first three stages of CNS development (dorsal induction, ventral induction, and neuronogenesis) are completed before the fourth month of gestation. The last three stages (neuron migration; organization, including synaptogenesis and arborization; and myelination) continue during the time many infants are in the NICU and have implications for the effects of the NICU environment and care. Areas of development during the last part of gestation that are particularly critical in considering neurobehavioral vulnerabilities of ill or immature infants include (1) autonomic homeostatic control, (2) alterations in the germinal matrix and migration of neurons and glial cells, (3) CNS organizational processes, (4) development of the neocortex, and (5) growth of the cortex and cerebellum (Blackburn, 2018; du Plessis & Volpe, 2018).

From about 28 to 32 weeks' GA, preterm infants begin to achieve some degree of physiologic homeostasis, with increasing control of the sympathetic system over their autonomic functioning. With increasing autonomic control, the infant develops greater autonomic stability. This autonomic stability can be seen, for example, in the decreasing incidence of apnea and bradycardia. As these infants move to greater cortical control over the next months, their development is characterized by periods of temporary organization followed by periods of disorganization as new levels of maturation and control are achieved. These periods of disorganization are reflected in the infant's sleep–wake patterns, proportion of transitional or indeterminate sleep, and fragmented behavioral responses, and reflexes (Moore et al., 2015).

The germinal matrix in the periventricular subependymal area is a site of origin for neuronal and glial cells. Neurons and glial cells migrate from the germinal matrix to their eventual loci within the CNS, where they further differentiate and take on unique and individual functions. Initially, the neurons migrate to areas deep within the cortex; later, neurons migrate further toward the surface of the cortex. Thus, neurons formed early come to lie in deeper layers of cortex and subcortex; those formed later are found in more superficial layers. The cortex generally has a complete component of neurons by 33 weeks' gestation (Yuskaitis & Pomeroy, 2017). Until 32 to 34 weeks' GA, the fragile, poorly supported blood vessels in this area receive a significant proportion of cerebral blood flow (du Plessis & Volpe, 2018). Insults to this area before this period may lead to germinal matrix and IVH (Blackburn, 2018; Fleiss, Mezger, & Gressens, 2018; Juul, Fleiss, McAdams, & Gressens, 2018; Poduri & Volpe, 2018a).

Organization, or "the processes by which the nervous system takes on the capacity to operate as an integrated whole," begins during the sixth month of gestation and extends many years after birth (Blackburn, 2018). Neuron growth and connections lead to development of brain sulci and gyri. A brain growth spurt occurs from 26 to 30 weeks, leading to more complex behaviors (Blackburn, 2018; du Plessis & Volpe, 2018). Organization of the CNS is critical for cortical and cognitive development. These processes may be particularly vulnerable to insults from the effects of the NICU environment (Kinney & Volpe, 2018b). Subplate neurons differentiate early and migrate to cortex from the germinal matrix to serve as guides for ascending and descending projections to target neurons. The subplate neurons provide critical connection sites for axons ascending from thalamus and other sites, until the neurons that these axons will eventually connect with have migrated from the germinal matrix. The subplate reaches its peak from 27 to 30 weeks (Kinney & Volpe, 2018b). Once cortical neurons have reached their eventual loci, they become arranged in layers and develop dendrites and axons that undergo extensive branching. The pattern of dendritic connections between neurons is a critical growth process that constitutes the "wiring" of the brain (also called arborization). These interconnections are critical for processing of impulses, cell-to-cell communication, and communication throughout the nervous system. Lack of connections can result in hypersensitivity, poorly modulated behaviors, and all-or-nothing responses, which can often be observed in preterm infants in the NICU. Similar behavior patterns can also be seen in some children in later infancy and childhood.

Organization also involves formation of connections or synapses between neurons and development of intracellular structures and enzymes for neurotransmitter production. Synaptogenesis is critical for integration across all areas of the nervous system. Synapses continue to restructure throughout development, and this process is thought to be the basis for memory and learning. Synaptogenesis is mediated by excitatory neurotransmitters such as glutamate. Glutamate acts on *N*-methyl-D-aspartate (NMDA) receptors to enhance neuronal proliferation, migration, and synaptic plasticity (du Plessis & Volpe, 2018). Another component of organization is reduction in the number of neurons and their connections through the death of many neurons and regression of dendrites and synapses. Neuronal death assists in elimination of errors within the nervous system, such as neurons that are improperly located, that fail to achieve adequate connections, or that are underused (Blackburn, 2018; du Plessis, Limperopoulos, & Volpe, 2018b). Finally, organization involves development of different types of glia cells, including astroglia, microglia, and oligodendrocyte (Kinney & Volpe, 2018b). Astroglia provide support for neurons, with axonal guidance, brain structural development and growth, blood–brain barrier function, and integration of information within the brain (Blackburn, 2018). Astroglia undergo rapid proliferation between 24 and 32 weeks' gestation (Poduri & Volpe, 2018b). Oligodendrocytes are the cells that produce myelin within the CNS. These glia are particularly vulnerable to hypoxic and ischemic injury prior to 32 weeks' gestation (premyelinating period; Kinney & Volpe, 2018b). Damage to the premyelinating oligodendrocytes is a prominent feature in WM injury in preterm infants (see Chapter 15, Neurologic System).

Organizational processes and modification of neurons continue into adulthood, but are particularly vulnerable during infancy. This ability of a neuron to change structure and function in response to external experiences and to store that information for memory and learning is referred to as neural (brain) plasticity (Blackburn, 2018; Fiori & Guzzetta, 2015). The neonate's brain is still under construction with enhanced plasticity. Enhanced plasticity of the

developing brain allows it to be influenced more strongly by the environment than the adult brain. However, this increased plasticity also creates selective brain vulnerability (Guyer, Pérez-Edgar, & Crone, 2018; Limperopoulos, 2010). The more immature the infant at birth, the greater the impact of neural plasticity. Sensory input influences later neuronal structures, processes, and responses that can translate to differences in the input, and those differences in the input further influence future developmental outcomes. New information and experiences will be filtered through processes and structures that have already adapted to previous input and experiences (Oakes, 2017). Plasticity in the preterm infant actually creates change in the input itself.

Adverse neonatal experiences may alter brain development during this vulnerable time and thus later development. Neuronal differentiation and organization are controlled by the interaction of genes with the environment. Each neuron has many synaptic connections that allow the brain to integrate and organize information. There is initially an overproduction of neurons and nerve connections. Many of these neurons and connections are later eliminated. Whether a connection is retained or eliminated is influenced by the infant's early environment and experiences. For example, the brain is more likely to strengthen and retain connections that are used repeatedly and to eliminate underused connections. Improper sensory input (too much or too little) or input that is inappropriate in terms of timing can alter brain development and structures. Thus, the environment of immature infants in the NICU and in the early months following discharge is critical for brain development and later cognitive function with a risk of alterations in neuronal networks, wiring, function, and behavior with exposure to early inappropriate sensory input (Fleiss et al., 2018; Kinney & Volpe, 2018b).

The human brain is arguably the most complex system in biology and yet its macroscopic layout is nearly complete by the time of term birth. The neonatal cerebral cortex displays a complex, adult-like gyrification pattern and all large-scale connections in the underlying WM are already in place (Kinney & Volpe, 2018b; Poduri & Volpe, 2018b). With the increasing availability of high-quality neuroimaging techniques, it is now feasible to study detailed early human brain development in vivo. Mapping the brain's anatomic and functional trajectories is crucial for early identification of altered development, since psychiatric and neurologic disorders may have a neurodevelopmental origin (Gao, Lin, Grewen, & Gilmore, 2017). These disturbances in brain development may be genetically programmed, epigenetically mediated, or environmentally influenced, and early detection may provide a window of opportunity for preventive strategies. These advances have led to exciting new insights into both healthy and atypical macroscale brain network development and have paved the way to bridge the gap between the brain's neurobiologic architecture and its behavioral repertoire.

Although the neurologic system is one of the earliest systems to develop in the embryo, it is not fully matured until adulthood. There are four areas of the nervous system function: autonomic, sensory, motor, and state regulation. All these areas develop before birth, yet maturation of these functions is not attained until after birth. Autonomic function includes self-regulation of respirations, heart rate (HR), temperature, and nutritional intake. The infant must adapt and respond to many changes simultaneously to survive in this new environment (Blackburn, 2018; Fink, Bronas, & Calik, 2018). The sensory system (discussed later) begins before birth, but maturation of each system continues after birth. In utero, the sensory systems develop in precise order, and for optimal development, that order should be unaltered. Tactile (touch) develops first, then vestibular, followed by olfactory (smell), gustatory (taste), auditory (hearing), and visual (sight), with neuroprotection for each system highlighted by Altimier and Phillips (2016). Motor function also begins before birth and is the result of coordination between neurodevelopment and muscular development. State regulation patterns after birth are individual; however, attentional abilities are reflective of the infant's increasing ability to habituate to the environment (Volpe, 2018).

The development of the brain, both structure and function, is shaped by the influence and interaction of four major factors: genetic endowment, internal or endogenous stimulation and sleep, external experiences and stimulation of the sensory organs, and the environment. The brain architecture, cell differentiation, cell migration, primary or initial cell location, and response to initial stimulation are directed by the genes or genetic endowment. Outside stimulation of the environment can influence or alter the expression or effect of a given gene. Epigenetics is changing the interpretation of "genetics" in relation to "environment," in that the genetic code is not exclusively responsible for the "destiny" of a child's development; environment also has a role in child development. Gene and environment interact over a lifetime and influence maturation of neural circuits and shape changes in physical and mental development. This property, called brain plasticity, is more prominent in early postnatal periods ("critical periods"), which are specific time windows when neural circuits display a heightened sensitivity in acquiring instructive and adaptive signals from the external environment. These periods are not a simple maturation process but represent a complex developmental system that involves different functions (visual, auditory, somatosensory, cognitive ones) and region-specific time courses within specific functional circuits (Inguaggiato, Sgandurra, & Cioni, 2017).

Spontaneous brain activity that occurs in the absence of outside stimulation during fetal neurodevelopment (internal or endogenous stimulation and sleep) occurs primarily during the last 20 weeks of gestational life. External experiences and stimulation of the sensory organs occur with each sensory system. The initial stimulation is internal or endogenous, but at a critical or sensitive point in development, outside stimulation and experience are needed for further development. Four components of the environment influence fetal, infant, and child development. These are the physical, chemical, sensory, and social/emotional environments. Events and stimuli from each of the four environments are capable of altering the course and outcome of developmental processes, which can be positive or negative (Graven & Browne, 2008).

Preterm infants in the NICU experience a very different pattern and type of sensory input than they would encounter in utero, and different from what the brain is expecting at any given GA. This creates a mismatch between the sensory environment of the infant and the requirements of the CNS for growth and development. Two types of neural plasticity have been proposed: experience-expectant and experience-dependent (Romeo et al., 2018; Rose & Bonhoeffer, 2018). Experience-expectant plasticity is linked to the brain's developmental timetable. Thus, specific sensory experiences and input are needed at specific times for neural development and maturation. Altered sequences or types of sensory input can modify or disrupt development. Experience-dependent plasticity involves interaction with the environment to develop specific skills for later use. This form of plasticity involves memory and learning and allows development of flexibility, adaptation, and individual differences in social and intellectual development.

The cerebellum is also vulnerable to insults from the early environment. The cerebellum is important in cognition and interconnections between different areas of the brain, including the thalamus, parietal lobe, and prefrontal cortex. The cerebellum undergoes a critical growth spurt from 24 to 40 weeks' gestation. This

spurt includes an increase in dendritic arborization, which is complete earlier than many other areas of the brain (see Chapter 15, Neurologic System). Insults may lead to altered cognitive function, language development, and behavioral development seen in some preterm infants (Bouyssi-Kobar et al., 2018; Brossard-Racine, du Plessis, & Limperopoulos, 2015; du Plessis Limperopoulos, & Volpe, 2018).

FETAL AND NEONATAL SENSORY DEVELOPMENT

The sensory system develops in a specific sequence: somatosensory (tactile and proprioceptive), vestibular, chemoreceptive, auditory, and visual. During fetal life, there is a lack of competing stimuli during rapid maturation of each system. For example, the infant develops chemoreception before the structures for hearing and vision are in place and after somatosensory and vestibular function has matured. Similarly, the hearing maturation in the fetus is most rapid during a time when vision is still immature and in an environment where vision is not being stimulated by light. Animal studies have demonstrated that out-of-sequence stimulation of one system interferes with development of not only that system but also other systems that are still immature. For example, in animal models inappropriate visual stimulation while hearing and vision are still developing may alter not only vision but also hearing development (Graven, 2011; Lickliter, 2011).

Tactile/Proprioceptive

Somatosensory and vestibular sensations mature early. The first sense to emerge during ontogenesis, around 8 weeks of gestation, is touch (Hooker, 1952). The developing fetus is constantly touched by its environment, the placenta, the umbilical cord, amniotic fluid, and the uterine surface, and touches its own body passively or actively as self-initiated movements develop. From 26 weeks of gestation, the fetus starts actively responding to vibration stimuli with HR acceleration (Kisilevsky, Muir, & Low, 1992) and increased movement rates (Kisilevsky, Gilmour, Stutzman, Hains, & Brown, 2012). Their reactivity to vibration steadily increases and then stabilizes by 32 weeks of gestation (Werchan, Baumgartner, Lewkowicz, & Amso, 2018).

The fetus prefers to touch body areas that are densely innervated and are more sensitive, such as the skin of the face with rich trigeminal innervation. Hand-to-face interaction appears early on around the mouth by 2 months of GA; hands become touch sensitive by 10 to 11 weeks. Nociceptors are found by 11 weeks, appearing first in the face, palms, and soles, are seen in areas such as the trunk, arms, and legs by 15 weeks, and are abundant by 20 to 22 weeks (Borsani, Della Vedova, Rezzani, Rodella, & Cristini, 2018).

Vestibular

Vestibular stimulation is mediated by receptors in the ear that detect changes in directions and rate of head movement and rotation. Vestibular system maturation reaches structural maturation by 14 to 20 weeks' gestation, with responses to vestibular stimulation seen as early as 25 weeks' gestation (Blackburn, 2018; Borsani et al., 2018). Fetuses display an arousal response to maternal "tactile stimulation," that is, when the mother touches her abdomen, and in particular during the third trimester, fetuses increase some of their movements as a response to the touch of the mother on her abdomen (Marx & Nagy, 2015). This differential response of the older fetuses might be due to the maturation of the CNS. During the third trimester of pregnancy, the CNS continues the maturation, neuronal differentiation, lamination, and the distribution of the thalamocortical axons. It is between the 26th and 28th weeks of gestation that the peripheral nervous system connections with the CNS become functional, which, in turn, allows the fetus to process and to react to external somatosensory and pressure stimuli.

Smell/Olfactory and Taste/Gustatory

Smell and taste are powerful sensory inputs that develop during fetal life and are important in the transition to postnatal feeding (Bloomfield, Alexander, Muelbert, & Beker, 2017). Olfactory receptor neurons are found in preterm infants as early as 24 to 27 weeks of gestation, and preterm neonates regularly respond to olfactory stimuli after 28 weeks' gestation (Sarnat, Flores-Sarnat, & Wei, 2017). Neonatal olfactory reflexes are most constant in wakefulness and light (active) sleep, but responses in deep (quiet) sleep may be diminished or absent. **Emergency Alert: Sedation induced by many medications, particularly antiepileptic drugs, also may suppress olfactory reflexes** (Sarnat et al., 2017). It is estimated that the mature human brain can discriminate a trillion odors (Bushdid, Magnasco, Vosshall, & Keller, 2014).

Olfaction is not only involved in guiding the human newborn to the nipple, but it also establishes infant attachment and parental bonding, and regulates child and adult social interactions (Bennett et al., 2017). In addition to the importance of smell in recognition of the mother, smell and taste initiate metabolic pathways that promote digestion and metabolic control (Bloomfield et al., 2017). Olfaction stimulates the digestive tract, improving tolerance of enteral feeds. Longer exposure of tube-fed preterm babies to smell or to smell and taste has been shown to shorten time to full enteral feeds as well as decreased hospital stay (Beker, Opie, Noble, Jiang, & Bloomfield, 2017; Bloomfield et al., 2017). A recent study by Cao Van et al. (2018) suggested that olfactory stimulation promoted a faster switch from feeding tube to satisfactory oral feeding in premature newborns, leading to a shortened length of hospital stay. The odor of maternal milk also appears to have an analgesic role in newborns (Zhang, Su, Li, & Chen, 2018).

Additionally, olfaction has been shown to impact the central appetite-regulatory pathways. Information on odor is passed from the olfactory bulbs to the primary olfactory cortex via the lateral olfactory tract. Functional MRI studies in adults demonstrate activation of the lateral and anterior orbitofrontal gyri (Adam-Darque et al., 2018). From there, information passes to the orbitofrontal cortex, where conscious perception of smell occurs, and also to the hypothalamus via the amygdala of the limbic system. Near-infrared spectroscopy (NIRS) studies in term and preterm neonates have demonstrated changes in cerebral oxygenation in the prefrontal area in response to odor stimulation This is assumed to reflect changes in blood flow and, therefore, neuronal activity (Aarnoudse-Moens, Weisglas-Kuperus, van Goudoever, & Oosterlaan, 2009).

The smell experience can involve the costimulation of the olfactory and trigeminal subsystems, both of which are functional before the end of the second trimester of gestation. The branches of the trigeminal nerve are sensitive to chemo stimulants of higher concentrations, which are involved in the perception of different trigeminal components of odors like the coolness, the pungency, and the irritating sensation triggered by alcoholic vapors. Ambient odors in the hospital environment can modify the physiologic and behavioral stability of preterm infants. Exposure to NICU odors (NO) can trigger cerebral hemodynamic changes in the olfactory cortex. Most of these NOs are perceived as irritants and trigger the

trigeminal system (Lagercrantz & Changeux, 2010). Very preterm infants react to and cortically process NOs, with strong trigeminal properties, which triggers the trigeminal pain system inducing pain behaviors (Frie, Bartocci, Lagercrantz, & Kuhn, 2018).

Numerous artificial odors, originating from skin care or cleaning products, from handwashing or from the decontaminated hands of caregivers or parents, are introduced into incubators. Because of their chemical composition and their olfactory and/or trigeminal properties, some of them are more irritating than others. The most commonly reported smell is released from the hands after disinfection with aqueous alcohol solutions. These products emit an alcoholic vapor, especially when the hands are insufficiently dried, and the dissemination of volatile fragrances strongly stimulates the trigeminal subsystem.

In the NICU, preterm infants are not only exposed to strong odors from healthcare products but also to air-jet–induced trigeminal stimuli from respiratory devices, such as those that provide nasal continuous airway pressure. Repeated exposure to these trigeminal odors plays a role in the habituation process. Kuhn, Zores, Astruc, Dufour, and Casper (2011) found that infants' olfactory and/or trigeminal systems were stimulated an average of 44 times a day if the baby was breathing room air, or 60 times a day if he/she was mechanically ventilated. At their peak, newborns breathing room air and those mechanically ventilated were exposed 146 and 206 times a day, respectively. Very preterm infants were exposed to olfactory stimuli an average of 1,320 and 1,800 times during their first month of life (Kuhn et al., 2011).

Habituation to olfactory stimuli is considered a simple form of nonassociative learning, during which the response to nonrelevant stimuli declines (Freedman, Radhakrishna, Escanilla, & Linster, 2013). Research indicates that trigeminal and olfactory stimuli can induce habituation (Flohr et al., 2015).

The emotional content of odors is highly plastic, as it is modifiable by a few hours of mere exposure or by the pairings with reinforcers provided by caregivers (W. Liu et al., 2007). It has been shown that people can recall a scent with 65% accuracy after 1 year, because smells are processed by the same part of the brain that handles memories and emotions.

Enhancing the olfactory environment can be achieved through the utilization of olfactory neuroprotective interventions (NPIs). These positive NPIs may include maternal breast scent via a breast pad or a soft-scented cloth. Skin-to-skin contact (SSC) helps support the discrimination of maternal breast scent. Mouth care provided with mother's milk helps the infant recognize the mother's smell and associate that smell with food and feeding when the infant is able to nipple feed. **Quality and Safety: Minimizing an infant's exposure to irritating odors in the NICU environment through a more cautious use of odorous healthcare products, perfumes, colognes, or aftershaves is considered essential for the care of infants.** Alcohol wipes should not be opened near an infant's head, and preferably, should be opened outside of the incubator environment. The odor of tobacco on caregiver/family bodies and clothing should be avoided. NICU staff and parents should be educated on this topic to prevent olfactory overstimulation (Altimier & Phillips, 2016; Kuhn et al., 2011).

The taste buds appear by 7 to 8 weeks and receptors by 16 weeks. By term, the infant has adult numbers of receptors. Nasal chemoreceptors develop from 7 to 20 weeks' gestation and respond to the fragrant molecules in amniotic fluid. The composition of amniotic fluid varies with maternal diet and bathes both oral and nasal chemoreceptors. Exposure to substances from maternal diet may play a role in programming later dietary preferences. Fetal swallowing rates change with exposure to different taste in amniotic fluid. Preterm infants respond to different tastes and smells by at least 28 weeks' gestation and possibly earlier. Nutrient odor may also influence nonnutritive sucking. Term infants are able to detect, localize, and discriminate a variety of distinct odors and tastes. They respond preferentially to breast odors, their mothers' scents, and other odors associated with positive reinforcements (Beker et al., 2017; Bloomfield et al., 2017; Lipchock, Reed, & Mennella, 2011).

Olfaction and gustation are not only critical for the enjoyment of food, but also have important metabolic roles, initiating the cephalic phase response that sets in train secretion of hormones important for metabolism and digestion before any food is actually ingested (Bloomfield et al., 2017). Early colostrum administration in preterm babies has been determined to be safe, and some have reported increased rates of infants receiving breast milk as the majority of enteral feeds 6 weeks later (J. Lee et al., 2015; Snyder et al., 2017).

Consistent evidence supports the hypothesis of prenatal programming of postnatal specific appetites. Different mechanisms seem to program the developing brain in terms of acceptance or rejection of a given chemosensory stimulus that will later define feeding or searching patterns of a palatable substance (Faas, 2013). For example, extracellular dehydration during pregnancy is sufficient to induce a remarkable increase in the neonate's salt appetite that can persist until adulthood. Neonates are able to detect the smell of the amniotic fluid and of a milk formula with which they were fed. Yet, when both odorants are presented in a two-way preference test, the prenatal substrate elicits more behavioral orienting responses than the postnatal olfactory-related feeding substrate, demonstrating a significant neonatal preference for the prenatal odor (Faas, 2013). Children born preterm have been shown to respond positively to olfactory stimulation associated with their mother's breast milk (Yildiz, Arikan, Gozum, Tastekin, & Budancamanak, 2011).

Providing a pacifier with mother's milk has been shown to increase nonnutritive sucking, intake, and growth and to shorten the length of hospitalization (Foster, Psaila, & Patterson, 2016; Z. Greene, O'Donnell, & Walshe, 2016). When preterm infants were provided both the smell and taste of milk simultaneously, they had a significant improvement in milk tolerance and weight gain (Beker et al., 2017). Infants also demonstrate more suck attempts when looking at human faces in conjunction with maternal scent, indicating a potential link between social visual preference and suck behavior (Zimmerman & DeSousa, 2018).

Auditory

Auditory perception begins during fetal life and continues to develop until adolescence (Lahav & Skoe, 2014). The structures of the auditory system, including the inner ear and cochlea, are mature enough to support hearing by approximately 20 weeks' gestation. During fetal life, the ossicles (three small bones) of the middle ear cannot perform their amplifying, translational functions because outer, middle, and inner ears are all fluid filled. At this time, the hair cells of the inner ear are stimulated directly by vibrations of the fetal skull. Bone-conducted stimulation of the cochlear hair cells produces actual hearing and is not a "separate sense." The consequence of transmission of sound waves in this manner is similar to an adult hearing loss of about 40 dBA (Zubiaurre-Elorza et al., 2018).

With maturation and experience, as each hair cell in the cochlea becomes associated with a specific counterpart in the auditory brain centers, the individual frequencies are organized precisely in both inner ear and brain, just as the keys on a piano (Appler & Goodrich, 2011).

Fetal hearing is thought to begin at 24 to 25 weeks. In preterm infants, auditory evoked potentials can be recorded and responses to sound observed as early as 25 to 26 weeks (Z. D. Jiang & Chen, 2014). Auditory cortex development begins by the second trimester but is not mature until later in childhood. Maturation of the cochlea and auditory nerve increases from 28 weeks on. Initially, the hearing threshold is around 65 decibels with a range of 500 to 1,000 Hz, increasing with increasing GA to a threshold of 20 to 25 decibels and range of 500 to 2,000 Hz by term (Zubiaurre-Elorza et al., 2018). Between 28 and 34 weeks, the preterm infant develops the ability to begin to orient to sound, turning the head in the direction of an auditory stimulus, and showing evidence of arousal and attention (Lahav & Skoe, 2014; McMahon, Wintermark, & Lahav, 2012; Philben, 2017). During the third trimester, the cochlea continues to mature and develop its ability to hear sounds across frequencies. The hearing threshold decreases with GA. Infants prefer their own mothers' voices even before birth (Kisilevsky, 2016).

Visual

The eyes begin to develop early in the embryonic period (24–26 weeks) but continue anatomic and functional maturation into the third trimester and early infancy (Graven, 2011). Vision is the least mature sense at birth, and even full-term infants undergo significant continued maturation during infancy. The lens is initially cloudy; the second layer of the lens forms by 30 weeks, followed by the third and fourth layers. Immature infants are very myopic, and cone differentiation does not begin until after 30 to 32 weeks. Infants born extremely preterm (<27 weeks' GA) have reduced function of both rods and cones when compared with children born at term (Graven, 2011; Molnar, Andréasson, Larsson, Åkerblom, & Holmström, 2017). In extremely premature infants, there seems to be an arrest in the normal retinal development that appears to persist later into childhood and adolescence, with reduced rod and cone functions. Rod and cone disorders are known to result in night vision problems, loss of the visual field, reduced color vision, and photophobia (Molnar et al., 2017). Prematurely born infants and children born small for gestational age (SGA) are also at an increased risk of face recognition impairment and face delayed memory, both in early and late childhood, independently of their GA at birth (Perez-Roche et al., 2017).

By 22 weeks' gestation, the layers of the retina have formed rod differentiation, and retinal vascularization begins by 25 weeks' GA; myelination of the optic nerve begins at 24 weeks. By 26 weeks, visual cortex neurons are in place with rapid development of visual neuronal connections and processes between 28 and 34 weeks' gestation (Graven & Browne, 2008). Prior to 28 weeks, infants have little pupillary response. This response becomes more mature but is still sluggish between 30 and 34 weeks, and is mature by 36 weeks. The visual cortex undergoes rapid dendritic and synaptic development between 24 and 34 weeks. By 34 to 36 weeks, the visual cortex is similar to that of the term infant, but still immature, with significant development in the first year after birth (Graven, 2011; Neil & Inder, 2018).

Multisensory Processing

The newborn human arrives into a startlingly complex sensory world in which it is inundated with information from all of the sensory systems simultaneously: touch, proprioception, vestibular input, smell, taste, audition, and vision, all of which provide information about partially overlapping features of objects and events, in almost uniformly varying neural codes. If, as infants or adults, we are to perceive a spatiotemporally coherent and meaningful environment from this multisensory mixture, and furthermore make efficient use of sensory information, our developing sensory systems need to determine how, when, and when not to combine stimuli across modalities.

Until recently, the classic view of multisensory processing has been that cortical regions are inherently specialized, for example, sound information is only processed in the temporal cortex, and multisensory processing only occurs when modality-specific information reaches higher-order association areas. This view has been challenged by the alternative that (1) the neocortex is largely a multisensory organ, (2) occipital and temporal cortices have been found to respond to both auditory and visual stimulation, and (3) multisensory interactions occur not only in higher-order association areas, but also concurrently in the midbrain and in sensory-specific cortices (Werchan et al., 2018). Functional NIRS (fNIRS) was utilized to show that temporal and occipital cortices were functionally coupled and that the extent of this coupling during a synchronous, but not an asynchronous, audiovisual event predicted whether occipital cortex would subsequently respond to sound-only information. These data suggest that multisensory experience may shape cortical dynamics to adapt to synchronous multisensory information in the environment. These findings provide new insights into the developmental precursors of the cortical dynamics that occur whenever infants experience multisensory information in their environment. Furthermore, the findings show that exposure to concurrent (i.e., temporally synchronized) multisensory events in early infancy rapidly recruits responsiveness to the visual and auditory attributes that characterize everyday multisensory events. Since normal multisensory experiences consist of integrated audiovisual attributes, it is likely that long-term, everyday, integrated, multisensory experience tunes the occipital cortex to also respond to unrelated salient sounds by the time we become adults (Werchan et al., 2018).

Quality and Safety: Defining types, timing, and frequency of sensory-based NPIs that prevent harm and optimize infant outcomes can guide environmental modifications and individualize care needed for these vulnerable infants and their families.

A NPI that protects all of the senses is that of SSC, which provides the infant with tactile, vestibular/kinesthetic, olfactory, auditory, and at times visual sensory inputs. SSC in the NICU setting has been associated with increased physiologic regulation, improved oxygen saturation levels, and decreased length of NICU hospital stay. Dr. Nils Bergman (2015) and others have made a strong case for the neurosupportive nature of SSC between newborn infants and their parents. "The optimal environment for any newborn, but particularly for the premature infant, is skin-to-skin contact with mother (or father), also known as kangaroo care" (Bergman, 2015). For all primates, the mother's womb is the normal environment where development begins and the mother's body is the normal environment where development continues after birth. In SSC, the newborn receives salient and expected sensory inputs that lead to physiologic regulation and a secure attachment, processes that are both mediated by the limbic system and essential for normal development. Dr. Bergman (2015) asserts that SSC is, therefore, not a care practice but is a place where all neuroprotective care practices would ideally be done. SSC is not an intervention but is our biologic default.

Because of the well-documented high level of stress to the newborn caused by separation from the mother, Dr. Bergman (2014) recommends zero separation. There are situations whereby a mother and infant must be separated, particularly if the mother is ill or unable to be present; however, zero separation is the biologic default and should be the goal. Bergman et al. have provided convincing evidence in two randomized controlled trials that healthy

preterm infants are more physiologically stable in SSC with their mothers during the first 6 hours after birth than separated from their mothers while inside an incubator (Luong, Nguyen, Thi, Carrara, & Bergman, 2016).

NEONATAL NEUROBEHAVIORAL DEVELOPMENT

In the past decades, our knowledge of early childhood development has been dramatically altered by an avalanche of new research in neurobiology, behavioral, and social sciences that has led to major advances in understanding the conditions that influence the well-being and early development of infants and young children. A deeper understanding of the importance of early life experience and the highly interactive influences of genetics and the environment on the developing brain has deepened our understanding of the early years. Attention to the powerful influence of the role of early relationships and the capabilities of the development of emotions in young children has finally taken center stage. Add to this the changes in our social structures and changes in our families, culturally and economically, including the shifting of parenting roles, along with changes in the workplace and in child care services for the very youngest, and the continuing high levels of economic hardship in many families, and it becomes clear that a professional review and rethinking of policy and practice requires dedicated attention and a thoughtful response.

Parents become the "coregulators" or extensions of the infant's internal regulatory systems working to regulate function in the infant just as he or she is working toward the same (Hofer, 2010). This requires of caregivers the ability to read and understand the infant's needs and the sensitivity, knowledge, and energy to respond in helpful, satisfying ways. Parents must establish "regulatory connections" with young children and then shift the independent task of regulation gradually over to them, one domain and one day at a time, being forever watchful that the balance in the child is not seriously disrupted. The ways that infants and young children learn about self-management involves behavioral, emotional, and cognitive self-control, which must evolve for competent functioning.

During early child development (birth to 6 years), children become consistently independent and develop the ability to manage their own behavior. Two concerns related to these developmental processes are sleep behavior and crying behavior. Infants with serious medical conditions that require intensive care, including preterm or medically fragile infants, have more difficult transitions to regulatory competence. Immature sick newborns are much less able to organize and stabilize sleep, waking, and feeding. They tend to be unpredictable, to cry more, and to be fussier. They tend to make less eye contact, smile less, vocalize less, and show less positive affect, and they are generally more difficult and harder for parents to read. During the first 3 months after birth for a full-term newborn, the infant depends on the relationship with the primary caregiver. The infant takes on an extensive undertaking that requires that he or she learn to get to sleep without help, stop crying when consoled, respond to the caregiver, and establish day–night, wake–sleep rhythms. Once the rapid developmental changes of the first 3 months of life after full-term birth are accomplished, the infant faces another level of regulation in controlling his or her emotions and behavior. Followed by the regulation of attention and the regulation of mental processes, a process known as executive function emerges and involves the ability to think, retrieve, and remember information, solve problems, and engage in complex activities, which involve oral language, reading and writing, math, and social behavior.

Early experiences clearly affect the development of the brain. Development begins during early fetal life and lays a foundation for all that is to follow. Als (1982, 1986) and colleagues developed a model, the Synactive Theory of Development, for understanding the organization of neurobehavioral capabilities in the development of the fetus and newborn infant. This model describes emerging behavioral organizational abilities of the neonate. This model is based on the assumption that infants actively communicate via their behavior, which becomes an important route for understanding thresholds of stress or stability. Behavior of the infant not only is the main route of communication but also provides the basis for the structure of developmental assessment and provision of developmentally appropriate care (Als, 1986).

This synactive theory of development provides a model through which one can specify the degree of differentiation of behavior and the ability of infants to organize and control their behavior. The focus is not on assessment of skills, but on the unique way each individual infant deals with the world around her or him. The synactive theory of development specifies the range of neonatal behavior as the infant matures as well as the ability of the infant to regulate behavior. This model is based on the assumption that the infant's primary route of communicating both functional stability and the limits for stress is through behavior. For example, infants who extend their limbs after being turned to supine to have their diaper changed may be communicating that they cannot control their limbs and movement in that position. Containing the limbs of these infants helps them to develop control and reduces stress over the loss of control (Als, 1986; Lawhon & Als, 2010).

Infants are seen as being in continual interaction with their environment via five subsystems: autonomic/physiologic, motor, state/organizational, attentional/interactive, and self-regulatory. These subsystems mature simultaneously, and within each subsystem a developmental sequence can be observed. Thus, at each stage of development, new tasks and organizations are learned against the backdrop of previous development. The subsystems are interdependent and interrelated. For example, physiologic stability provides the foundation for motor and state control; the infant cannot respond socially to caregivers until motor and state control is achieved. The loss of integrity in one subsystem can influence the organization of other subsystems in response to environmental demands. In the preterm, less organized infant, the systems interplay, continuously influencing each other. In the healthy full-term infant, these systems are synchronized and function smoothly. Thus, full-term infants can regulate their autonomic, motor, state, and attentional systems with ease and without apparent stress. However, less mature infants tend to be able to tolerate only one or minimal activity at a time and may easily lose control if their individual thresholds are exceeded. Instability in the autonomic system can be seen in the pattern of respiration (pauses, tachypnea), color changes (red, pale, dusky, mottled), and various visceral signs (regurgitation, twitching, stooling). Organization of the motor system is assessed by observing the infant's tone and posture (flexed, extended, hyperflexed, flaccid); specific movement patterns of the extremities, head, trunk, and face; and level of activity. The development of motor responses is closely linked to state organization (Als et al., 1994).

The state system is understood by noting the available range of states of consciousness (sleep to arousal, awake to alert, crying), how well each state is defined (in terms of behavioral and physiologic parameters), transitions between states, and the quality of organization of these states.

States may be poorly defined at first, especially in the immature infant (Whitehead, Laudiano-Dray, Meek, & Fabrizi, 2018). For example, jerky body twitches and fussing may accompany sleep and wake states. In addition, the immature infant may not be able to achieve clearly defined states as seen in the mature infant (see section on Sleep–Wake States). Initially, preterm infants tend to be unstable and fragile, with sudden changes in their autonomic, motor, and state systems. These infants often have minimal response to handling or other sensory input until a threshold is reached, then quickly develop a cascade of responses, ending in several color changes, flaccidity, bradycardia, and apnea. As the infant matures, the responses are more variable, and the infant is less likely to totally decompensate (Als, 1986). **Quality and Safety: Changes within the autonomic, motor, and state systems at all stages of development are not just reactions to stress and overstimulation, but can signal that the infant's tolerance threshold has been exceeded. By recognizing these signs early, the nurse can intervene to prevent mild to severe decompensation.**

The attentional/interactive system involves the infant's ability to orient and focus on sensory stimuli, such as faces, sounds, or objects—that is, the external environment. This system also includes the range of abilities in states of consciousness: how well periods of alertness are defined and how transitions into and out of alertness are handled. At first, this alertness may be very brief, with a dull look or glassy-eyed stare. As this system matures, the infant is able to interact with greater ease and for longer periods. Social responsiveness requires that the infant have enough state control to sustain some awake and alert states (Als, 1986). The self-regulatory system includes behaviors the infant uses to maintain the integrity and balance of the other subsystems, to integrate the other systems, and to move smoothly between states. For example, some infants can tuck their limbs close to their body in an effort to gain control when stressed, whereas others seem to relax if they can brace a foot against the side of the crib.

In summary, the process of development appears to be that of stabilization and integration of some subsystems, which allows the differentiation and emergence of others that in turn provide feedback for the integrated system. In this process, the whole system is reopened and transformed to a new level of more differentiated integration, from which the next newly emerging subsystem can further differentiate and press to actualization and realization (Als, 1986). By observing and assessing the newborn infant's responses to the caregiver and other aspects of the environment across these five subsystems of behavioral functioning, one can develop and implement a plan of care to support the infant's emerging neurodevelopmental organization and reduce stress. The NICU staff, especially nurses, play a significant role in shaping the environment and making caregiving more responsive to infants. This requires careful observation and documentation of infant behavior as is given to physiologic status and development of an individualized plan of care. Infant responses to the environment will be influenced by factors such as state; basic needs (e.g., hunger); sensory threshold; parameters of the animate and inanimate environment, including readability, predictability, and responsivity; infant health status; and level of neurobehavioral maturity.

Infant behavioral responses include specific autonomic, motoric, and state cues, which indicate disorganization and stress and the need for immediate intervention, and stability and self-regulatory cues, which indicate that the infant is coping positively. Thus, cues provide information about an infant's needs and status, handling of sensory input, stress and sensory overload, tolerance for stimuli, and need for rest and time-out. Table 31.1 provides examples of infant cues.

TABLE 31.1

EXAMPLES OF INFANT NEUROBEHAVIORAL CUES

Stability Cues/Engagement Cues	Stress Cues/Disengagement Cues
Alertness, attention, orienting to people and objects	Altered vital signs (heart rate, respiratory rate)
Arm and leg flexion	Arching
Eyes open, alert	Color changes or visceral signs such as spitting
Grasping	Diffuse states, rapid state changes
Hand to mouth activity	Finger splay
Modulated states and state transitions	Flaccid or hypertonic tone
Modulated tone and movement	Frantic activity
Self-consoling activities	Grimacing
Stable vital signs, color	Hand to face or ear
Stable visceral and motor signs	Staring, averting gaze Tremors or jitteriness

Assessment of Neonatal Neurobehavioral Development

Developmental assessment of newborn functioning emerged with the awareness of the amazing capabilities of neonates. The newborn infant, who for years was thought to be nonreactive and incapable of social participation, is now seen as an active participant in social interaction and capable of self-regulation. Even with a greater understanding of newborn capabilities, researchers and clinicians have been unable to consistently predict the future course of an infant's development from early neurologic or behavioral assessments. Thus, there is no one comprehensive assessment tool for all infants (El-Dib, Massaro, Glass, & Aly, 2011). Historically, two types of neonatal assessments have evolved—the neurologic examination and the behavioral examination. The neurologic examination assesses the function of the CNS and typically includes assessment of motor tone and reflex behaviors within the context of infant state. The behavioral examination complements and elaborates on the neurologic assessment. An assumption underlying the behavioral examination is that the observable behavior of an infant is a reflection of his or her underlying neurologic status. The behavioral examination seeks to describe the quality of behavioral performance. More recently, these two forms of assessment have been combined into the neurodevelopmental or neurobehavioral assessment.

The neurodevelopmental examination is important because it yields a large pool of early observable behavior, including information about the infant's neurologic status and abilities to cope and

interact with the environment. In addition, data from this examination can assist the clinician in estimating maturity and in identifying and evaluating problems that could be precursors to later developmental problems. Because the neurodevelopmental examination provides an immediate basis for determining the status of the infant's development, the results can be used for planning intervention strategies as well as for screening for infants in need of further diagnostic assessments and early intervention.

Who Needs to Be Assessed?

All neonates and their caregivers can benefit from ongoing neurobehavioral assessment. These assessments provide information on the infant's behavioral capabilities, interactive qualities, and adaptations to the extrauterine environment. This information can be used in planning care, developing individualized intervention strategies, modifying care as the infant matures, and parent teaching and other activities to promote parent–infant interaction. However, for some infants, neurodevelopmental assessment is critical for documentation of neurodevelopmental status, screening, and early case finding.

Certain groups of infants are at increased risk for developmental disabilities and later cognitive impairment (Adams-Chapman et al., 2018; Younge et al., 2017). Infants that fall into the highest risk category include very low birth weight (VLBW) infants and those with significant intracranial hemorrhages. Preterm infants with known sensory impairment and chronic illness are also at risk for later cognitive dysfunction. Infants with respiratory distress syndrome (RDS) are at greater risk if they also develop CLD. Severe BPD is generally associated with a prolonged and complicated hospital course, increasing the risk for later neurodevelopmental problems. Surgical NEC is also associated with adverse neurodevelopmental outcome (Adams-Chapman et al., 2018). Preterm infants as a group are at greater risk than term infants of comparable postmenstrual ages. Preterm infants often exhibit manifestations of altered brain organization, including disrupted sleep, difficult temperament, both hyperresponsivity and hyporesponsivity to sensory input, prolonged attention to redundant information, inattention to novel stimuli, and poor quality of motor function (Chorna, Solomon, Slaughter, Stark, & Maitre, 2014). These precursors of learning problems in school are not fully explained by either the severity of illness among preterm infants or later conditions in the home environments.

Neurobehavioral Assessment in the NICU and Early Infancy

For high-risk newborns, early assessment of neurobehavior that accurately predicts neurodevelopmental outcome is the first step toward determining early intervention needs. Neurobehavioral assessment can be performed at several different levels and is an essential part of comprehensive care of the high-risk infant in the NICU. Individuals such as Brazelton, Als, and their colleagues have sought to assess preterm and full-term newborn behavior and adaptations. Their work is based on an understanding of newborns as competent individuals with emerging developmental processes, who are engaged in dynamic interactions and negotiations with their environment. As a result, several tools have been developed to describe and quantify neurobehavioral organization of both preterm and full-term newborns.

Tools for neurobehavioral and neuromotor assessment include Amiel-Tison neurological assessment at term (ATNAT), assessment of preterm infants' behavior (APIB), Brazelton neonatal behavioral assessment scale (NBAS), neonatal intensive care unit network neurobehavioral scale (NNNS), Prechtl's assessment of general movements (GMs), neurobehavioral assessment of the preterm infant (NAPI), Dubowitz neurologic assessment of the preterm and full-term infant (Dubowitz), neuromotor behavioral assessment (NMBA), and the test of infant motor performance (TIMP; Als, Butler, Kosta, & McAnulty, 2005; Als, Lester, Tronick, & Brazelton, 1982; Amiel-Tison, 1976; Brazelton & Nugent, 2011; Campbell, 2005; Carmichael, Burns, Gray, & O'Callaghan, 1997; Dubowitz, Ricciw, & Mercuri, 2005; Einspieler & Prechtl, 2005; El-Dib et al., 2011; Korner & Constantinou, 2001; Lester, Tronick & Brazelton, 2004; Noble & Boyd, 2012; Snider et al., 2005). Several assessments for neurobehavioral assessment are described further. A recent analysis found that all of these measures "demonstrated adequate content and construct validity" (Noble & Boyd, 2012). The authors concluded that in the absence of a criterion standard for neonatal neuromotor assessments, the NNNS and APIB have strong psychometric qualities with better utility for research. Similarly, the GMs, TIMP, and NAPI have strong psychometric qualities but better utility for clinical settings. The GMs and TIMP showed the strongest associations with neurodevelopmental outcome (Craciunoiu & Holsti, 2017). The tools that are described here are the NBAS (Brazelton & Nugent, 2011); the APIB (Als, 1982; Als et al., 2005); the NNNS (Lester & Tronick, 2004); and the NAPI (Korner & Constantinou, 2001; Snider et al., 2005).

Brazelton Neonatal Behavioral Assessment Scale. The NBAS is a comprehensive behavioral assessment of the healthy full-term neonate containing six clusters with 28 behavioral items and 18 reflex/motor items. The NBAS combines evaluation of basic reflex responses with the integration of motor capacity, state regulation, and interactive abilities (Brazelton & Nugent, 2011). Infants are followed through the various states of sleep, arousal, and wakefulness and assessed on their ability to self-regulate in the face of increasingly vigorous activity. A primary focus is observation of the infant's individual and unique ability to respond to outside stimulation while regulating responses to and coping with pleasurable or stressful situations. The infant's best performance is scored. The results are an assessment of the infant's ability to (1) organize states, (2) habituate to external stimulation, (3) regulate motoric activity in the face of increasing sensory input, (4) respond to reflex testing, (5) remain alert and oriented to visual and auditory stimuli, (6) interact with a caregiver, and (7) self-console.

The NBAS has been used in numerous studies of neonatal behavior, including investigations of cross-cultural differences, characteristics of drug-addicted infants, effects of obstetric medication, and aspects of maternal–infant interaction (Brazelton & Nugent, 2011). An especially valuable use of the NBAS for nurses and other clinicians is as an intervention. For example, when an NBAS is performed in front of the infant's parents, the parents become increasingly aware of and amazed at the remarkable abilities of their infant. An understanding of their newborn's capacity to interact visually, turn to their voices, regulate state and motor activity, and self-console expands the parents' perception of the infant as a unique, competent individual and enhances parent–infant interaction (Brazelton & Nugent, 2011).

The newborn behavioral observations system (NBO) is another tool from this group that provides a series of 18 neurobehavioral observations for clinicians and parents to observe the infant together and determine the infant's capabilities and needs. The NBO is a neurobehavioral observation tool designed to sensitize parents to infants' capacities and individuality and to enhance the parent–infant relationship by strengthening parents' confidence and practical skills in caring for their children. The NBO's focus on

relationship building is intended for infant mental health professionals who strive for a relational, family-centered model of care versus a pathology-based model (Nugent, 2007; Nugent, Bartlett, Von Ende, & Valim, 2017).

In response to a need to identify the preterm infant's neurobehavioral repertoire, the NBAS was expanded and modified for use with low birth weight infants. Items were added to the original scale, including difficulty of elicitation of alerting, degree of facilitation necessary to support the infant, control over stimulation, robustness, endurance, degree of exhaustion, quality of alertness, and balance of tone (Brazelton & Nugent, 2011; Nugent et al., 2017). These subscales are also useful in describing at-risk full-term infants, such as drug-exposed infants.

Assessment of Preterm Infant Behavior. The APIB was developed to respond to the need for a more discrete and comprehensive assessment of preterm infant functioning. The APIB is based on the Synactive Theory of Development, which describes the early behavioral organization and development of the neonate. The APIB is particularly useful for the preterm and full-term high-risk infant from birth to 44 weeks' postmenstrual age. The purpose of this assessment is to determine organization of the CNS and how infants cope with the intense environment of the NICU. The focus of the APIB is not only assessment of skill performance or specific responses to various stimuli, but also the unique way each individual infant deals and interacts with the world around him or her. As described previously, infants are seen as being in continual interaction with their environment and as communicating their responsiveness via five subsystems (autonomic, motor, state, attentional, and self-regulatory; Als, 1986; Als et al., 2005).

The APIB consists of six packages or sets of maneuvers adapted from the NBAS. The packages are organized to provide increasing input with which the infant must react, starting with stimulation while the infant is asleep to assess habituation. Subsequent packages move through maneuvers ranging from low and medium tactile manipulations to high tactile and vestibular handling. Throughout the assessment, the infant is continually observed for responses related to each of the five subsystems. Thus, the infant is observed and scored on each of the five subsystems and for examiner facilitation (ability to use support) before, during, and after administration of the items in each package. These responses are called the system scores and range on a nine-point scale from organized (1) to disorganized (9).

The APIB has been used for research and clinical purposes. As a research tool, it has been used to describe and identify neonatal behavioral organization in preterm and other high-risk infants (Als, 1986; Als et al., 1982, 2005). Clinically, psychologists, neonatologists, neurologists, nurses, developmental specialists, and therapists have used the APIB to provide consultation in the NICU regarding developmental interventions for specific infants. The APIB has recently been used to examine the neurobehavioral functioning in preterm infants diagnosed with IVH grades III and IV (Barbosa & Powlesland, 2018). The APIB is useful in determining an infant's degree of fragility and ability to tolerate different caregiving parameters. By measuring maturity of the five subsystems, one can determine maturity of each system and tolerance for handling as well as generate developmental care plans specific to each infant at that stage of development. The APIB is also useful in assessing infant readiness for changes in caregiving routines and in the physical and social environment. Assessing the degree of fragility and tolerance for activities can provide an invaluable piece of information about the infant's functional level and assist staff in making decisions about whether to protect the infant or to advance to the next level of care, as is illustrated in the following case.

A 28-week preterm infant had just been extubated and graduated to oxygen by nasal cannula and moved from the open bed to the incubator. An APIB revealed a responsive infant but one who was working extremely hard to regulate his system amid two major changes: extubation and change of physical environment. Although successful regulation was noted, it was also apparent that the infant was at maximal capacity in organizing himself. He showed efforts to suck and maintain hand to mouth; however, he could not maintain these postures for long without help. It was apparent that the infant's threshold had been reached and that any more change or stress would have caused a loss of control in his system's integrity. Immediately after the assessment, the neonatologists ordered nipple feedings once a day. With this new demand, the examiner felt that this infant would exceed his threshold and be unable to regulate himself. The developmental specialist recommended waiting 1 week for the infant to stabilize and to integrate his new experiences before taking on any new demands. This recommendation was not followed, and feeding continued. Two days later, the developmental specialist returned and noted that the infant had a trial of nippling. He had desaturated, become bradycardic, required bag-mask ventilation, and was considered to have "flunked" nippling. The order was terminated, with the plan to try again in a week. When feeding was reordered a week later, the infant tolerated it well.

Training in the APIB (www.nidcap.com) is extensive and requires knowledge of the NICU, including care practices and routines, staffing patterns, and typical infant experiences in that setting as well as physiologic limitations and medical problems. Interrater reliability, and concurrent and construct validity have been reported (Als et al., 2005).

Neonatal Individualized Development Care and Assessment Program. The NIDCAP incorporates several levels of developmental training in assessment techniques and intervention planning for high-risk preterm and full-term infants. Included in this program is an observation tool (level 1 NIDCAP naturalistic behavioral observation), which is extremely useful for the NICU nurse. This assessment involves an observation of the infant before, during, and after a routine caregiving episode. It provides the NICU nurse with information on the infant's individual cues for both stress and stable, organized function. The nurse can then structure the infant's experiences, including caregiving interventions and the physical and social environment, to support the infant at the current level of tolerance. This support includes an awareness of the timing of caregiving events, sequencing events, and interventions to prevent or reduce stress as well as to enhance stable behavior. Support for parents in understanding their infant's unique behavior and needs is also provided (Lawhon & Als, 2010; Lawhon & Hedlund, 2008).

NIDCAP training involves didactic sessions and clinical demonstration of the observational tool, after which the trainee completes a specified number of observations on infants of different GA, postbirth age, and health status. This observation period is followed by an assessment of reliability for certification by the trainer.

NNNS. The NNNS was developed for use with preterm and other at-risk infants such as those with perinatal drug exposure to measure the process of neurobehavioral organization, capturing both the normal range of behaviors and those present in high-risk infants (Lester et al., 2004; Lester & Tronick, 2004). The NNNS builds on several earlier assessments, including the neurologic examination of the full-term newborn infant (Prechtl, 1974; Prechtl & Beintema, 1968), abstinence syndrome scoring, and several of the assessments described in this section (NBAS, APIB, and NAPI;

Lester & Tronick, 2004). The NNNS can be used with infants from about 30 weeks' gestation to 46 to 48 weeks' postmenstrual age and assesses both behavioral function and neurologic integrity: (1) neurologic status (active and passive muscle tone, primitive reflexes, and CNS integrity); (2) behavioral state, sensory, and interactive responses; and (3) stress/abstinence scale. Items are administered only if the infant is in an appropriate state for that item. Administration of the assessment takes about 30 minutes (Lester & Tronick, 2004; Lester et al., 2004). More recently, a complex pattern of stability and change emerged when comparing NNNS summary scores from birth to 1 month. Orienting, regulation, and quality of movements significantly increased, whereas lethargy and hypotonicity significantly decreased, demonstrating that birth-to-1-month changes in NNNS performance suggest improvements in neurobehavioral organization (Provenzi et al., 2018). These data are useful for research purposes and for clinical evaluation of neurobehavioral performance in both healthy and at-risk 1-month-old infants.

NAPI. The NAPI is an assessment developed at Stanford University to assess the differential maturity of infants between 32 weeks' postconceptional age and term (Korner & Constantinou, 2001; Korner, Constantinou, Dimiceli, Brown, & Thom, 1991). Components include assessment of behavioral states, active tone, strength, reflexes, excitation and inhibition proneness, and orientation to visual and auditory stimuli. The NAPI has been used to monitor the developmental progress, to identify persistent lags in development, as an outcome measure in intervention studies and other studies, to describe individual differences in preterm infant development, and to identify infants with neurobehavioral alternations. The reliability and validity of this test and normative data have been established (Gorzilio, Garrido, Gaspardo, Martinez, & Linhares, 2015; Hyman, Snider, Majnemer, & Mazer, 2005; Korner et al., 1991; Korner & Constantinou, 2001; Snider et al., 2005).

Assessment Beyond Neonatal Development

As the infant matures, moves out of the neonatal period, and becomes a "long termer" in the NICU with chronic respiratory or other problems, neurodevelopmental assessments continue to provide important information. For the infant who requires prolonged hospitalization, a developmental assessment at the bedside can provide information on how the infant interacts with objects and people, organizes behavior, and copes with the environment, as well as on the infant's neurologic status. No formal developmental assessments have been standardized for these NICU populations. Most developmental psychologists or specialists adapt items from other examinations such as the Bayley Scales of Infant Development II (Bayley, 1993) or the more recent Bayley Scales of Infant and Toddler Development (Bayley, 2005). A recent study utilizing the *Bayley Scales of Infant and Toddler Development*, Third Edition (Bayley-III) suggested that corrected age for infants born preterm be applied differently in cognitive, language, and motor domains; correction for GA should be applied for the cognitive domain only, whereas for the motor domain, chronologic age should be used (Morsan, Fantoni, & Tallandini, 2018).

Because of the nature and severity of their illnesses, these infants may not be able to tolerate a complete examination at one session. To learn about the infant's behavioral capabilities and coping abilities adequately, the examiner must consider events that occurred for several hours before the assessment and be aware of the environment in which the infant normally lives and of his or her usual types of sensory experiences. Important areas of assessment include (1) availability of alerting, (2) ability to use interventions for consoling or developmental activities, (3) self-soothing capacity, (4) motor activities and strengths, (5) tolerance for handling (how long? with whom?), (6) degree of fragility, (7) degree of distractibility, (8) hand use, (9) parts of body available for use, and (10) respiratory capacity.

Sleep–Wake States

Another aspect of neurobehavioral development that is considered a part of any developmental program is sleep–wake states and how they affect responses to stimuli. Sleeping and waking states are clusters of behaviors that tend to occur together and represent the level of arousal of the individual, the individual's responsivity to external stimulation, and the underlying activation of the CNS. Three states have been identified in adults: wakefulness, non-(rapid eye movement) REM sleep, and REM sleep. In infants, it is also possible to identify states within waking and states that are transitional between waking and sleeping, because infants are less able to make rapid changes between states than adults. Infants also have more difficulty sustaining alertness when awake. Because the electrophysiologic patterns associated with sleeping and waking states in infants are somewhat different from those in adults (Heraghty, Hilliard, Henderson, & Fleming, 2008), the sleep states are usually designated active and quiet sleep, rather than REM and non-REM sleep (Raju & Radtke, 2012).

The development of organized sleep–wake states is a major feature of the neonatal period and developing infant. Although subsequent changes in the sleep–wake cycle with age are less profound, they represent predictable physiologic changes occurring as a function of age. Similarly, there are characteristic EEG patterns seen as a function of maturity in the neonate and developing child. These EEG changes continue to evolve into adulthood, offering an electrophysiologic marker of brain development.

Neonatal nurses need to be aware of the infant's present sleep–wake state and typical sleep–wake patterns when making assessments, because infant behavior and physiology are affected by state. The functioning of cardiovascular, respiratory, neurologic, endocrine, and gastrointestinal systems differs in different states. Moreover, sleeping and waking states affect the infant's ability to respond to stimulation. Thus, infant responses to nursing interventions and to parental interactions depend to a great deal on the infant's state when the stimulation begins. Also, during kangaroo care, infants exhibit more quiet sleep than when alone in the incubator (M. S. Scher et al., 2009). Timing routine interventions to occur when the infant is most responsive is an important aspect of some current systems of individualized nursing care (Becker, Grunwald, Moorman, & Stuhr, 1991; Bertelle, Mabin, Adrien, & Sizun, 2005). Finally, studies have indicated that sleeping and waking patterns are closely related to neurologic status (Heraghty et al., 2008). Thus, aberrant sleep–wake patterns could potentially be used to identify infants at risk for neurologic complications or poor developmental outcome.

State Scoring Systems. In adults, sleeping and waking are usually scored by EEG. However, because of the neurologic immaturity of infants, EEG is less reliable and needs to be combined with observation. When EEG and behavioral scoring of states in preterm infants are compared, there is a high degree of agreement (Sahni, Schulze, Stefanski, Myers, & Fifer, 1995; Sevestre, Oger, Bertelle, Mabin, & Sizun, 2013). Thus, by directly observing infants, whether full term or preterm, and identifying global categories that are made up of a number of specific behaviors that tend to occur together and reflect a similar level of arousal and responsiveness to the environment, nurses can validly score sleeping and waking states in newborn infants. The behaviors

that seem to be most important for scoring are respiration, eye movements, and motor activity (Brandon & Holditch-Davis, 2005; Tilmanne, Urbain, Kothare, Wouwer, & Kothare, 2009).

Nurse researchers currently use four standardized systems for scoring behavioral observations of sleep–wake states. The systems were developed by Brazelton (1984), Thoman (1990), Als et al. (1982), and Anderson (1999). These systems define states in very similar ways and are probably equally useful for clinical purposes. Table 31.2 presents a comparison of the state definitions used in these systems.

Clinicians and researchers differ in the ways they use these scoring systems. Neonatal nurses spend a lot of time observing infants and altering their care in response to infant behavioral changes. Experienced clinicians are undoubtedly already familiar with the characteristics of sleeping and waking states in these infants, even though they may be unable to name specific states. Thus, all they need to do to include judgments of sleeping and waking states is to use the state definitions of any standardized scoring system to systematize their clinical impressions.

For research, however, it is essential that the investigator receive training in the use of a particular scale so that it is used reliably. Clinicians reading research need to understand the differences among the scoring systems so that they can better interpret the findings and understand reports using different names for the same sleep–wake state. While many of these tools were described in previous sections, this discussion focuses on the scoring and emphasizes sleep-wake states.

Early State Scoring Systems. Sleeping and waking scoring systems for infants originated in the work of neurologists, pediatricians, and behaviorists in the 1960s. The neurologists needed a way to systematize the observations they made along with EEG studies, and behaviorists and pediatricians were particularly interested in the waking states and the effect of state on responsiveness to stimulation. Wolff (1959, 1966), a pediatrician, conducted extensive observations of newborn infants in the hospital and at home. As the result of his observations, he proposed a seven-state system. Prechtl and Beintema (1968), pediatric neurologists, proposed a simple five-state system that could be used either to score observations made along with EEG or to ensure that motor reflexes were elicited under optimal conditions. Finally, a team of pediatricians and neurologists at the University of California at

TABLE 31.2

APPROXIMATE EQUIVALENCE OF THE FOUR MAJOR SLEEP–WAKE STATE SCORING SYSTEMS

Brazelton	Thoman	Als	Anderson
6. Crying	Cry	6B. Lusty crying	12. Hard crying
		6A. Crying	11. Crying
5. Considerable motor activity	Fuss	5B. Considerable activity	10. Fussing
	Nonalert waking activity	5A. Active	9. Very restless awake
			8. Restless awake
4. Alert	Alert	4B. Bright alert	7. Alert inactivity
		4AH. Hyperalert	
		4AL. Awake and quiet	
3. Drowsy	Daze	3B. Drowsy	6. Quiet awake
	Drowse		5. Drowsy
	Sleep–wake transition	3A. Drowsy with more activity	4. Very restless sleep
2. Light sleep	Active sleep	2B. "Noisy" light sleep	3. Restless sleep
	Active–quiet transitional sleep	2A. Light sleep	2. Quiet sleep: irregular respiration
1. Deep sleep	Quiet sleep	1B. Deep sleep	1. Very quiet sleep
		1A. Very still deep sleep	

Note: Because the criteria used by these systems differ and because they are based on different conceptual frameworks, exact equivalence among them is not possible. Isolated instances of infant behavior may be scored quite differently than suggested by this table.

Los Angeles (UCLA) developed a manual to define the behavioral and EEG criteria for sleeping and waking (Anders, Emde, & Parmelee, 1971). These are still in use today, and each behavioral state scoring system currently in use is a refinement of these earlier systems.

Brazelton's State Scoring System. T. Berry Brazelton was a pediatrician from Harvard University in Cambridge, Massachusetts. He and his colleagues developed a state scoring system to be used as part of a behavioral evaluation of newborn infants, the NBAS (Brazelton, 1984; Brazelton & Nugent, 2011). The purpose of this tool was to assess the individuality of the infant within the interactional process. This state scale was derived both from Dr. Brazelton's clinical experiences and from the existing state systems of Prechtl and Beintema (1968) and Thoman (1975). Brazelton's state scoring system consists of six states: deep sleep, light sleep, drowsy, alert, considerable motor activity, and crying. During the administration of the NBAS, this scoring system is used to identify predominant states, state transitions, and the quality of the alertness. However, it can also be used for scoring sleep–wake states during other situations. By 1983, more than 100 papers had been published using the NBAS and Brazelton's state scale (Brazelton, 1984), and many more have been published since then.

Brazelton's state scoring system has a number of advantages that make it the scoring system of choice for clinicians and also useful for researchers. This state system is easy to learn because the differences between the states are fairly obvious and there are only six states. Because of the widespread use of Brazelton's state scoring system, individuals experienced with this scale are located in virtually every part of the United States. In addition, there are reliability training centers located throughout the country for those who want to use the entire NBAS or plan to use the state scoring system in research. Thus, obtaining training in this scoring system is relatively easy. Finally, most researchers and experienced clinicians are familiar with the state definitions from this scale so that findings of sleeping and waking observations made with this scoring system are readily understood.

On the other hand, this state scoring system does have some limitations for use in research. First, because of the small number of states, it is not always sensitive enough to identify differences between normal full-term infants and infants with perinatal complications. Moreover, the NBAS state scoring system is appropriate for use only with infants between 36 and 44 weeks' GA. The sleeping and waking states of infants born before 36 weeks' gestation and those born after 44 weeks' gestation will not be completely captured with this system. For example, older infants frequently are motorically active and alert during play, but in Brazelton's system, alertness is scored only when the infant is motorically quiet. Young preterm infants are frequently unable to make much sound when crying; thus, their cry periods would be scored as considerable motor activity.

Thoman's State Scoring System. Evelyn B. Thoman was a psychobiologist who worked at the University of Connecticut. Although trained as an experimental psychologist to work with animals, she became interested in the interactions between human infants and their mothers when she went to work with Dr. Anneliese Korner at Stanford University in 1969 and studied them for the rest of her career. She developed her first state scoring system in 1975 (Thoman, 1975) based on the work of Wolff (1966) and Korner (1972). Although some researchers continue to use this system today, it has undergone considerable revision (Thoman, 1990). The Thoman state scoring system consists of 10 sleeping and waking states: alert, nonalert waking activity, fuss, cry, daze, drowse, sleep–wake transition, active sleep, active–quiet transitional sleep, and quiet sleep. Dr. Thoman and others have shown that both acceptable interrater reliability and test–retest reliability can be obtained with her system (Holditch-Davis & Edwards, 1998a; Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004). Predictive validity is demonstrated by evidence that early sleeping and waking behaviors scored on Thoman's scale are related to later developmental outcome (Holditch-Davis, Belyea, & Edwards, 2005; Thoman, Denenberg, Sieval, Zeider, & Becker, 1981).

Thoman's state scoring system has a number of advantages. The documented reliability and validity of this system is of value to researchers. The sleeping and waking states are differentiated enough that they can be used with infants with perinatal complications (Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004; Thoman, Holditch-Davis, Graham, Scholz, & Rowe, 1988). This system has been used with preterm infants (Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004; Liaw et al., 2013; Lorenz et al., 2017) and with infants older than 1 month after term (Holditch-Davis, Miles, & Belyea, 2000). The states in this system can also be combined when an investigator does not need such fine discriminations.

This scoring system has two disadvantages. A 10-state system is somewhat more difficult to learn than a six-state system because it requires subtler discriminations. However, individuals experienced in using a six-state system, such as Brazelton's, can readily learn this system. Also, because this state scoring system is not as widely used as Brazelton's, obtaining training in its use is more difficult.

Als State Scoring System. Heidelise Als is a psychologist working at Harvard Medical School with Dr. Brazelton's colleagues. For a number of years, she has worked with them to modify the NBAS (Brazelton, 1984) to make it more appropriate for use with premature infants. The APIB is administered in much the same way as the NBAS, but the infant's behavior is scored in much greater detail so as to quantify not only the infant's skills but also the infant's reactivity and stress in response to environmental stimulation (Als et al., 1982; Pressler & Hepworth, 2002). Like the NBAS, the APIB is best administered to infants between 36 and 44 weeks' GA, but the observational portion of the tool can be used with younger preterm infants (Als, 1986). The state scale from the NBAS has been expanded into a 13-state system by subdividing each of the six states so that the immature and unclear sleeping and waking states of preterm infants can be more adequately described. These 13 states are very still deep sleep, deep sleep, light sleep, "noisy" light sleep, drowsy with more activity, drowsy, awake and quiet, hyperalert, bright alert, active, considerable activity, crying, and lusty crying. The state subscale of the APIB has been shown to differentiate between premature and full-term infants after term (Als, Duffy, & McAnulty, 1988; Mouradian, Als, & Coster, 2000) and to correlate with electrophysiologic measures of brain activity (Duffy, Als, & McAnulty, 1990). In addition, the APIB and the state subscale are used to provide assessments that are the basis for planning individualized interventions as part of the NIDCAP (Als, 1986; Als et al., 1986; Pressler & Hepworth, 2002).

The Als state scoring system has a number of advantages and disadvantages for clinicians and researchers. First, a 13-state system is more difficult to learn than a six-state system such as Brazelton's (Brazelton & Nugent, 1995). However, since the Als system was developed from the Brazelton states, individuals familiar with the Brazelton system should have no difficulty learning it, and when the complexity of the 13 states is not needed they can be collapsed to the six states from the NBAS. Second, inasmuch as

the APIB, like the NBAS, was never intended for use with infants older than 1 month after term, the state scale may not adequately capture the states of older infants.

Anderson's Behavioral State Score (ABSS). Gene Cranston Anderson is a doctorally prepared nurse researcher who worked at Case Western Reserve University in Cleveland, Ohio. She has long been interested in interventions that keep mother and infant together after birth, reduce infant crying, and promote feeding. She developed a 12-state scoring system, the ABSS, to be used with preterm infants based on her own observations of these infants (Anderson, 1999) and on the work of Parmelee and Stern (1972). Parmelee was one of the contributors to the UCLA state manual (Anders et al., 1971). The ABSS consists of very quiet sleep, quiet sleep with irregular respirations, restless sleep, very restless sleep, drowsy, quiet awake, alert inactivity, restless awake, very restless awake, fussing, crying, and hard crying. The states are arranged so that there is a linear relationship between the states and HR and energy consumption, with the states with the lowest numbers having the lowest mean HRs. The ABSS has been used to show the effects of noise-reducing earmuffs (Khalesi, Khosravi, Ranjbar, Godarzi, & Karimi, 2017) on preterm infant state patterns.

As with the other scoring systems, the ABSS has a number of advantages and disadvantages for clinicians and researchers. Because the ABSS was designed for use with preterm infants, the utility of this scale for full-term infants and older infants is unknown, although its similarity to other state scoring systems suggests that it should be applicable for healthy full-term newborn infants. The ABSS may also be difficult to learn because of the complexity of 12 states. As Table 31.2 illustrates, the sleep states in this system differ markedly from the sleep states defined in other state scoring systems; so, this is not a good scoring system to use if one is primarily interested in studying sleep states and wants to compare findings with other studies. Finally, the linear relationship between the states in this system and heart rate may make it the ideal choice for researchers who are primarily interested in studying the energy consumption of infants. However, this feature means the ABSS has a very different theoretical basis than the other state scales. The other state scoring systems differentiate among states based on qualitatively different aspects of the infant's behavior, but the ABSS emphasizes quantitative differences among the states, although more recently Anderson emphasized qualitative differences between states.

Automated Scoring of States. Because scoring sleeping and waking from EEG or behavioral observations is time intensive, automated methods of scoring sleep–wake states are being developed for research and clinical use. One method often mentioned is video recording. Although video recording is often used for behavioral scoring (Cremer et al., 2016) or along with EEG (Axelin, Kirjavainen, Salanterä, & Lehtonen, 2010; dos Santos, Khan, Rocha, & Nunes, 2014), it does not reduce the time involved because the video recordings need to be scored.

A method currently being used for EEG is amplitude-integrated EEG (aEEG) monitoring, in which EEG traces are digitally recorded for visual scoring and calculation of signal parameters. This technique is currently in use for both research and clinical care (Axelin et al., 2010; El-Dib, Massaro, Glass, & Aly, 2014; Vesoulis et al., 2015). Also, new criteria for scoring sleeping and waking from aEEG are currently being developed (Dereymaeker et al., 2017; Koolen et al., 2017; Palmu, Kirjavainen, Stjerna, Salokivi, & Vanhatalo, 2013).

For behavioral scoring of state, several different methods of scoring are currently in use in research. HR variability has been used to score sleep–wake states (Werth, Atallah, et al., 2017; Werth, Long, et al., 2017). Several researchers have scored sleeping and waking using actigraphy, an activity recorder that is placed on the infant's arm or leg (Gertner et al., 2002; Lan et al., 2018). Although commercial scoring algorithms are available, actigraphy cannot reliably differentiate between active sleep and quiet sleep in preterm infants or full-term newborn infants, and it sometimes confuses waking and active sleep (Rioualen et al., 2015; Sadeh, Dark, & Vohr, 1996). Thus, it should only be used for scoring sleeping versus waking, and then with caution.

Several researchers have developed systems for scoring sleeping and waking from body movements and respiration. Thoman and Glazier (1987) developed a computerized system for scoring sleeping and waking in full-term infants from movements and respiration. They validated this system against direct observation of state. Brandon and Holditch-Davis (2005) validated a semiautomatic method of scoring sleeping and waking from respiratory patterns, motility, and electro-oculography in preterm infants. They showed this system scored state similar to direct observation. Although these systems are promising, they have only been used in research to date.

Description of Individual States. Because the definitions of sleep–wake states are so similar among these scoring systems (see Table 31.2), it is possible to describe in general the sleeping and waking states displayed by infants. For clarity's sake, generic state names are used in all further descriptions. When they are not available, the state names from the Thoman system are used. Each sleeping and waking state is made up of a different constellation of behaviors and serves a different function for the infant. Physiologic functioning is also different in each of these states.

Infants are most responsive to the environment when in the waking states, and, in particular, when alert. When the infant is alert, the eyes are open and scanning. Motor activity is typically low, particularly in full-term newborns, but premature infants and infants older than 1 month after term may be motorically active. Alertness is the state in which the infant exhibits focused attention on sources of stimulation (Brazelton & Nugent, 1995). Thus, this is the best state in which to test reflexes (Prechtl & Beintema, 1968). Alertness has been suggested to be the optimal state for feeding (Griffith, Rankin, & White-Traut, 2017; White-Traut, Berbaum, Lessen, McFarlin, & Cardenas, 2005). This state is also the one in which infants are most receptive to interactions with their parents and other adults. Yet alertness rarely occurs in the preterm period (Holditch-Davis & Edwards, 1998a) and occurs relatively infrequently during the first month after term, only about 10% to 15% of the total day (Colombo & Horowitz, 1987).

Crying, another waking state, serves a communication function. However, the meaning of cries differs in different situations and may depend on their intensity (Fuller, 1991). Although crying that occurs when the infant is alone may elicit parental attention, crying that occurs during social exchanges may actually disrupt the parent–infant relationship. In full-term infants, crying during social interactions is related to the overall amount of maternal stimulation and to consistency in the patterning of maternal activities over weeks (Acebo & Thoman, 1995; Thoman, Acebo, & Becker, 1983). Studies have indicated that the higher the HR, the greater the energy consumption of the infant (Woodson, Field, & Greenberg, 1983). In addition, this state is associated with decreased oxygenation in the bloodstream (Levesque, Pollack, Griffin, & Nielsen, 2000) and brain (Brazy, 1988).

The final waking state, nonalert waking activity, is characterized by periods when the infant is motorically active but not alert or crying. Usually the infant's eyes are open. One study of

nonalert activity found that excess amounts of this state in full-term infants were associated with inconsistency in the patterning of states over weeks (Becker & Thoman, 1982), and, in turn, inconsistency in state patterning was related to poor developmental outcome (Thoman et al., 1981). Premature infants, after term, exhibit elevated levels of this state (Holditch-Davis & Thoman, 1987) and are known to be at increased risk of poor developmental outcome (Adams-Chapman et al., 2018; Marlow, Wolke, Bracewell, & Samara, 2005; Mwaniki, Atieno, Lawn, & Newton, 2012; M. C. Sullivan, Msall, & Miller, 2012). However, whether there is a relationship between these findings is unknown.

The states transitional between sleeping and waking have rarely been the focus of studies. In fact, the Prechtl scoring system omits them altogether on the grounds that they are not true states but just transitions between states (Prechtl & Beintema, 1968). However, newborn infants, both term and preterm, actually spend significant amounts of time in them, ranging from about 6% of the day at 29 weeks' GA to 14% in the first month after term (Holditch-Davis, 1990; Holditch-Davis & Thoman, 1987). Thoman (1990) describes three states transitional between waking and sleeping: drowse, when the infant is quiet and appears sleepy with eyes opening and closing slowly; daze, when the infant is quiet with eyes that are open but dazed in appearance; and sleep–wake transition, when the infant exhibits mixed signals of waking and sleeping, is motorically active, and may appear to be waking up. Drowse and daze typically occur in the midst of periods of waking or as the infant is falling asleep. Sleep–wake transition typically occurs at the end of sleeping as the infant is awakening but may also occur in the middle of sleep, particularly in premature infants. Drowse, daze, and sleep–wake transition are often combined in research reports. However, studies have indicated that these states have different patterns of correlations with other states (Thoman, Holditch Davis, & Denenberg, 1987). During the first month after term, premature infants have been found to spend significantly more time in sleep–wake transition and less time in drowse or daze than full-term infants (Holditch-Davis & Thoman, 1987). If these three states had been combined, these differences would have been missed. In addition, hospitalized preterm infants spend more time in sleep–wake transition when they are with nurses rather than parents, but do not differ in the amount of drowsiness that occurs with these different caregivers (Miller & Holditch-Davis, 1992). During kangaroo mother care, infants show less sleep–wake transition than when alone in their incubators (Lorenz et al., 2017). They also exhibit more sleep–wake transition and less drowsiness during procedural care than during feeding and changing (Brandon, Holditch-Davis, & Belyea, 1999).

There are two major sleep states—active sleep and quiet sleep—although some state systems define a transitional state between them. In active sleep, the infant's respiration is uneven and primarily costal in nature. Sporadic motor movements occur, but muscle tone is low between these movements. Most behaviors, including hiccups, yawns, jitters, negative facial expressions (frowns and grimaces), and large movements, are less frequent in active sleep than waking but more frequent than in quiet sleep, but startles and jerks occur most frequently in active sleep (Holditch-Davis, Brandon, & Schwartz, 2003). The most distinct characteristic of active sleep is REMs that occur intermittently.

Active sleep is the most common state from birth throughout infancy, but it makes up only about 20% of sleep in adults. Because of this dramatic developmental decrease and the frequent movements seen in infants during active sleep, many clinicians think of active sleep as a disorganized and primitive state. Surprisingly, this state has relatively recent phylogenetic origins, occurring only in birds and mammals. Thus, it has been hypothesized to be necessary for brain development (Del Rio-Bermudez & Blumberg, 2018; Roffwarg, Muzio, & Dement, 1966). This hypothesis has received support in full-term infants (Denenberg & Thoman, 1981). In studies of infant animals, prolonged deprivation of active sleep altered brain functioning, resulting in hyperactivity, distractibility, and altered sexual performance (Mirmiran, 1986). Metabolic rates are higher in active than in quiet sleep (Heraghty et al., 2008). Inasmuch as respiratory patterns are relatively unstable in active sleep (Elder, Larsen, Galletly, & Campbell, 2010; Holditch-Davis, Scher, & Schwartz, 2004) and oxygenation is lower and more variable (Ross & Rosen, 2014), the large amount of active sleep seen in young preterm infants (dos Santos et al., 2014; Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004) may contribute to their respiratory difficulties.

The other sleep state, quiet sleep, is characterized by a lack of body movements and the presence of regular respiration. A tonic level of motor tone is maintained in this state. Most behaviors, including hiccups, yawns, mouth movements, jitters, negative facial expressions, and large movements, are less frequent in quiet sleep than in waking or active sleep; the exception is sighs, which occur most frequently in quiet sleep (Holditch-Davis et al., 2003). The major purpose of quiet sleep seems to be rest and restoration. This state has been hypothesized to be necessary for healing (Adam & Oswald, 1984). Quiet sleep may also be needed for growth because it is in this state that growth hormone is secreted in adults. However, a study of full-term infants did not find any relationship between growth hormone secretion and quiet sleep (Shaywitz, Finkelstein, Hellman, & Weitzman, 1971). Oxygenation is higher during this sleep state (Ross & Rosen, 2014) and respiration more regular (Elder et al., 2010; Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004). Thus, quiet sleep may be beneficial for infants with respiratory problems.

The amount of quiet sleep is also very sensitive to the environment. Infant stimulation studies, for example, have found that quiet sleep is the state most likely to be increased by vestibular and kinesthetic interventions (Ingersoll & Thoman, 1994; Johnston, Stremler, Stevens, & Horton, 1997; Lorenz et al., 2017). The stimulation provided by routine nursing care, on the other hand, results in significantly less quiet sleep than times when the preterm infant is undisturbed (Brandon et al., 1999), and the amount of this state is further reduced when the infant experiences painful or uncomfortable procedures (Holditch-Davis & Calhoun, 1989). Thus, this is the state most likely to be affected by the NICU environment.

Effect of Physiologic Parameters on State. Physiologic functioning varies in different states, and abnormalities in physiologic functioning can alter the sleeping and waking of infants. This discussion focuses on the interrelationship of sleeping and waking and five areas of physiologic functioning of interest to neonatal nurses—illness, the CNS, circulatory system, respiration, and weight gain.

Perinatal Illness. The state patterns of infants who experienced perinatal complications may differ markedly from the state patterns of healthy full-term infants. SGA full-term infants, for example, have more disorganized sleep (more active sleep without REMs) than healthy full-term infants (Watt & Strongman, 1985). At 2 weeks of age, SGA preterm infants had abnormal EEG scores more often and displayed sleep–wake cycling less frequently than average for gestational age (AGA) preterm infants (Schwindt et al., 2015). At 1 month, SGA preterm infants have lower delta percentage on EEGs than AGA full-term and preterm infants and higher theta, alpha, and beta power. Also, preterm infants born to mothers with preeclampsia have less quiet sleep than other preterm infants (Topcuoglu, Kolsuz, Gursoy, Ovali, & Karatekin, 2016).

The sleep of premature infants after term differed from that of full-term infants of the same corrected ages, in that there is a lower total amount of sleep, longer episodes of quiet sleep, more body movements, more frequent REM episodes, and a lower correlation among the various behavioral criteria of the sleep states (Holditch-Davis & Thoman, 1987; Watt & Strongman, 1985). Premature infants show day–night differentiation in their sleeping and waking patterns at the same or an earlier postmenstrual age than full-term infants (C. Guyer et al., 2015; Whitney & Thoman, 1994). In addition, their EEG patterns differ from those of full-term infants. Premature infants display longer bursts during trace alternans, earlier sleep spindle appearance, more immature EEG patterns, poorer phase stability for EEG frequencies, and more transitional sleep (Karch et al., 1982; Nunes, Khan, Gomes Filho, Booij, & da Costa, 2014). Premature and full-term infants also differ on architectural, phasic, continuity, spectral, and autonomic measures (M. S. Scher, Johnson, Ludington, & Loparo, 2011; M. S. Scher, Sun, Steppe, Guthrie, & Sclabassi, 1994). In particular, premature infants display shorter sleep state cycles, less quiet sleep, more arousals in quiet sleep, and less REM in active sleep (Scher et al., 2011). However, some researchers have found that children born prematurely have similar rates of sleep problems from 5 months through for corrected age as full-term infants (Wolke, Söhne, Riegel, Ohrt, & Osterlund, 1998), whereas others have found that 2-year-old prematurely born children at 2 years were more restless during the night (Caravale et al., 2017).

The ways in which the waking states differ between full-term and premature infants of similar postmenstrual ages are less well established. Over prolonged observation periods, premature infants exhibited more alertness and nonalert waking activity and less drowsiness than full-term infants (Holditch-Davis & Thoman, 1987).

The severity of illness that the infant experiences during the perinatal period has relatively small additional effects on sleeping and waking. In general, critical illness has immediate effects on sleeping and waking patterns, but these effects disappear after the infant recovers as long as there are no neurologic complications and as long as infants are observed at the same ages corrected for GA at birth. Karch et al. (1982) studied healthy and ill preterm infants at comparable ages and found that ill infants exhibited more quiet sleep, more indeterminate sleep, and less wakefulness. Palmu et al. (2013) found that ill preterm infants receiving mechanical ventilation had fragmented sleep states. Lan, Yin, Chen, Chang, and Liaw (2017) found that infants with more severe illnesses had more frequent sleep and wake bouts. Respiratory treatments affect infant sleep: the longest sleep cycle of mechanically ventilated preterm infants was shorter than that of nonventilated infants (Curzi-Dascalova, 1992), and infants receiving high-flow nasal cannula oxygen slept less and were more active than infants receiving nasal continuous positive airway pressure (CPAP; Collins, Barfield, Davis, & Horne, 2015). Holditch-Davis and Hudson (1995) used changes in sleep–wake states to identify a wide variety of acute medical complications in preterm infants, including hydrocephalus, sepsis, and cold stress. At term, preterm infants with medical complications showed lower sleep cyclicity scores than healthier preterm or term infants (Feldman, 2006) and at 18 months corrected age, infants with more severe neonatal illness showed less loud snoring and restless sleep (Wang, Difiore, Martin, Rosen, & Hibbs, 2013).

Studies of infants who have recovered from their illnesses have found fewer differences. High and Gorski (1985) did not find any differences in the sleeping and waking patterns of convalescent premature infants differing in the severity of their previous illness. Likewise, Holditch-Davis (1990) found that the only difference in the development of sleeping and waking states in convalescent preterm infants was that more severely ill infants showed less fussing and somewhat poorer organization of quiet sleep. However, Holditch-Davis, Scher, Schwartz, and Hudson-Barr (2004) found that longer mechanical ventilation was associated with more active sleep and less active sleep without REMs, and that infants with lower birth weights had more regularity of respiration in quiet sleep. On the other hand, Brandon, Holditch-Davis, and Winchester (2005) found that longer mechanical ventilation was associated with less active sleep. In addition, scores on the NBAS state scale did not differ significantly between sick and healthy full-term infants at the time of hospital discharge (Holmes et al., 1982).

Infants with CLD are more likely than other premature infants to have oxygen desaturations when sleeping (Barbeau & Weiss, 2017). Yet, how this illness affects sleeping and waking patterns is unclear. Holditch-Davis and Lee (1993) compared preterm infants with and without CLD from 32 to 36 weeks' postmenstrual age on sleeping and waking during 4-hour observations in the intermediate care unit. The only difference between the infants with and without CLD was that infants with CLD had more irregular respiration in quiet sleep. Although many clinicians believe that infants with CLD are more sensitive to stimulation, there were also no differences in sleeping and waking when the infants with and without CLD were with caregivers (Holditch-Davis, 1995). However, at 36 weeks' postmenstrual age, preterm infants with CLD had fewer periods of quiet sleep per hour and their EEG patterns differed as compared to preterm infants without this complication (Sommers, Tucker, & Laptook, 2011). At term age, premature infants with CLD were found to have less active sleep, more frequent arousals, and more frequent body movements in sleep than premature infants who never experienced any respiratory illnesses and performed more poorly on the interactive and motor clusters of the NBAS (Myers et al., 1992).

Treatments for perinatal illnesses also may affect the sleeping and waking states of preterm infants. For example, supplemental oxygen was associated with increased quiet sleep and total sleep time (Simakajornboon, Beckerman, Mack, Sharon, & Gozal, 2002). One study of preterm infants between 28 and 32 weeks' postmenstrual age found that oxycodone was associated with a reduction in active sleep and an increase in sleep onset in quiet sleep as compared to a placebo, oral glucose, or swaddling by parents (Axelin et al., 2010). Prenatal magnesium sulfate affected the organization of sleep states leading to dysmaturity (a combination of accelerated and delayed state organization), whereas antenatal steroids had no effect (Black, Holditch-Davis, Schwartz, & Scher, 2006). Preterm infants whose mothers received antenatal phenobarbital did not differ in HR or sleep–wake states in the first 3 days of life from infants not receiving the medication, suggesting that the antenatal dosage was not sedating (McCain, Donovan, & Gartside, 1999).

Neurologic System. Because sleeping and waking states are assumed to reflect the underlying activation of the CNS, it is not surprising that a close relationship exists between sleep–wake states and CNS functioning. Four factors illustrate this interrelationship. First, sleeping and waking exhibit a large amount of development in the first year of life, the time of the most rapid CNS development. Sleeping and waking states affect neurologic responses. Infants with neurologic abnormalities exhibit abnormal sleeping and waking patterns. Finally, sleeping and waking states can be used to predict developmental outcome.

Development of Sleeping and Waking States. Infants exhibit definite developmental changes in their sleeping and waking state patterns throughout the first year of life. The age at which

sleep–wake states first appear is unknown. Studies of preterm infants have found that by 24 weeks' GA, cycling between waking and sleeping can be identified by EEG in some preterm infants (Pavlidis, Lloyd, Mathieson, & Boylan, 2017). By 24 to 27 weeks' GA (the earliest ages studied), infants exhibit distinct waking and sleeping states (Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004; Palmu et al., 2013; M. S. Scher, Johnson, & Holditch-Davis, 2005). However, before 30 weeks' GA, the various behaviors associated with sleep and waking—eye movements, body movements, respiration, and muscle tone—are not well coordinated; not until at least 36 weeks' GA do preterm infants exhibit the same degree of correlation between these parameters as do full-term infants (Curzi-Dascalova, Peirano, & Morel-Kahn, 1988; dos Santos et al., 2014). Studies of sleeping and waking states in fetuses conducted using observations made during ultrasound examinations have had similar findings (DiPietro, Hodgson, Costigan, Hilton, & Johnson, 1996).

Infants exhibit greater amounts of active sleep and indeterminate states during the preterm period and lower amounts of waking states than after term (Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004; Lan et al., 2017). Active sleep occupies as much as 60% to 80% of the day for young preterm infants (Barbeau & Weiss, 2017; Holditch-Davis & Edwards, 1998a; Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004), although one study found that preterm infants spent more time in quiet sleep in the morning (Llaguno et al., 2015). The major developmental change during the preterm period is a decrease in the amount of sleep due to a decrease in active sleep (Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004; Ingersoll & Thoman, 1999; Lan et al., 2017). In addition, quiet sleep and waking states, especially crying, increase (Barbeau & Weiss, 2017; Cremer et al., 2016; Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004). The organization of the sleep states, as measured by the percentages of the state with typical state criteria, by the correlation between criteria, and by the presence of definite sleep state cycles, also increases throughout the preterm period (Barbeau & Weiss, 2017; Feldman, 2006; Holditch-Davis, Scher, Schwartz, & Hudson-Barr, 2004; Soubasi et al., 2009). EEG criteria also change with age over the preterm period: maximum amplitude of EEG decreases; minimum amplitude increases; and smooth delta waves, delta brushes, and theta bursts decrease (Vesoulis et al., 2015). The mean duration and frequency of episodes of each state also change over the preterm period: quiet waking, active waking, and sleep–wake transition episodes occurred more frequently than active waking and quiet sleep, but length of these periods increased over age (Holditch-Davis & Edwards, 1998b; Ingersoll & Thoman, 1999). These changes may be affected by gender as male preterm infants exhibited less active sleep, more drowsiness, and more waking than females (Foreman, Thomas, & Blackburn, 2008).

The sleeping and waking states of infants in the first month after term differ dramatically from those of infants in the preterm period. Healthy full-term neonates sleep about 13.5 hours a day (Thomas & Foreman, 2005), have a sleep–wake cycle of about an hour in length, and spend more sleep time in active sleep (Korotchikova, Stevenson, Livingstone, Ryan, & Boylan, 2016). Slightly higher amounts of sleep states occur at night (Thoman & Whitney, 1989; Whitney & Thoman, 1994). Waking states make up the rest of the day, with alertness (14%) and drowsiness (13%) being the most common (Holditch-Davis & Thoman, 1987).

The major developmental trends exhibited by full-term infants in the first month are a decrease in active sleep and an increase in the amount of alertness (Denenberg & Thoman, 1981; Kohyama & Iwakawa, 1990). Moreover, the mean lengths of episodes of the sleep states change, with active sleep decreasing and quiet sleep increasing (Thoman & Whitney, 1989). Similar trends occur for premature infants during this period (Mirmaran, Baldwin, & Ariagno, 2003; Whitney & Thoman, 1994). In addition, both full-term and premature infants begin to show entrainment to a day–night schedule of sleeping and waking by about a month after term (Shimada et al., 1999).

Sleeping and waking states continue to develop throughout the first year. Waking periods become longer and more consolidated (Holditch-Davis, Tesh, Burchinal, & Miles, 1999; Louis, Cannard, Bastuji, & Challamel, 1997), and night wakings decrease (Mäkelä et al., 2018). The infant spends an increasing proportion of wakefulness in the alert state. The amount of time spent crying decreases (Michelsson, Rinne, & Paajanen, 1990; St. James-Roberts & Plewis, 1996). In addition, total sleep time decreases, with almost all of this decrease due to a decrease in active sleep time (Holditch-Davis et al., 1999; Louis et al., 1997; Mäkelä et al., 2018). The amount of quiet sleep remains the same or increases from term age on; thus, by about 6 months of age, the amount of quiet sleep exceeds the amount of active sleep (Louis et al., 1997). In addition, the number of sleep episodes decreases and becomes consolidated primarily into nighttime, although most infants continue to exhibit some amount of night waking (Ottaviano, Giannotti, Cortesi, Bruni, & Ottaviano, 1996; A. Scher, 1991). By 1 year, the infant is taking about two daytime naps (Weissbluth, 1995) and sleeping about 10 to 12 hours through the night. Prematurely born infants may display shorter night sleep, more activity during the night, and more sleep problems than full-term infants (Asaka & Takada, 2010; Huang, Paiva, Hsu, Kuo, & Guilleminault, 2014).

The nature of these changes depends somewhat on the caregiving environment. Thus, breastfed infants exhibit less total sleep, longer sleep latency, more fragmented sleep, more non-REM sleep, and shorter duration of REM sleep than formula-fed infants (Figueiredo, Dias, Pinto, & Field, 2017; Schwichtenberg & Poehlmann, 2009; Tikotzky et al., 2010), but not at 2 weeks (Figueiredo et al., 2017). Also, 2-week-old and 6-month-old full-term infants with depressed mothers took longer to fall asleep and had more disrupted sleep than infants of nondepressed mothers (Armitage et al., 2009).

Other developmental changes during the first year affect the organization of sleep. The cycling between active and quiet becomes more consistent over the first few months. Many preterm infants display hour-long sleep cycles by 36 weeks' postmenstrual age (Borghese, Minard, & Thoman, 1995). The sleep states also develop the EEG patterns typical of adults. By 3 months of age, the EEG stages within quiet sleep can be identified, and this state can now be called non-REM sleep (Ellingson & Peters, 1980).

Neurologic Responses. Infants exhibit different neurologic responses in different sleeping and waking states. The magnitude of neurologic reflexes is known to differ greatly in different states (Prechtl & Beintema, 1968). Therefore, standardized infant assessments and neurologic examinations specify which states are optimal for testing each reflex (Brazelton & Nugent, 1995; Prechtl & Beintema, 1968). The amplitude, waveform, and latency of visual evoked potentials are different in different sleeping and waking states, with the greatest differences being between sleep and waking (Apkarian, Mirmiran, & Tijssen, 1991).

Neurologic Problems. The state patterns of infants with neurologic insults differ markedly from those of healthy infants. Infants with Down syndrome have been found to spend more time awake and to have abnormally long periods of quiet sleep (Prechtl, Theorell, & Blair, 1973). Premature infants with IVH have been found to be more likely to lack sleep–wake cycles than healthier preterm infants (Olischar, Klebermass, Waldhoer, Pollak, & Weninger, 2007). Full-term infants with hyperbilirubinemia show decreased

amounts of wakefulness (Prechtl et al., 1973). As compared to full-term infants with only mild bilirubin elevations, infants with moderately elevated bilirubin values exhibited significantly lower scores in state regulation and range on the NBAS, and exhibited minor neurologic abnormalities as shown by increased latency of brainstem auditory evoked potentials (Vohr et al., 1990). On the other hand, very preterm infants on phototherapy did not differ on the amount of quiet sleep from very preterm infants not on phototherapy (Cremer et al., 2016). Abnormal cry patterns have been found in infants who have neurologic injuries, hyperbilirubinemia, or are at risk for sudden infant death syndrome (SIDS; Corwin et al., 1995). Greater EEG quiet sleep and decreased delta power in quiet sleep were associated with worse neurologic examinations of infants at risk for seizures (Shellhaas, Burns, Barks, & Chervin, 2014). Infants (5–24 months of age) with congenital Zika syndrome showed less total sleep and more night waking than healthy infants (Pinato et al., 2018).

In addition, infants exposed prenatally to drugs or alcohol exhibit abnormalities in their state patterns, possibly as the result of neurologic insults caused by the drugs. For example, alcohol-exposed infants exhibit sleep disruptions and abnormal cries (Nugent, Lester, Greene, Wieczorek-Deering, & O'Mahony, 1996). Preterm infants whose mothers smoked prenatally had more active sleep, more waking after sleep onset, more motor activity in sleep, and altered peripheral chemoreceptors (decreased baseline activity in active sleep and increased response time in quiet sleep; Stéphan-Blanchard, Chardon, et al., 2010; Stéphan-Blanchard, Telliez, et al., 2008). Infants exposed to marijuana exhibit a decrease in quiet sleep time (M. S. Scher, Richardson, Coble, Day, & Stoffer, 1988). Methadone-exposed infants exhibit abnormal cries with short first expirations and are more irritable and less able to sustain a high-quality alert state (Huntington, Hans, & Zeskind, 1990; Jeremy & Hans, 1985). Infants experiencing opiate withdrawal exhibit more waking, more sleep fragmentation, and less quiet sleep (O'Brien & Jeffery, 2002). Infants who were exposed to cocaine or opiates during pregnancy showed more alertness and less quiet sleep than nonexposed infants (White-Traut et al., 2002). Infants who were prenatally exposed to cocaine showed less active sleep and more indeterminate sleep; they also showed less orientation and poorer state regulation, including more jitters, high-pitched cries, and hyperalertness, than drug-free infants (Bauer et al., 2005; Regalado, Schechtman, Del Angel, & Bean, 1995). On the other hand, Woods, Eyler, Behnke, and Conlon (1993) did not find any differences on the NBAS between cocaine-exposed and drug-free infants.

Prediction of Developmental Outcome. Finally, the organization of sleeping and waking, as indicated by individual state criteria or the overall patterning of states, can be used to predict the developmental outcome of infants. Greater amounts of quiet sleep in the preterm period relate to better alertness and orientation, less irritability, and better orientation to inanimate visual and auditory stimulation on the NAPI (Korner & Thom, 1990), an assessment similar to the APIB, at 32 and 36 weeks' postmenstrual age (Brandon et al., 2005). Delayed maturity of EEG patterns of preterm infants was found to be associated with poor neurologic outcome (Ferrari et al., 1992; Hahn & Tharp, 1990), and less mature sleep–wake cycling scores in the preterm period were associated with lower cognitive and motor development between 9 and 18 months corrected age (El-Dib et al., 2014; C.-M. Jiang et al., 2015). Also, in preterm infants, lower EEG energies, especially in active sleep, and prolonged interburst intervals predicted lower neurodevelopmental performance at 12 and 24 months and greater likelihood of death, cerebral palsy, other neurologic problems, or sensory impairments (Thiriez et al., 2015; Wikström et al., 2012). Sleep difficulties at 2 years were related to shorter attention (Caravale et al., 2017). Elevated amounts of intense bursts of REMs and long sleep cycle lengths at 6 months were associated with developmental problems in full-term infants (Becker & Thoman, 1982; Borghese et al., 1995) and low amounts of REMs were associated with lower Bayley mental development scores at 6 months corrected age in preterm infants (Arditi-Babchuk, Feldman, & Eidelman, 2009). Measures of sleep–wake states during the preterm period—including the total amount of sleep, the overall state organization as compared with other infants, predominant pattern of state transitions, and sleep cycle length—have been found to predict Bayley scores at 6 months to 3 years corrected age (Gertner et al., 2002; Holditch-Davis et al., 2005; Weisman, Aderka, Marom, Hermesh, & Gilboa-Schechtman, 2011; Whitney & Thoman, 1993). However, the amount of indeterminate sleep—any period not meeting the criteria for one of the five states defined by Prechtl and Beintema (1968)—in premature infants at term was not related to developmental status at 2 years (Maas et al., 2000). In apparently normal full-term infants, the stability of state patterns in the first month has been found to predict developmental outcome (Thoman et al., 1981). This finding has been replicated in premature infants after term (Whitney & Thoman, 1993) and in siblings of infants who died from SIDS (Thoman et al., 1988).

Circulatory System. Sleeping and waking states affect the infant's circulatory system. Overall, HR is higher in waking than sleeping states (Llaguno et al., 2015). Mean HRs in the two sleep states are very similar, but HR is more variable in active sleep (Elder et al., 2010; Galland et al., 2000); high frequency HR variability increases with age, the low frequency/high frequency ratio decreases, and low frequency blood pressure variability decreases, especially in active sleep (Yiallourou, Witcombe, Sands, Walker, & Horne, 2013). The difference in variability is large enough that it is possible to differentiate between the two sleep states on the basis of HR variability (Werth, Long, et al., 2017). Thus, neonatal nurses need to be aware of the infant's state when determining HR, and routine vital signs probably should not be obtained while the infant is crying.

Sleeping and waking states also affect the infant's circulation. Cerebral blood flow is highest during waking (Greisen, Hellstrom-Vestas, Lou, Rosen, & Svenningsen, 1985). It is significantly higher in active sleep than in quiet sleep in full-term infants (Milligan, 1979), but not in infants less than term age (Greisen et al., 1985). Variability in cerebral blood flow velocity is lowest in quiet sleep, whereas marked fluctuations occur during active waking (fussing and nonalert waking activity; Ramaekers, Casaer, Daniels, Smet, & Marchal, 1989). Blood pressure is slightly higher when the infant is awake than when asleep (Van Ravenswaaij-Arts, Hopman, & Kollee, 1989) and lower in quiet sleep than active sleep (Witcombe, Yiallourou, Walker, & Horne, 2008).

Respiration. The effect of sleeping and waking states on the respiratory system is even greater than on the circulatory system. The nervous system controls of breathing differ in different states (Phillipson, 1978; Ross & Rosen, 2014). During wakefulness, breathing is regulated by metabolic controls, general stimulation from the reticular activating system, and voluntary activities. In quiet sleep, metabolic controls predominate, and maintaining acid–base and oxygen homeostasis is the primary stimulus for breathing. Medullary respiratory center activity varies during active asleep depending on whether the infant is experiencing REMs and motor activity (phasic active sleep) or not (tonic active sleep), indicating that these two types of active sleep include different controls on breathing. During phasic active sleep, behavioral controls similar to the voluntary controls in waking predominate. In tonic active sleep, the major respiratory control results from direct stimulation

of the state in a manner similar to the reticular stimulation of respiration during wakefulness. As a result of these different controls, infants exhibit higher respiratory rates and lower tidal volumes in phasic active sleep than in tonic active sleep (Ross & Rosen, 2014). In addition, the Hering–Breuer reflex is strong in active sleep in preterm infants (Hand et al., 2004).

Respiratory activity responds differently to chemical stimulation in different states. Baseline arterial oxygen and carbon dioxide levels are lower in active sleep than in either waking or quiet sleep (Mok et al., 1988; Ross & Rosen, 2014), possibly because of hypoventilation or ventilation–perfusion inequalities in this state. Arousal in response to hypoxia differs in quiet sleep and active sleep, with some studies finding that it is slower in quiet sleep (Parslow, Harding, Adamson, & Horne, 2004) and others finding it slower in active sleep (Fewell & Baker, 1987). Response to hypercapnia is also different in different states. There is a shift to the right in the carbon dioxide response curve in quiet sleep as compared to waking (E. Cohen, Xu, & Henderson-Smart, 1991; Phillipson, 1978). This response is further reduced in tonic active sleep and is absent in phasic active sleep (C. E. Sullivan, 1980).

As a result of these differing neurologic controls on breathing, a number of respiratory variables in both full-term and preterm infants are influenced by sleep and waking states. Respiration rates are higher and more variable in active sleep (Elder, Campbell, Larsen, & Galletly, 2011; Holditch-Davis, Scher, & Schwartz, 2004). Active sleep has also been shown to result in hypoventilation in preterm infants because of central inhibition of spinal motoneurons (Schulte, Busse, & Eichhorn, 1977) and poor coordination between chest and abdominal muscles (Gaultier, 1990). Thus, paradoxical movements of the chest wall and abdominal muscles during breathing are common during active sleep in preterm infants, and oxygen saturation is somewhat lower (Elder et al., 2011). However, it is not clear whether lung volume is decreased in active sleep in full-term infants. Expiratory volumes and flow rates are larger in waking infants than in sleeping ones (Lodrup, Mowinckel, & Carlsen, 1992).

The frequency of central apnea also differs between the two sleep states. Central apnea rarely occurs during waking. Most studies indicate that brief apneic pauses of less than 20 seconds in length occur more frequently in active sleep than quiet sleep in both full-term and preterm infants (Curzi-Dascalova, Bloch, Vecchierini, Bedu, & Vignolo, 2000; Holditch-Davis, Scher, & Schwartz, 2004; Vecchierini, Curzi-Dascolova, Ha, Bloch, & Gaultier, 2001). However, the frequency of periodic respiration (cyclic breathing alternating with brief apneic pauses) does not appear to differ between the sleep states (Decima, Fyfe, Odoi, Wong, & Horne, 2015; Holditch-Davis, Scher, & Schwartz, 2004; Horne et al., 2018). The mean length of apneic pauses is longer in quiet sleep (Holditch-Davis, Scher, & Schwartz, 2004). In addition, a variety of stresses, including an increase in body temperature and sleep deprivation, have been shown to increase apnea frequency, primarily in active sleep (Gaultier, 1994).

However, it cannot be concluded from these studies that pathologic apneas (apneic episodes longer than 20 seconds and usually associated with bradycardia and hypoxemia) are more common in active sleep because studies rarely included episodes of pathologic apnea. Pathologic apnea is often too rare to permit statistical analyses comparing states (Holditch-Davis, Scher, & Schwartz, 2004). However, Tourneux et al. (2008) found that pathologic apnea with oxygen desaturation was more common in active sleep, whereas the frequency of pathologic apnea without desaturation did not differ between the sleep states. In addition, some association between active sleep and pathologic apnea is suggested by the fact that the methylxanthines, caffeine and theophylline, used to treat this condition are generally found to increase the amount of wakefulness and decrease the amount of sleep in addition to their direct effects on respiration (Brandon et al., 2005; Thoman et al., 1985). On the other hand, Hayes et al. (2007) found decreased waking, brief arousals, and movement bouts with caffeine or theophylline treatment. Infants have also been found to have greater respiration regularity in active sleep during treatment with theophylline and caffeine (Holditch-Davis, Scher, & Schwartz, 2004). Some studies have found that theophylline and caffeine had minimal effects on sleep–wake development (Curzi-Dascalova, Aujard, Gaultier, & Rajguru, 2002; Holditch-Davis & Edwards, 1998a), whereas others found theophylline was related to greater maturity of active sleep–quiet sleep cycles on the EEG (H. J. Lee et al., 2010).

Weight Gain. Studies have found that obesity is related to shorter sleep duration in both adults and children, probably because of a bidirectional relationship in which inadequate sleep increases hunger and excess weight interferes with sleeping (J. Liu, Zhang, & Li, 2012; Meyer, Wall, Larson, Laska, & Neumark-Sztainer, 2012). How early in life this relationship begins is unclear, but recent studies of preterm infants found that sleep patterns in the preterm period (more rapid rate of development of quiet sleep, slower development of active sleep, and lower amounts of active sleep at 29–31 weeks) were associated with a faster rate of weight gain in the preterm period and from 1 to 27 months corrected age and a higher BMI at 1 month (Lan et al., 2017; Winkler et al., 2017). Full-term infants with shorter sleep durations in the first 6 months were more likely to have higher weight-to-length ratios (Tikotzky et al., 2010). These findings suggest that adequate sleep may protect against the development of obesity even in infancy.

Effect of Healthcare Interventions on State. Sleeping and waking states are also affected by the types and timing of stimulation that the infant receives from the environment. Thus, healthcare interventions have the potential to either promote state organization or to disrupt it. The effects of four common nursing interventions—routine NICU care, painful procedures, social interaction, and infant stimulation—on infant sleeping and waking are examined in this section.

Effect of Environmental Stimulation. The hospital provides stimulation that may be inappropriate for the development of premature infants and is likely to result in disorganized sleeping and waking patterns. Research in the 1980s and 1990s indicated that the NICU provided infants with an extremely bright and noisy environment with little diurnal variation and frequent interventions for technical procedures but little positive handling (Duxbury, Henly, Broz, Armstrong, & Wachdorf, 1984; Zahr & Balian, 1995). Similar findings occurred recently in Brazil and the United States (Axelin, Cilio, Asunis, Peloquin, & Franck, 2013; Orsi et al., 2017). The sickest infants actually received the most handling (Zahr & Balian, 1995), even though they lacked the physiologic reserves to cope with it. Recent use of developmental care has probably reduced these effects but some remain. For example, even relatively small increases of 5 to 15 decibels above ambient noise during sleep resulted in arousals for many preterm infants, decreases in respiratory rate in quiet sleep, and decreases in oxygen saturation (Kuhn et al., 2012, 2013).

Premature infants also may become hypoxic in response to virtually any form of stimulation. The severity of the negative physiologic responses to one procedure, endotracheal suctioning, has been related to the infant's state during the procedure (Bernert et al., 1997). Preterm infants who cried during suctioning had greater changes in oxygenation and HR than infants who slept through suctioning. Convalescent infants are handled less than ill

infants and experience social interactions as a greater percent of their care (High & Gorski, 1985).

Several of the aspects of routine NICU care are known to contribute to disruption of infant sleeping and waking patterns. Nursing and medical interventions frequently result in state changes. The frequency of these interventions in the NICU has been found to be as high as five times per hour (Duxbury et al., 1984). Preterm infants change their sleep–wake states about six times per hour, and 78% of these changes are associated with either nursing interventions or NICU noise (Zahr & Balian, 1995). Preterm infants are rarely able to sustain quiet sleep during nursing interventions (Brandon et al., 1999; Liaw et al., 2012) and usually awaken with each intervention. Thus, frequent nursing interventions are particularly likely to reduce the amount of quiet sleep (Liaw et al., 2012). Preterm infants normally spend only a small percentage of their time in waking states (Holditch-Davis, 1990), but this percentage increases significantly when they are with nurses (Brandon et al., 1999; Liaw et al., 2012). Also, developmental changes in the amount of waking occur only over the time infants are with nurses, and the distribution of states differs depending on the nursing activity, with active waking more common and drowsiness less common during more intrusive care (Brandon et al., 1999). On the other hand, preterm infants showed more quiet sleep after nursing interventions than before them (Symanski, Hayes, & Akilesh, 2002), and bathing did not affect sleep–wake patterns (H.-K. Lee, 2002).

Moreover, neonatal nurses and physicians often do not consider infant sleep–wake states and other infant cues when choosing the time for routine interventions. Although two studies found relationships between nursing care and sleeping and waking for groups of preterm infants (Barnard & Blackburn, 1985; Lawson, Turkewitz, Platt, & McCarton, 1985), these results probably represent infant reactions to nursing care or infants conditioned to anticipate regular nursing procedures rather than nurses responding to infant states. Infant activity has been found to decrease after nursing interventions (Blackburn & Barnard, 1985). Gottfried (1985) found that nurses responded to fewer than half the cries of growing preterm infants. Yet, a lack of responsiveness to infant cues may serve to slow the development of stable diurnal patterns of sleeping and waking that have been suggested to be the first task of infancy (Barnard & Blackburn, 1985).

In light of the recommendation by the American Academy of Pediatrics Task Force on Sudden Infant Death Syndrome (2011) that infants be placed on their backs to sleep, the effects of positioning on infant sleep–wake states also need to be considered. Full-term infants in the supine position show greater wakefulness, less quiet sleep, higher cerebral oxygenation levels, lower HRs, higher rates of brief respiratory pauses, and better airway protection during sleep than when prone (Elder et al., 2010; Ghorbani, Asadollahi, & Valizadeh, 2013; Wong et al., 2011). Similar effects on sleeping and waking, HR, and oxygenation have been found in growing preterm infants and in preterm infants with CLD (Ariagno et al., 2003; Bhat et al., 2006; Fyfe et al., 2014; Jarus et al., 2011; Saiki et al., 2009). Arousals occur most frequently when preterm infants are in supine position and least frequently in prone position (Modesto et al., 2016; Richardson & Horne, 2013). In addition, respiration rates are more variable in the supine position in preterm infants, but not in full-term ones (Elder et al., 2011), and arousals are more common (Ariagno, van Liempt, & Mirmiran, 2006). On the other hand, lateral positioning was associated with an increase in quiet sleep (Liaw et al., 2012). Thus, supine positioning is probably not appropriate for preterm infants with respiratory compromise.

However, in growing preterm infants, prone positioning was associated with a reduced ventilatory response to carbon dioxide as compared to supine position (Smith, Saiki, Hannam, Rafferty, & Greenough, 2010). Thus, in preterm infants who are no longer acutely ill, positioning decisions require balancing infant needs for rest and oxygenation with physiologic changes with respiratory maturation and the need to provide an example for parents. Although prone sleeping has decreased after discharge for preterm infants, mothers of preterm infants are still less likely to place their infants in supine position than mothers of full-term infants (Hwang et al., 2016).

Finally, the lighting of the NICU, as discussed earlier in this chapter, contributes to sleeping and waking problems in infants. Lighting in most NICUs is continuous, high level, and fluorescent. The frequency of eye opening and waking states is related to the level of illumination in the NICU; less eye opening occurs when the lights are brightest (Moseley, Thompson, Levene, & Fielder, 1988; Robinson, Moseley, Thompson, & Fielder, 1989). Higher lighting levels are associated with greater wakefulness and less quiet sleep (Orsi et al., 2017). Changes in lighting levels during sleep (even when mild light protection is used) are more likely to result in awakening than periods with constant light levels (Zores et al., 2018). These findings support the common nursing and parental intervention of shading infant eyes with one's hand to elicit alertness. In addition, infants exposed to NICUs that vary the intensity of lighting on a diurnal pattern open their eyes significantly more than those exposed to continuous illumination (Robinson et al., 1989).

In view of the problems with routine NICU care, researchers have attempted to alter this environment to promote better sleeping and waking patterns in infants. When Gabriel, Grote, and Jonas (1981) consolidated nursing care so that convalescent premature infants were disturbed less often, the infants were awake less often and had longer sleep episodes. Fajardo, Browning, Fisher, and Paton (1990) cared for preterm infants in quiet, private rooms with day–night cycles, demand feedings, and social interactions by the nurses. These babies showed an increase in the mean length of active sleep and in the organization of sleep states as evidenced by a decreased number of states. Reducing noise levels in the NICU was associated with greater quiet sleep (Varvara, Effrossine, Despoina, Konstantinos, & Matziou, 2016). Using earmuffs for preterm infants to reduce NICU noise levels was associated with lower mean respiratory rates, HRs, and oxygen saturation and more quiet sleep and less waking states than infants without ear muffs (Khalesi et al., 2017). Cobedded preterm twins spent more time in the same state, spent more time in quiet sleep, and cried less than twins bedded separately (Hayward et al., 2015).

Als and colleagues (1986) developed a system of individualized interventions for preterm infants that included sensitivity to infant cues and careful avoidance of sleep disruptions. Their experimental infants did not exhibit different state patterns compared to the control infants, but the experimental infants did have fewer medical complications and improved performance on the APIB. A replication study found improved state regulation and state stability as measured on the APIB (Buehler, Als, Duffy, McAnulty, & Liederman, 1995). Using a modification of the Als intervention system, Becker, Chang, Kameshima, and Bloch (1991) also found improvements in infant morbidity, but did not find differences in state behaviors on the NBAS at the time of hospital discharge; however, the experimental infants showed higher oxygen saturations, fewer disorganized movements, and more alertness during nursing care than did controls (Becker, Grunwald, Moorman, & Stuhr, 1993). Later studies found that infants receiving the intervention slept more than infants receiving traditional handling (Bertelle et al., 2005). However, still other studies did not find that the Als intervention system had any effect on sleep–wake states, either in

the preterm period or after discharge (Westrup, Hellström-Westas, Stjernqvist, & Lagercrantz, 2002).

A number of researchers altered NICU lighting patterns. Blackburn and Patteson (1991) compared preterm infants in a nursery with continuous lighting with infants in a nursery with lighting that was dimmed at night. Infants in cycled light exhibited less motor activity during the night and lower HRs over the entire day than the control infants. When preterm infants in the intermediate care unit were given four half-hour nap periods a day during which their incubators were covered and they received no nursing or medical procedures, they exhibited less quiet waking and longer uninterrupted sleep bouts than preterm infants without naps (Holditch-Davis, Barham, O'Hale, & Tucker, 1995), and they experienced a more rapid decline in apnea and more rapid weight gain (Torres, Holditch-Davis, O'Hale, & D'Auria, 1997). Reducing light levels in the NICU was associated with greater amounts of quiet sleep (Varvara et al., 2016). Because exposure to light at night for nursing procedures might alter growing preterm infants' biological rhythms, Kaneshi et al. (2016) tested the effects of using red light that the infants could not see. They found no differences in sleep patterns or physical growth between preterm infants exposed to a red light versus a white light. Brandon, Holditch-Davis, and Belyea (2002) compared preterm infants who received care in near darkness with infants who received cycled light. Although there were no differences in state patterns (Brandon et al., 2005), the infants receiving cycled light showed more rapid weight gain (Brandon et al., 2002). In other studies, preterm infants receiving cycled light showed earlier day–night patterning of activity than infants cared for in dim light (Guyer et al., 2015; Rivkees, Mayes, Jacobs, & Gross, 2004). Cycled lighting was associated with less fussing and crying even though no other differences in sleeping or waking were found compared to infants kept in dim lighting (Guyer et al., 2012). However, a fifth study found no differences in sleep or circadian patterns after discharge in infants exposed to dim lighting or cycled lighting (Mirmaran et al., 2003), nor did sleep or neurodevelopmental outcomes differ based on whether the cycled light began at 28 or 36 weeks' postmenstrual age (Brandon et al., 2017). All these findings suggest that neonatal nurses need to examine their routine practices to see if changes could be made to better promote stable sleeping and waking patterns in infants.

Painful Procedures. Infants in intensive care inevitably experience painful procedures. Neonatal nurses need to be alert to the effects of these procedures on infant sleeping and waking states. During painful procedures, infants are more likely to be awake and less likely to be in quiet sleep than during routine nursing care (Fearon, Kisilevsky, Hains, Muir, & Tranmer, 1997; Van Cleve, Johnson, Andrews, Hawkins, & Newbold, 1995). All but the youngest and sickest preterm infants are likely to cry (Johnston, Sherraud, et al., 1999), although the length of time until the cry begins depends on the infant's sleeping and waking state at the beginning of the procedure (Grunau & Craig, 1987). Healthy full-term infants have the longest latency to cry when in quiet sleep, and young, preterm infants who are asleep at the beginning of the procedure and have recently undergone another painful procedure are the most likely to show only a minimal behavioral response to a painful procedure (Johnston, Sherraud, et al., 1999; Stevens, Johnston, & Horton, 1994). Preterm infants tend to stay awake after a painful procedure, but this tendency is not any greater than the tendency to stay awake after routine handling (Holditch-Davis & Calhoun, 1989).

Nursing comfort measures also have the potential to minimize some of the state effects of pain without having negative effects on infant sleep. Yet how frequently practicing nurses actually use them is unclear. Franck (1987) identified nine different comfort measures that nurses reported using to soothe infants who were receiving painful procedures (Chapter 23). To date, only a few of them have been studied. Pacifiers were found to reduce crying and arousal in full-term and preterm infants when given during and after the procedure (Fearon et al., 1997). A sucrose-flavored pacifier was found to be even more effective than a plain pacifier in reducing the amount of crying by full-term and preterm infants during blood drawing and circumcision (Johnston et al., 1997; Johnston, Stevens, et al., 1999). Swaddling has been shown to reduce arousals in sleep and increase REM sleep in full-term infants (Gerard, Harris, & Thach, 2002). Facilitated tucking—a modified form of swaddling in which the infant's arms and legs are contained in a flexed position next to the trunk—was effective in reducing responses to heelsticks (Corff, Seidemanm, Venkataraman, Lutes, & Yates, 1995). Preterm infants who received facilitated tucking during and after heelsticks exhibited less crying, less sleep disruption, and fewer state changes after the heelstick than without tucking (Obeidat, Kahalaf, Callister, & Froelicher, 2009). Combining oral sucrose with sucking with or without tucking during heelsticks resulted in significantly more quiet sleep and less crying than in infants without any intervention (Liaw et al., 2013). Lan et al. (2018) found that when nurses used a supportive care bundle, sleep latency was lower than in preterm infants receiving standard care. Rocking was not effective in reducing cry and facial expressions in preterm infants in response to a heelstick, although the infants were in quiet sleep more (Johnston et al., 1997). Thus, there is evidence that use of swaddling and pacifiers with sucrose can help reduce the sleeping and waking changes caused by painful procedures. However, additional research is needed to determine the effects of other comfort measures and how comfort measures affect more severe pain, such as postoperative pain.

Social Interaction. Sleeping and waking states are known to influence the interactions between full-term and premature infants and their mothers after term age, and in turn maternal interactions alter infant sleep–wake patterns. For example, infant crying may lead the mother to pick up the infant. At another time, a mother may awaken a sleeping infant for a feeding, thereby altering the infant's sleeping and waking patterns. Mothers have been found to exhibit different patterns of interactions when infants are in different states (Rosenthal, 1983). In addition, maternal emotional stress has been found to relate to the amount of night sleeping that full-term infants exhibit at 4 and 12 months (Becker, Chang, et al., 1991).

Social interaction is known to affect sleep–wake patterns of premature infants after hospital discharge, and sleep–wake patterns in turn alter social interactions. At 4 to 6 weeks corrected age, breastfed premature infants exhibited more crying, especially during daytime, than formula-fed infants did (Thomas, 2000). At 6 months corrected age, premature infants were more likely to be drowsy or asleep during feeding and alert during nonfeeding periods, and the behaviors of mothers differed during feeding and nonfeeding (Holditch-Davis et al., 2000). Mothers were more likely to engage in behaviors that involved close contact during feeding, such as holding, having body contact, and rocking their infants, whereas during nonfeeding periods, they were more likely to engage in more distal behaviors, such as gesturing and playing with the infant. Mothers who displayed more sensitive interactions or less negative affect had infants who took more naps and slept more in the daytime (Schwichtenberg, Anders, Vollbrecht, & Poehlmann, 2011; Schwichtenberg & Poehlmann, 2009; Schwichtenberg, Shah, & Poehlmann, 2013). Conversely, preterm infants with higher sleep cyclicity scores at term were

found to experience greater synchrony with their mothers at 3 months corrected age (Feldman, 2006).

Less is known about the effect of social interaction in the hospital on infant sleeping and waking states. Minde, Whitelaw, Brown, and Fitzhardinge (1983) found that ill preterm infants exhibited less eye opening—and thus probably less waking—when they were interacting with their mothers than did healthier preterm infants. Mothers report being aware of the sleeping and waking behaviors of their preterm infants—especially eye movements, orientation, and body movements—when they attempt to interact; they also report having used specific infant responses as guides to increase or decrease their interactive activity (Oehler, Hannan, & Catlett, 1993). Waking, eye opening, increased body movements, positive facial expressions, and calming encouraged increased interaction; body movements, negative facial expressions, and withdrawing discouraged maternal interaction. However, preterm infants exhibited the positive interactive behaviors for rather small portions of the time with their mothers (Oehler, 1995).

Moreover, social stimulation affects the physiologic status of preterm infants. The variation in infant oxygen saturation during parent touching was related to behavioral state and GA, such that infants who were more aroused and awake at the beginning of touch and had younger GAs at birth showed greater variation in their oxygen saturations (Harrison, Leeper, & Yoon, 1991). Using a standardized protocol of social stimulation, Eckerman, Oehler, Medvin, and Hannan (1994) found that preterm infants of at least 33 weeks' postmenstrual age responded to talking by eye opening and arousal, but when touching was added to the talking, the infants showed increased periods of closed eyes and negative facial expressions. Infants with more neurologic insults showed even greater negative responses to touching. This finding suggests that preterm infants are responsive to social stimulation of low intensity, but if the intensity of social stimulation is increased, they are no longer able to cope with it. Medical complications further decrease infants' ability to cope with moderate-intensity social stimulation.

Preterm infants have also been found to respond differently to nurses and parents. In one study, preterm infants opened their eyes more when interacting with parents than when interacting with nurses (Minde, Ford, Celhoffer, & Boukydis, 1975). In another study with sicker infants, preterm infants spent more time in active sleep and less time in sleep–wake transition when with their parents than when with nurses (Miller & Holditch-Davis, 1992). In both of these studies, parents and nurses behaved differently toward infants, with nurses more likely to engage in routine nursing and medical procedures and parents more likely to hold infants and provide positive social stimulation. These findings suggest that preterm infants respond to the less active, more social stimulation provided by parents at first by sleeping and then, as they mature, by awakening to engage in interaction. The early sleeping may serve to conserve infant energy consumption and promote growth.

Kangaroo care, mothers holding their preterm infants in skin-to-skin contact, has been found, in many studies, to increase the amount of sleeping—especially quiet sleep—and decrease crying and sleep–wake transition as compared with periods when the infant is alone in the incubator (Chwo et al., 2002; Lorenz et al., 2017, Ludington-Hoe et al., 2006; Scher et al., 2009), or when infants are being held in the mothers' arms (Bastani, Rajai, Farsi, & Als, 2017). In addition, preterm infants experiencing kangaroo care show more mature EEG patterns than infants not experiencing kangaroo care (Kaffashi, Scher, Ludington-Hoe, & Loparo, 2013). A few researchers, however, have not found any changes in state patterns during kangaroo care (de Leeuw, Colin, Dunnebier, & Mirmiran, 1991). Studies using historical controls or allowing mothers to choose whether they wanted to provide kangaroo care found that infants receiving kangaroo care had more rapid maturation of sleep–wake states (longer bouts of quiet sleep and alertness and shorter bouts of active sleep) and higher orientation and state scores on the NBAS (Feldman & Eidelman, 2003; Ohgi et al., 2002), and that by 10 years of age, the children had better organized sleep than children not receiving kangaroo care (Feldman, Rosenthal, & Eidelman, 2014).

Finally, interventions to promote emotional connections between mothers and their preterm infants have had effects on infant sleeping and waking. Infants receiving the Family Nurture Intervention (kangaroo care combined with stress reduction for the mothers) during the preterm period showed increases in EEG power in the frontal area during both active and quiet sleep at term (Welch et al., 2014) and faster development of cortical patterns within sleep (Welch et al., 2017).

Infant Stimulation. A number of the stimulation interventions used with preterm infants are known to affect sleeping and waking states. In some cases, the goal of the intervention is to alter sleeping and waking states either to lower the infant's arousal so as to provide more energy for growth or to promote more mature state patterns. In other cases, the state effects are side effects of interventions that were designed to alter other aspects of the infant's functioning. This section examines the effects of several different types of infant stimulation interventions currently in use in NICUs.

Nonnutritive sucking is an intervention that has been variously used to soothe irritable infants and to promote feedings and growth. It is known to decrease restlessness and increase sleep time, particularly quiet sleep, in full-term and preterm infants (Liaw et al., 2012; Schwartz, Moody, Yarandi, & Anderson, 1987). Nonnutritive sucking is effective in reducing crying after painful procedures and promoting either alertness or sleeping (Fearon et al., 1997). When given to preterm infants just before feedings, nonnutritive sucking helps them to arouse into a quiet, waking state and then maintain this state, in which they are most likely to feed effectively (Kamhawy, Holditch-Davis, Alsharkawy, Alrafay, & Corazzini, 2014; Pickler, Frankel, Walsh, & Thompson, 1996). When nonnutritive sucking was used as an intervention to bring preterm infants to a waking state before feeding, infants receiving the intervention took five fewer days to achieve full oral feedings than control group infants (McCain, Gartside, Greenberg, & Lott, 2001). Other researchers did not find a change of state with nonnutritive sucking but did find that preterm infants who received nonnutritive sucking before feedings had higher feeding performance scores and more sleep after feedings (Pickler, Higgins, & Crummette, 1993).

Swaddling has been used to modify preterm infant sleep–wake states. Clothing that provided swaddling for preterm infants was associated with more quiet sleep (Kitase et al., 2017). Combined swaddling and nesting have been found to increase quiet sleep and total sleep time as compared to periods when the infants were not receiving any intervention (Abdeyazdan, Mohammadian-Ghahfarokhi, Ghazavi, & Mohammadizadeh, 2016).

Gentle touching is another form of infant stimulation. Harrison, Oliveet, Cunningham, Bodin, and Hicks (1996) provided 15 minutes of daily gentle human touch to preterm infants in the first 2 weeks of life. Infants had significantly less active sleep and motor activity during the periods of gentle touching. When the frequency of this intervention was increased to three times a day, preterm infants exhibited less active sleep, motor activity, and distress during gentle touching periods but did not differ from control group infants on any outcome variable (Harrison, Williams, Berbaum, Stem, & Leeper, 2000). After gentle touching and after

Yakson touch, a Korean process of gentle caresses, preterm infants exhibited greater sleep and less waking and fussing than infants in a control group (Bahman Bijari, Iranmanesh, Eshghi, & Baneshi, 2012; Im & Kim, 2009), and one study found that this effect was stronger for infants receiving Yakson touch (Im, Kim, & Cain, 2009).

Infant massage is another common infant stimulation technique. It provides both tactile and kinesthetic stimulation, because it is necessary to move the infant to provide tactile stimulation to different parts of the body. The purpose of this type of stimulation is primarily to promote growth and augment development, but it also affects infant sleeping and waking states. White-Traut and Pate (1987) used the Rice Infant Sensomotor Stimulation, a 10-minute structured massage of the infant's entire body from head to toe, to provide extra stimulation for growing preterm infants. They found that during massage infants were more alert. In another study, the intervention protocol was altered to be more contingent to infant cues (White-Traut, Nelson, Silvestri, Patel, & Kilgallon, 1993). Again, the experimental infants showed increased alertness during the intervention and continued to be alert for 30 minutes afterward. In another study, the massage intervention was compared with auditory stimulation alone; auditory stimulation along with massage; and auditory, massage, and rocking combined (White-Traut, Nelson, Silvestri, Cunningham, & Patel, 1997). Infants showed increasing alertness during the intervention in the massage and massage plus auditory groups, whereas the auditory group showed more quiet sleep. The massage, auditory, and rocking group showed minimal changes during the intervention but sustained alertness for 30 minutes afterward. The combined auditory, massage, and rocking intervention was then tested on preterm infants with periventricular leukomalacia (White-Traut et al., 1999). Infants who received this combined intervention showed an increase in alertness over the intervention period and were hospitalized for nine fewer days. Increased alertness also resulted from this intervention when it was used with infants with prenatal substance exposure (White-Traut et al., 2002). A similar massage protocol that involved both tactile and kinesthetic stimulation resulted in preterm infants showing more mature electrical activity on the EEG (Guzzetta et al., 2011).

In other studies, stroking of the infant's body followed by passive flexion and extension of the extremities for 15 minutes three times a day for 5 to 10 days was shown to result in increased weight gain in preterm infants (Dieter, Field, Hernandez-Reif, Emory, & Redzepi, 2003; Scafidi et al., 1990), possibly because of increased vagal activity, gastric motility, and IGF-1 (Field, Diego, & Hernandez-Reif, 2011). During massage treatments, infants exhibited more active sleep (Scafidi et al., 1990), but whether these state effects persisted after the treatment period is less clear. In two studies, massage-treated infants exhibited better scores on the NBAS and spent less time asleep (Dieter et al., 2003), whereas in another, no differences in the state organization of treated and control infants were found (Scafidi et al., 1990). Infants receiving moderate pressure massage showed a greater decrease in active sleep, less agitated behavior, and less crying than infants receiving a light pressure massage (Field et al., 2004; Field, Diego, Hernandez-Reif, Deeds, & Figuereido, 2006).

Rocking is a form of infant stimulation usually performed in order to soothe the infant. It has been administered either directly while holding the infant or by placing the infant in special cribs or incubators modified to rock at specific speeds. The immediate effects of rocking are reduced crying (Byrne & Horowitz, 1981). However, the rhythm and direction of rocking are important in determining which of the other states the infant was most likely to exhibit (Byrne & Horowitz, 1981). Exposing preterm infants to rocking over a 2-week period had longer lasting results (Cordero, Clark, & Schott, 1986). They exhibited increased quiet sleep and decreased active sleep.

In yet another study, preterm infants were placed in a nonrigid reclining chair twice a day for 3 hours from about 30 weeks' postmenstrual age until hospital discharge (Provasi & Lequien, 1993). Sleeping and waking states were observed for a 2-hour period for control infants and two 2-hour periods for the experimental infants (once in their beds and once in an infant seat) shortly before discharge. Experimental infants spent more time in quiet sleep and active sleep and less time in quiet and agitated waking than the control group infants, but no differences were found in the state patterns of the experimental infants when in their bed and in the infant seat.

Music has also been used as a form of infant stimulation in the NICU. Amon et al. (2006) found that preterm infants experiencing live music as compared to recorded music or no music showed a greater reduction in HR and more sleep 30 minutes after the intervention. Six hours of music for late preterm infants resulted in fewer interruptions in quiet sleep and more mature sleep cycles compared to standard care periods (Stokes, Agthe, & El Metwally, 2018). Loewy, Stewart, Dassler, Telsey, and Homel (2013) compared three different types of music to routine NICU sounds. Infants receiving any of the music interventions had more active sleep than during the control period, but only after listening to the lullaby did infants show less activity during quiet alert. Dorn et al. (2014). compared the effects of a lullaby with maternal voice recording presented daily for 30 minutes for 2 weeks. These interventions did not differ in their effects on sleep–wake behaviors or activity cycles.

In a final type of infant stimulation, Thoman and Graham (1986) placed a "breathing" stuffed bear in the incubator with a preterm infant. The goal of this intervention was to provide a form of rhythmic stimulation that would help the infant organize his or her sleeping and waking patterns. In addition, this form of stimulation was voluntary. Because the bear took up only a small part of the incubator and babies were usually put to sleep in positions in which they were not in physical contact with the bear, infants could choose whether or not to remain in contact with the bear whenever their random movements brought them into contact with it. As compared with the control group, experimental infants spent a much greater percentage of time in contact with the area of the incubator with the bear. By the end of the intervention period, experimental infants exhibited significantly more quiet sleep time. This study has been replicated with two additional samples, and both have shown increased contact with the breathing bear as well as more quiet sleep and less active sleep than infants given a nonbreathing bear (Ingersoll & Thoman, 1994; Thoman, Ingersoll, & Acebo, 1991).

Usefulness of Neonatal Sleep–Wake States for Assessment. Sleeping and waking states are ubiquitous characteristics of neonates. The infant's behavioral and physiologic responses are filtered through neural controls mediated by the sleeping and waking states. Although it is certainly possible to give competent nursing care to high-risk infants without considering their sleep–wake states, recognizing specific states will enable the nurse to better interpret both physiologic and behavioral changes. By observing sleeping and waking, the nurse will be able to determine whether physiologic parameters are consistent with those expected in a particular state. Changes in sleeping and waking patterns can be used to help the nurse identify the need for interventions and to aid the evaluation of these interventions. Most importantly, by observing sleeping and waking behaviors, the nurse will come to know each infant better and thus be better

able to provide individualized care. This knowledge of individual infants can then be shared with parents to help them develop positive interactions with their children.

SUMMARY

High-risk infants are both dependent on and vulnerable to their early environment—the NICU and intermediate nursery—to maintain their physiologic function, to promote growth and development, and to provide opportunities for the organization of state, behavioral, and social responsiveness. The immaturity and physiologic and neurobehavioral instability of these infants make them particularly vulnerable to environments that do not support their emerging organization and patterns or that do not attend to their cues and respond appropriately. Nurses can and do play a big role in controlling sleep in the NICU environment. It is important that parents are included in these efforts to promote positive sleep–wake patterns in the NICU and once the infant is home.

In summary, the goals in addressing the neurobehavioral needs of high-risk infants are the following:

1. Provide an environment that enhances and supports the infant's developing capabilities and sleep–wake patterns
2. Protect the infant from sensory overload and minimize stressors
3. Assist parents in understanding their infant's unique abilities including sleep–wake patterns
4. Help parents interact with their infant in ways appropriate to the infant's health status, sleep–wake state, and level of maturity

No matter how vigilantly we care for babies in the NICU, it is important to recognize that every interaction and touch provided to a preterm infant affects brain development and contributes to the overall developmental outcome of the infant, and impacts the family. There is ample evidence that neuroprotective family-centered developmental care in the NICU results in improved neonatal and neurodevelopmental outcomes, increased family satisfaction, and even enhanced employee satisfaction once a culture of change has been established. Both the risk of initial brain injury and subsequent neurodevelopmental problems can be reduced by optimizing currently approved and recommended best neuroprotective practices (Altimier & Phillips, 2013, 2016; Altimier & White, 2014). By consistently applying the principles and practices we know to be beneficial for extremely premature infants, we can improve the NICU experience for babies, families, and staff and make a significant difference in the long-term physical, cognitive, and emotional health and well-being of these fragile babies and their families.

Consistent acceptance, practice, and accountability to neuroprotective family-centered developmentally supportive care standards must be established to provide high-quality care for infants and families. Use of established guidelines, policies, and procedures to guide neonatal practice is essential. To provide this level of care and optimize the experience of neonates in the NICU environment, an understanding of their behavioral capabilities, their surrounding physical environment, and their family support system is essential. Healthcare professionals need to be cognizant of the growing body of research regarding the impact of the NICU environment and family participation on neurodevelopmental outcomes. Changes in developmental care can often begin with a few caregivers altering the way they care for premature infants and their families. Role modeling, mentoring, coaching, and collaboration are essential in the promotion of optimal neuroprotective family-centered developmentally supportive care.

PARENT VOICES

Jenny R. McCormick

My son was only 2 days old when the doctor came into my recovery room to let me know that his brain had hemorrhaged–intraventricular hemorrhage (IVH). I was told that the hemorrhage was on the left side of his brain. As the days progressed, my son's brain bleed went from a grade I bleed to a bilateral grade III/IV bleed. This was by far the scariest time for me during our NICU journey. We became very familiar with waiting for results from ultrasounds and meeting with his neurologist. Because of his brain bleed, we were given such a poor prognosis and our fears were many. Thankfully, we had a great NICU team working with us to keep us informed, to provide education in a clear manner that made it easier for us to understand what we were dealing with; above all, as they seemed to understand my worry and exhaustion, they went out of their way to provide updates daily and as soon as possible. This, in turn, helped my husband and me learn how to advocate for our child, research, and ask questions, while feeling like our voices were being heard. Today, my son is 6 years old and, though delayed in many areas, he is thriving.

Keira Sorrells

Aside from having the most wonderfully supportive lactation nurses in our unit, the neonatal therapists were equally incredible. I will never forget when I walked in for a visit and our primary nurse said she had scheduled an appointment for the occupational therapist (OT) to teach me infant massage. This was a highlight of our time in the NICU where the OT gently coached me and encouraged me to care for my daughter using the healing power of touch. She taught me important cues to look for as well as potential areas for concern as we worked together. Being able to provide this type of massage for my girls allowed me an additional manner in which to bond, empowered me to feel more like a "real" mom, and was something I continued to do for my girls into their toddler years.

CHAPTER 32

The Neonatal Intensive Care Unit (NICU) Environment

Leslie B. Altimier and Robert D. White

INTRAUTERINE VERSUS EXTRAUTERINE ENVIRONMENTS

It is well known that premature infants experience multiple physical and developmental challenges related in varying degrees to the fact that their "fetal" development occurs outside the womb in the extrauterine environment of the NICU. To better understand the correlation of early environmental factors to the developmental problems associated with prematurity, it is essential to examine (and often modify) the environment in which these infants spend a critical period of their development. This chapter highlights differences in the intrauterine environment (maternal womb) compared with the extrauterine environment (NICU); the effects these differences have on fetal/infant neurosensory and neurobehavioral development; and what can be done to optimize the NICU environment to provide a healing, nurturing place for premature infants to grow, mature, and form secure bonds of attachments with their families.

From the first moments of life, the premature infant is abruptly separated from the dimly lit, temperature-controlled, fluid-filled womb of the mother in which it has been growing and is suddenly exposed to a significantly cooler environment that often contains noxious smells and tastes, loud sounds, bright lights, and a multitude of painful procedures along with repetitive, non-nurturing handling. These altered sensory experiences can have a negative impact on an infant's brain and emotional development. The mismatch between the NICU environment and the preterm infant's developing brain and neurologic system increases the risk for poor developmental outcomes, including emotional, cognitive, motor, and sensory abnormalities (Gorzilio, Garrido, Gaspardo, Martinez, & Linhares, 2015).

The full-term healthy infant, more often than not, has a consistent nurturing caregiver as well as an appropriate variety of stimulations. The full-term infant with 40 weeks of intrauterine development is ready for a variety of sensory experiences, including tactile, gustatory, olfactory, auditory, and visual experiences. Appropriate patterns of adaptation, cognitive learning, and motor control are formed when sensory information interacts in developmentally appropriate ways with experience. On the other hand, a premature infant typically is exposed to numerous caregivers and high levels of inappropriate sensory input that can alter adaptation patterns.

The neurologic and sensory systems do not exist as separate entities but are interdependent and comprise the neurobehavioral and neurosensory development of the infant. Every sensory experience is recorded in the brain, leading to a behavioral response, thereby leading to yet another sensory experience. The human brain comprises 86 billion neurons and an even more staggering number of synapses, dendrites, axons, and glia cells connecting and supporting them, with the vast majority of these cells formed during prenatal development. After birth, the "fetal" brain continues making synaptic connections at a rate of 40,000 connections per minute and must continue critical neurologic growth and maturation in the often harsh extrauterine NICU environment (Azevedo et al., 2009; Keunen, Counsell, & Benders, 2017). While axons continue to grow, facilitating major connections in the white matter to find their cortical targets, the overlying cortex transforms its relatively smooth surface into a highly convoluted mantle with secondary and tertiary sulci that resembles the adult human brain (Striedter, Srinivasan, & Monuki, 2014). MRI studies in preterm infants have reported a fivefold increase in cortical surface area and doubling of cortical curvature measures in the time frame that coincides with the third trimester of pregnancy (Moeskops et al., 2015).

Brain development in the fetus, neonate, and infant includes not just sensory systems but motor systems, social/emotional systems, and the cognitive system, which are connected and integrated during development. The maternal womb, or intrauterine environment, is conducive to positive sensory input, which is crucial for normal brain development in a developing fetus. The intrauterine environment protects the developing fetus against harsh outside stimulation while providing a variety of tactile, vestibular, chemical, visual, and auditory sensory stimuli in an integrated, multimodal fashion (Lickliter, 2011). The intrauterine environment of a developing fetus is characterized by generalized extremity flexion and containment, limited light and noise exposure, sleep cycle preservation, and unrestricted access to the mother via somatosensory, auditory, and chemosensory pathways. The uterine wall provides secure boundaries for the developing fetus. Vestibular and tactile stimuli come from maternal and fetal movements and from contact with warm amniotic fluid as well as from contact with body parts and the wall of the uterus. Hormonal cycles of the mother provide rhythmic and cyclical stimulation. Nutritional needs of the fetus are met by the placenta. Auditory input includes maternal voice, bowel sounds, blood flow through the placenta

and umbilical cord, and filtered sounds from the extrauterine environment, transmitted through liquid and solid media.

Prematurely born neonates in the NICU are exposed to fluctuations in temperature, touch, light, sound, olfaction, oxygen, and nutrients that are very different from those they have experienced in utero. These negative sensory inputs replace the positive sensory inputs in the developing brain, which can permanently alter normal brain development. The architecture of connections in the brain is made with dendritic growth, synaptic networks, apoptosis, myelination, and pruning. Research shows that outside stimulation from the environment can induce changes in the pattern of brain development designed to occur in the last trimester of pregnancy and in early life, altering the development and impacting the quality of these connections (Keunen et al., 2017).

MRI performed on brains of infants born 10 weeks prematurely showed 30% less gray matter (the brain's thinking cells) and 40% less white matter (connections in the brain; A. Dunn, 2003; Keunen et al., 2017). Hebbian Associative Learning was derived by Donald Hebb in 1949 and includes what is now known as Hebb's law. While Hebb's law states that "neurons that fire together, wire together," it implies that "neurons that don't, won't," or that "neurons that fire apart, wire apart." This means that repeated experiences (positive or negative) reinforce particular patterns of synaptic connections (wiring) and a lack of appropriate experiences diminishes the firing of neurons, impacting the ability to "hardwire" synapses, thus altering the developing brain (Hebb, 1949).

When an infant is born prematurely, the still-developing brain and sensory systems are affected by the continuous interplay of stimuli in the NICU. Events, stimuli, and environmental factors can support the processes of sensory development or create significant interference. Sensory interference may occur when immature sensory systems are stimulated out of turn or with inappropriate stimuli. It is essential that background neurosensory stimulation be kept at a level such that sensory systems can discriminate and accommodate meaningful signals or stimulation. This observation is especially true for sound, touch, smell, position, and comfort, which are part of early neurosensory development and in utero learning (or NICU learning; Graven, 2006).

Because the developing brain is extremely sensitive to the appropriate levels of sensory stimuli, alterations can result in abnormal structural and functional development of the brain and could account for the behavioral, cognitive, and functional deficits that many premature infants manifest (Keunen et al., 2017; Rees, Harding, & Walker, 2011). Babies of low birth weight, or very low birth weight (VLBW), many of whom are also small for gestational age, are at increased risk for auditory and visual impairment including sensorineural hearing loss and deficits in visual acuity, color vision, and contrast sensitivity. Additionally, long-term alterations in retinal function and subtle deficits in neural conduction in auditory pathways have all been demonstrated (Bouyssi-Kobar et al., 2018).

It is well documented that prematurely born infants have a high risk of developmental and behavioral disorders compared with those born at term (Hutchon, 2018; Leversen et al., 2011; Saigal & Doyle, 2008). Because sensory experience is the basis for much of learning in infancy, sensory problems that affect preterm infants may contribute to their high incidence of later developmental disorders (Chorna, Solomon, Slaughter, Stark, & Maitre, 2014). Hearing and visual impairment, language delays, and sensory processing issues may also occur because fetal sensory development has been interrupted by preterm birth and exposed to the unpredictable sensory input of the NICU (Malcolm, 2015; Papageorgiou & Pelausa, 2014). Although hearing and vision impairments are well-known sensory outcomes of prematurity, abnormalities in sensory processing, the organization of sensation for use, and sensory reactivity, an observable and immediate modulation of behavior in response to a sensory stimulus, are more difficult to identify and characterize (Papageorgiou & Pelausa, 2014).

Even the full-term neonate's neurologic system is in a highly active stage of development at birth. With volumes of research demonstrating long-term disabilities in preterm-born children, understanding how we can better support the infant's fragile neurologic system to minimize these impairments can guide in helping the infant to grow and thrive within the artificial extrauterine environment of the NICU. Part of this support is the adoption of the conceptual framework and philosophy of developmental care and neuroprotection. Neuroprotection has been defined as strategies capable of preventing cell death (McGrath, Cone, & Samra, 2011). Advances in neuroimaging and research have provided broader insight into third trimester brain development, and what traditionally has been viewed as simply developmentally supportive care is now recognized to be neuroprotective care (Altimier & Phillips, 2016; Discenza, 2015; McGrath et al., 2011). Validating benefits of developmental care has been difficult because it is practiced in so many variations in different settings (Montirosso et al., 2016).

The pioneering work by Brazelton and Als found that assessing the individual infant's ability to cope with excessive stimulation provides the caregiver information to modify each infant's environment and treatment strategies with the goal to minimize excessive stimulation that is found to cause physiologic instability (Als, 1986; Brazelton, 1974; Brazelton, Parker, & Zuckerman, 1976). Infants born prematurely have demonstrated markedly improved outcomes when the stress of environmental overstimulation is reduced, and family bonds are supported. This can be accomplished by creating a supportive NICU environment utilizing innovative NICU design and by incorporating neuroprotective care into the care of high-risk neonates and their families. Neuroprotective interventions (NPI) in the NICU are strategies used to support the developing brain or to facilitate the brain after a neuron injury in a way that allows it to heal through developing new connections and pathways for functionality and by decreasing neuronal death (Altimier & Phillips, 2013, 2016; Pickler et al., 2010). NPIs that promote normal development and prevent disabilities include organizational, therapeutic, and environment-modifying measures, such as family-centered developmental care (Altimier & Phillips, 2013, 2016). Along with the caregiving environment, the physical environment, including space, activity, temperature, humidity, smell, noise, and light, has an impact on infant development (Altimier, 2015). Zeitgebers, timekeeping cues given by the environment such as a change in light or temperature, function to regulate the internal body clock (White, 2017).

The Neonatal Integrative Developmental Care Model describes seven core measures of neuroprotective family-centered developmental care to support preterm infant development: (1) healing environment (physical, sensory, and emotional), (2) positioning and handling, (3) partnering with families, (4) minimizing stress and pain, (5) safeguarding sleep, (6) protecting skin, and (7) optimizing nutrition. Neuroprotective care related to each core measure is outlined by Altimier and Phillips (2013, 2016). Each core measure has a related standard with defined infant characteristics, measurable goals, and corresponding NPIs. Although there are multiple models of developmental care, a common feature of each is the recognition that fragile preterm and sick infants and their families benefit from a specialized environment and care practices that have been adapted to their specific developmental needs.

PROVIDING A HEALING ENVIRONMENT

The optimal healing environment for any infant is physical contact with his/her mother. Every effort should be made to keep mothers and newborns together in skin-to-skin contact (SSC) whenever possible. This is the developmentally expected habitat for all newly born infants where they can be coregulated by their mothers to achieve ongoing physiologic stability. Unless the infant or mother is medically unstable, this environment provides the greatest level of support for optimal growth and development of preterm infants. In addition to the presence of an infant's mother (or other primary caregiver), a healing environment encompasses the physical environment (space, privacy, and safety), the sensory environment (touch, temperature, tastes, smells, noise, and light), and the social environment (families and staff). When mother (or primary caregiver) cannot be present or SSC is not an option (for either maternal or infant reasons), even more attention must be given to the design and maintenance of the physical, sensory, and social environments.

The physical environment involves not only space but also characteristics of space that affect position, movement, and motor development. Privacy and safety are separate, but equally important are factors in the physical environment. The sensory environment includes the exposures and experiencing of touch/movement, temperature/thermoregulation, taste/gustation, smell/olfaction, noise/vocalization, and light/vision as well as nutritional and chemical exposure. All sensory stimuli carry social and emotional connections and characteristics, and, in addition to creating cortical changes, have direct effects in the areas of social and emotional learning and memory, especially in the limbic system, where stress regulation, memory processing, and emotional development occur. The social environment includes family and staff and involves their availability for touch and emotional connections. Positive attitudes of compassion, caring, and love or negative attitudes of fear, anxiety, or anger are perceived by staff, family, and even the infants themselves, and affect the quality of interactions in the NICU environment.

There is considerable interaction between and within the physical, sensory, and social environments, and they are differentiated only for the purpose of discussion about opportunities for improvement in creating a holistic healing NICU environment for preterm and sick neonates and their families. Adverse physical, sensory, or social environmental factors can significantly interfere with growth, health, and appropriate neurodevelopment and neuroprocessing and can lead to lifelong alterations in function and well-being (Graven & Browne, 2008), while a carefully designed, healing environment can provide the support needed for optimal physical, mental, and emotional development (White, 2011).

The Physical Environment—Space, Privacy, and Safety

In 1976, the March of Dimes published *Toward Improving the Outcome of Pregnancy*, a landmark publication written by a multidisciplinary committee to provide a rationale, plan, and policy for regionalized perinatal care, as well as details of facility design and staff roles. In 1992, a multidisciplinary NICU Committee, under the auspices of the Physical and Developmental Environment of the High-Risk Infant Project, reached consensus on the first edition of recommended standards for NICU design. The purpose of this committee was to provide healthcare professionals, architects, interior designers, state healthcare facility regulators, and others involved in the planning of NICUs with a comprehensive set of minimum standards based on clinical experience and an evolving scientific database. The intent was to optimize design within the constraints of available resources and to facilitate excellent healthcare for the infant in a setting that supports the central role of the family and the needs of the staff. This group recognized that one way to promote the ideals of neurodevelopmental care and family-centered care (FCC) is through appropriate environmental modifications or construction of new NICU facilities. NICU design should meet the neurodevelopmental needs of the infants, provide adequate space and facilities for FCC, and meet the needs of the NICU staff. This committee has continued to update the NICU design standards with the latest recommendations published in 2013 that are available at https://nicu.science.nd.edu/stan%206.html (White, Smith, & Shepley, 2013).

When designing a NICU's physical environment, attention should be given to the NICU configuration, the location within the hospital, minimum space, clearance, and privacy requirements for the infant space. Family, staff, administrative, and general support space also needs to be delineated. Attention should focus on illumination guidelines (ambient, day lighting, and procedural) and acoustic guidelines (floor, wall, and ceiling surfaces). Electrical, gas, mechanical, isolation, ambient temperature, humidity, and ventilation recommendations likewise are outlined in the recommended standards. While the Facility Guideline Institute (FGI) provides guidelines for hospitals that serve as building requirements for NICU design, the guidelines lack sufficient detail to aid in many design decisions such as the rationale behind why a recommendation is being included. The Recommended Standards for Newborn ICU Design aim to address the gaps in guidance by providing interpretations of the standards, which include contextual information for why the design features are important (FGI, 2018a; White, 2013).

Research supports the concept that NICU design impacts outcomes. One systematic review collectively linked a range of aspects of the physical environment of the NICU to the well-being of patients, family comfort, and the caregiving process. Single-family rooms (SFRs) were deemed superior compared to open-bay units for patient care and parent satisfaction (Domanico, Davis, Coleman, & Davis, 2011). Others have demonstrated improved outcomes including increased privacy, increased parental involvement in patient care, improved noise control, improved sleep, decreased length of hospital stay, decreased rehospitalizations, reductions in costly hospital acquired infections, and lower direct costs of care (Julian et al., 2015; Ortenstrand et al., 2010; Sadatsafavi, Niknejad, Shepley, & Sadatsafavi, 2017; Shahheidari & Homer, 2012; Stevens et al., 2014).

When considering NICU design and unit configuration, it is important to remember that families and staff have different needs (M. Dunn, MacMillan-York, & Robson, 2016). Family needs include an emphasis on privacy and individualized care, whereas staff needs often emphasize efficiency and visibility. Parents prefer the intimacy of a SFR and the quieter atmosphere with decreased noise levels. Research shows that parental presence and holding in the NICU may promote healthy attachment and improve early neurobehavior in preterm infants and the SFR provides an environment that supports longer parental stays (Barton & White, 2016; Reynolds, Duncan, & Smith, 2013). High maternal involvement is associated with improved 18-month neurodevelopmental outcome, especially in infants cared for in a SFR NICU (Lester et al., 2016). In a study by Vohr et al. (2017), infants cared for in SFR NICUs had higher Bayley III cognitive and language scores, higher rates of human milk provision at 1 and 4 weeks, and higher human milk volume at 4 weeks (Vohr et al., 2017).

On the other hand, staff working in SFRs expressed concerns about higher workloads due to decreased visibility of infants as well as diminished opportunities for staff interaction and communication (Doede, Trinkoff, & Gurses, 2018).

Beacon Children's Hospital in South Bend, Indiana, unveiled their new innovative NICU in 2017, which consists of beautiful, spacious, and functional SFR NICU rooms. The SFRs have a number of elements that promote improved sensory development for the baby and family participation in care, which is the primary purpose for the SFR.

- Every patient room has a window. This is an important feature that helps maintain circadian rhythms for the baby, parents, and staff. Research shows that views of nature reduce stress and provide positive distraction for parents who may be distraught or depressed.
- Every SFR includes a family area with a toilet and shower that supports longer stays for family, encouraging their involvement in the care of their child.
- An interior garden courtyard is available that provides daylight and views of nature into the center of the unit.

Beacon Children's took the SFR concept a step further by introducing a new multipurpose patient care room called the NIC2 room. The innovative NIC2 room allows for couplet care (care for the postpartum mother and the NICU infant) to occur in the same room, eliminating separation. This facilitates early bonding of the mother with the child, which historically has been limited during the first few days of the baby's life. At the center of every room, at the baby's bedside, is a kangaroo chair—a specialized recliner that allows the mother to lean back and hold her baby(ies) safely, skin to skin. The NIC2 rooms have multiple purposes and functions beyond couplet care, such as accommodating multiples or group care, allowing for increased flexibility.

Like the SFR, the NIC2 room has a toilet room with a shower and sleeping space for two on a pull-out sofa bed. The toilet room has a sliding door, making it easy to access and reducing the inconvenience of the door swinging into the room. A breast pump is provided in every room, contained within the wardrobe on a dedicated shelf with a power outlet. Lockable drawers within the wardrobe are provided to secure personal valuables for the family. Also in the wardrobe is a refrigerator for the family to use. A separate refrigerator for breast milk is located on the counter at the footwall of the room in every SFR. The NIC2 room has two breast milk refrigerators in the event that two unrelated babies are in the same room.

All lighting in the room is dimmable for control over light levels at all times. No lights are located directly over the baby's bed, so that there is no chance of direct light shining into the baby's eyes. The procedure light is mounted to the headwall on an adjustable arm. Colored light-emitting diode (LED) lights at the footwall of the room, in a hue chosen by the family, will wash the wall with color to personalize the room. The color can be easily changed to vary the experience in the room and to suit the mood from day to day. Wall sconces in the family area of the room provide a soft level of light for reading or conversation. Two solid-surface shelves on the wall provide space for families to personalize the room for the baby.

Specific guidelines around SFRs are outlined in Standard 6 (White, Smith, Shepley, & Committee to Establish Recommended Standards for Newborns, 2013). The single-room NICU is a strategy that could address environmental concerns and minimize iatrogenic effects by reducing the risk of infection and stress on preterm infants while increasing opportunities for private parental interaction with their hospitalized infants. Whenever possible, a mother's arms should be the preferred locus of neonatal care (White, 2004). This concept has been enthusiastically endorsed by many and effectively applied in a number of healthcare settings. It is essential that the NICU be designed in such a way that families feel comfortable spending prolonged periods of time with their infant and encouraged to engage in intimate, nurturing encounters (M. Dunn et al., 2016).

The FGI: 2018 Guidelines for Design and Construction of Hospitals and Outpatient Facilities states that all patient rooms in the hospital setting must be single private rooms; yet, why then does the decision to build SFRs or bay/pod type rooms in the NICU remain controversial? Cost savings associated with SFR units should be justified in terms of clinical outcomes as well as construction and operation costs. Lester et al. (2014) have published compelling information regarding improved outcomes of NICU neonates, but only with appropriate developmental care in the SFR environment. Two types of cost must be taken into consideration when analyzing the implications for SFRs compared to open-bay/pod NICUs: onetime construction costs and ongoing operating costs. SFRs compared to a multiple-bed room design require an additional square footage per bed (minimum 165 square feet clear in the SFR vs. 120 square feet clear in the multiple-bed room), based on the Recommended Standards for Newborn ICU Design (White, 2013). These 45 net square feet per bed, or 67.5 gross square feet (GSF) using a 1.5 conversion factor, denotes the incremental difference between the two designs and does not imply that NICUs should be built to minimum standards for either multiple-bed or single-room design (Shepley, Smith, Sadler, & White, 2014). The amount of space allocated beyond the minimum should be equivalent for both designs based on a NICU's functional needs.

Direct costs of NICU care in SFRs have been found to be no greater than traditional open-bay/POD NICUs (Stevens et al., 2014). In a theoretical business plan for a SFR NICU, using data from two independent studies, Shepley et al. (2014) demonstrated that the cost of constructing a SFR NICU may be recuperated within the first 12 months of operation.

Ongoing operating cost in the predominantly SFR NICU entails a post-occupancy cost for increased heating and cooling. Larger NICUs required up to one additional Full-time equivalent (FTE) in support personnel but the nurse to patient ratio was not modified (Domanico et al., 2011; Sadatsafavi et al., 2017).

Specifications of materials used in the NICU also have an impact on the psychological, behavioral, physiologic, and environmental outcomes in the NICU. Selected finishes should focus on safety and the ambient environment to provide the psychological and physiologic outcomes for neonates, families, and caregivers. Mitigation of Hospital aquired infections (HAI) and unwanted sound is crucial to improving neonatal outcomes. Other outcomes, such as social support and the reduction of stress, anxiety, and fatigue, become attainable through the conscientious, evidence-based design in the NICU (Harris, 2016).

The number of NICUs designed to meet basic criteria for "green" design is increasing (Shepley, Song, & Marshall-Baker, 2016). LEED (Leadership in Energy and Environmental Design), a system authored by the U.S. Green Building Council along with the recommended standards for newborn ICU design, both provide information related to building a NICU with an environmentally sustainable design (U.S. Green Building Council, 2009). Several actions are important to accomplishing sustainable objectives (Gottlieb & Dickeman, 2007):

- Evaluating medical devices, building materials, and electronics
- Recycling and waste reduction
- Conserving energy

- Emphasizing sustainable foods
- Specifying green cleaning products
- Exploring the potential use of organic linens
- Addressing staff transportation and climate change
- Regulating pharmaceutical waste

Visual and physical access to nature and daylight are critical components of sustainability.

The U.S. Green Building Council also acknowledges the role of these environmental features and designates access to the natural environment as a source of points toward LEED certification.

While diurnal variation is important to the infants, the primary beneficiaries of the relationship with nature and daylight in the NICU are staff and families. For example, studies have revealed that family satisfaction is associated with the presence of gardens and nurses have preferences for access to natural conditions in lounge areas (Altimier, 2015).

The Sensory Environment

Defining the optimal sensory environment in the NICU is an elusive task. There is conflicting data on the dangers of both overstimulation and sensory deprivation in premature infants. Replicating the in utero environment is not possible in the NICU environment, nor is it the most appropriate thing to do. Continuation of the sensory environment found in utero can be disadvantageous to neurodevelopment of the preterm infant ex utero. For example, circadian rhythms are driven by endogenous processes and rely upon circadian time cues (zeitgebers) to remain appropriately oriented to the individual's environment and desired routine. The circadian rhythm of a fetus is guided by multiple maternal zeitgebers, none of which is readily available to the newly born infant. Instead, new zeitgebers must be established, most notably lighting cycles and breast milk (White, 2017). Accomplishing this is not as easy as turning a light on and off at the appropriate time of day, nor is the solution to simply leave the infant in a low-light environment continuously. Sensory deprivation of any sense (touch, movement, taste, smell, sound, or light) is clearly undesirable, as is overstimulation. It is also not as simple as getting the quantity of a particular stimulus right and giving it at the exact right time. Quality matters, and the target is continually moving, as the infant's medical condition, peripheral sensory apparatus, and brain maturity change almost daily (White, 2018).

Tactile/Touch and Temperature/Thermoregulation. One of the first principles of neonatal care is thermoregulation. At birth, the newborn infant moves from a warm fluid-filled intrauterine environment to a cooler dry environment. A major goal of neonatal care is to provide a thermoneutral environment in which an infant's basal metabolic requirements are minimized.

The physical environment (macroenvironment) should incorporate the following factors:

- Temperature: 72°F to 78°F (22°C–26°C)
- Relative humidity: 30% to 60%
- Six air changes per hour (with two from outside air)
- All air filtered with at least the efficiency specified in the FGI Guidelines (FGI, 2018b)

To enhance the development of the preterm infant, frequent attention is often on the thermoregulation (microenvironment) of the infant. The optimal environment for the infant is SSC with the mother, also known as kangaroo care (KC). SSC increases oxytocin levels in both mothers and fathers, a hormone known to induce relaxation, facial recognition, and bonding. SSC also increases prolactin levels in the mother, which is linked to increased breast milk production. Due to the close proximity to the mother's breasts, SSC is associated with higher rates of breastfeeding. Thermal synchrony is observed when mothers or fathers hold their babies in SSC, making it possible to warm a cool baby or cool an overly warm baby. Free unrestricted parental access is important to facilitate early and prolonged SSC and has been associated with higher KC rate as well as breast milk feeding rate (de Vonderweid & Leonessa, 2009).

When the parents are unavailable for SSC or SSC is not possible, thermoregulatory efforts should focus on the infant's individual bed space (microenvironment), whether it is a radiant warmer, incubator, or open crib. To maintain a constant central temperature within narrow limits (36.5°C–37.5°C), VLBW infants or premature infants need to be preferably cared for in a dual-function incubator or incubator (Altimier, 2012). The dual-function incubators include the incubator mode (closed-type incubator) and the radiant warmer mode (open-type incubator). This technology allows for care of a critically ill premature infant in a highly humidified environment (incubator mode), which can then be switched to the radiant warmer mode during a treatment, procedure, or for family space.

In addition to flexible modalities to ensure a thermoneutral environment, when considering incubators, attention should be given to those that have dramatically decreased decibel levels, further protecting the developing auditory system in the preterm infant. Covers specifically made for incubators are available to minimize light reaching the infant's eyes. Positioning an infant in a midline, flexed, and contained position with the assistance of therapeutic positioning aids and swaddling decreases the surface area of the infant exposed to environmental air, thus reducing radiant and convective heat losses. A flexed and contained position offers additional temperature stability for the infant by minimizing extraneous movement and energy expenditure (Altimier, 2012).

Chemosensory: Taste/Gustatory and Smell/Olfactory. Among all senses, from birth onward, olfaction plays a critical role in sensory communication. It allows the newborn to adapt its suckling and feeding behaviors, to be attracted to maternal odors, and to improve the mother–infant interactions. At term, only 25% of neurons in the olfactory bulb are mature and less than 10% of the olfactory tract is myelinated (Sarnat & Yu, 2015).

Providing supports for mothers and infants to be together early in the NICU stay is essential to support the gustatory and olfactory sensory development. Providing odor and taste of the mother's milk has been shown to facilitate the infant's mouthing, sucking, arousal, and calming from irritability, especially in preparation for oral feeding (Rattaz, Goubet, & Bullinger, 2005; Sullivan & Toubas, 1998). Providing a pacifier with mother's milk has been shown to increase nonnutritive sucking, intake, and growth and to shorten the length of hospitalization (Als et al., 2003; Bingham, Abassi, & Sivieri, 2003; Chaze & Luddington-Hoe, 1984). Providing multisensory experiences (when developmentally appropriate) such as combining odor and taste with proprioceptive and kinesthetic visual and auditory input can potentiate sensory organization during feeding. Holding the baby close to the caregiver's body serves to provide this organized multisensory environment (Browne, 2008).

The olfactory system is functional by 28 weeks' gestation (Liu et al., 2007). Olfaction (smell) is initiated by neural excitation in response to specific molecules in the immediate surroundings. Olfactory information (in the uterus for the fetus and at the breast for the neonate) is transmitted directly from the nose to the cerebral cortex. Maternal odor influences neonatal behavior (Milford & Zapalo, 2010). A mother's scent has been found to facilitate state regulation and optimal feeding experiences for both term and preterm infants. Since olfaction is functional in the second

trimester, sensory stimuli from the NICU environment rather than the mother may interfere with its development, as well as other sensory development and attachment (Schaal, Hummel, & Soussigan, 2004).

Neonates' sense of smell can be negatively stimulated by unpleasant odors. A variety of odorous products, such as cleaners, skin preparations, antibiotics, and alcohol (wipes and hand-gels), is often present in the typical NICU environment. The neonate can also be exposed to fragrances or aftershave worn by staff members. Infants may respond to noxious olfactory stimuli with altered respirations, transient apnea, and/or an increased heart rate (HR; Gardner & Goldson, 2002). The smell of NICU detergent, once detected by the neonate, elicits a response that decreases cerebral blood flow to the right hemisphere of the brain (Bartocci et al., 2000).

The emotional content of odors is highly plastic as it is modifiable by a few hours of mere exposure or by the pairings with reinforcers provided by caregivers (Liu et al., 2007). It has been shown that people can recall a scent with 65% accuracy after 1 year, because smells are processed by the same part of the brain that handles memories and emotions.

Enhancing the olfactory environment can be achieved through the utilization of olfactory NPIs. These positive NPIs may include maternal breast scent via a breast pad or a soft scent cloth. SSC helps support the discrimination of maternal breast scent. Mouth care provided with mother's milk helps the infant recognize the mother's smell and associates that smell with food and feeding when the infant is able to nipple feed.

Staff should not wear perfume, cologne, or aftershave in the NICU. Available unscented procedure preparation products should be used. Alcohol wipes should not be opened near an infant's head, and preferably outside of the incubator environment. Cleaning products utilized in the NICU should be unscented. Laundry services should also use unscented products. The odor of tobacco on caregiver bodies and clothing as well as the odors of dry-cleaning chemicals should be avoided. NICU staff and parents should be educated on this topic to prevent olfactory overstimulation.

Noise/Auditory. At birth, ears are capable of discerning more than 300,000 sounds. The brain processes sound a thousand times faster than images and registers sounds even during sleep. The constant bath of noise affects everything from concentration to health. The word *noise* comes from nausea, the Latin word for sickness. Excessive noise levels in the NICU can damage the developing cochlea and delicate auditory structures, especially the hair cells of the cochlea, resulting in hearing loss and arousal (Moon, 2011). Arousal is important with premature infants who are unable to inhibit responses. High noise levels in NICUs affect infants as well as staff and families. Loud transient noise has been shown to cause immediate physiologic effects such as increased HR, blood pressure, and respiratory rate (RR), apnea and bradycardia, hypoxia, and increased intracranial pressure (Wachman & Lahav, 2011). Noise also contributes to sleep disturbance, hearing impairment, and decreased oxygen saturation, which have a negative impact on nervous system development (Chen et al., 2009; Domanico, Davis, Coleman, & Davis, 2010; Graven, 2006; Krueger, Schue, & Parker, 2007).

Both the facility itself and operations occurring in the NICU impact the acoustical environment. Heating and ventilation systems are a challenge in a unit that attempts to provide private, separate areas that require a full ceiling-to-floor separation. From a budgetary perspective, it may substantially increase the cost of the unit renovation or construction. Those units that have met the fiscal and physical challenges of providing adequate ventilation have done so in an attempt to provide a more homelike atmosphere.

Much of the therapy provided in the NICU is noisy, making it difficult to facilitate developmentally beneficial auditory stimuli. These high noise levels are often a result of equipment, alarms, nonacoustical finishes, communication devices, and talking, as well as the underlying heating, ventilation, and air conditioning system. NICU sound levels vary based on the hour of day and are often related to activities such as shift change and medical rounds (Krueger et al., 2007). SFRs and larger clinical patient areas help reduce environmental noise because sound transmission declines geometrically as distances are increased (White, Smith, & Shepley, 2013).

The recommended guidelines for the acoustic environment state that infant rooms, staff work areas, and family areas shall be designed to produce minimal background noise and to contain and absorb as much transient noise as possible.

The combination of continuous background sound and operational sound in the infant area/room shall not exceed an hourly Local environmental quality (Leq) of 45 dB [decibels], an hourly L10 (noise level exceeded for 10% of the time of the duration of the measurement) of 50 dB, and transient sounds or Lmax (the RMS (root mean squared) maximum level of a noise source or environment) shall not exceed 65 dB, all A-weighted, slow response. In staff work areas, family area, and staff lounge areas, the combination of continuous background sound and operational sound shall not exceed an hourly Leq of 50 dB and an hourly L10 of 55 dB levels, both A-weighted, slow response. Transient sounds or Lmax shall not exceed 70 dB, A-weighted, slow response in these areas. (White et al., 2013)

Achieving these desired sound levels can help promote infant sleep and allow the baby to hear human voices at normal conversations (Philben, 2004). Although it is known that alarms and high-decibel sounds are not good, soothing sounds and talking to the preterm infant are critical to auditory processing and language development. Speech and language impairments of both simple and complex language functions are common among former preterm infants. Risk factors include lower gestational age and increasing severity of illness including severe brain injury. Even in the absence of brain injury, however, altered brain maturation and vulnerability imposed by premature entrance to the extrauterine environment is associated with structural and microstructural brain changes. These alterations are associated with language impairments with lasting effects in childhood and adolescence and increased needs for speech therapy and education supports (Vohr, 2014). Because nurses tend to be task oriented, this may need to be practiced to become "routine" during caregiving tasks (Bader, 2014).

One study by Pineda et al. (2012) showed that infants in SFRs with no parent present for significant periods of time were found to have decreased verbal scores after NICU discharge (Pineda et al., 2012). Caskey and colleagues showed that infants whose parents talked to them had increased vocalizations while in the NICU (Caskey, Stephens, Tucker, & Vohr, 2011).

Crowded rooms full of equipment can influence healthcare personnel's ability to provide environmentally appropriate care to premature infants. Noise levels of equipment have been a challenge to minimize due to industrial design standards and alarm management parameters; however, more companies are focusing greater attention on the noise levels generated by such equipment. Noise criterion ratings should be considered when selecting new equipment. Including this parameter into purchasing decisions is worthwhile.

Infant bed areas should be situated to produce minimal background noise and to contain and absorb as much transient noise as possible. Many sound control features should be considered when designing a NICU. Evidence-based sound-reducing strategies have been shown to decrease decibel levels by 4 to 6 dB when

planning environment management as part of a developmental, family-centered NICU (Byers, Waugh, & Lowman, 2006). Current air duct and ventilation systems should be evaluated for noise as well as dust. Acoustic ceiling tiles in direct patient care areas should have a noise reduction coefficient (NRC) rating of at least 0.90 for 80% of the entire surface area or an average NRC of 0.85 for the whole ceiling, including solid and acoustically absorptive surfaces (White et al., 2013). Porcelain sinks rather than stainless steel sinks can also minimize noise. Carpet decreases the noise level and promotes a homelike environment, yet rubber or vinyl flooring material directly at the bedside can ease the routine cleaning. Carpeting should be avoided in direct patient care areas, as well as around sinks and in clean and soiled utility rooms. One important issue is the noise created by the equipment used to clean the carpet. Utilization of a centralized vacuum system can limit noise levels and decrease dust levels. Other surfaces such as sound-absorbing wall surfaces and acoustical partitions may be used to additionally minimize noise (Altimier, 2015).

Thoughtful design of traffic patterns and workspaces can help remove a great deal of unwanted noise. Beds that are built in a pod design rather than down a long hall can reduce staff travel time as well as decrease noise levels for the beds at the near end of the hallway (White et al., 2013). Additionally, patient care supplies, linen, and trash placed strategically on walls that access the hallway through sliding cupboards/doors help reduce traffic into the patient room/care area.

Background sound levels in the NICU may interfere with an infant's ability to discriminate speech of parents and other caregivers. Neonates are also exposed to vibration and noise when transported and when on high-frequency ventilation. Noise and vibration combined may have a synergistic effect. Telephones audible from the infant area should have adjustable announcing signals. Noise can be limited through use of communication devices such as personal wireless phones that are set to vibrate. This technology minimizes the need for hardwired phones placed close to the infant and can reduce the need for beepers, overhead paging systems, and intercoms.

Dampening sounds from equipment, such as waste receptacles, sinks, paper-towel dispensers, and moveable equipment, is suggested for sound containment. Eliminating radios and all other unnecessary sounds, transferring infants from warmers to incubators with quiet motors as soon after admission as possible, and covering incubators with thick quilt/blankets with sound-absorbent material will also assist with sound abatement. Fire alarms in the infant area should be restricted to flashing lights without an audible signal. The audible alarm level in other occupied areas must be adjustable.

Music therapy has been used in some units to calm and soothe the environment. There is not enough evidence to say what source, type, intensity, or duration of music may be beneficial to preterm infants. With such an emphasis to achieve the quietest environment possible for the developing neonate, there is much uncertainty as to what, if anything, should be introduced to provide developmental benefit when the parents are not present.

Noise levels would be regularly monitored and reported to staff for self-assessment and to provide interventions and opportunities for improvement. Both intensity and duration of sound exposure should be considered when evaluating the noise level in a NICU. Some units are placing microphones in the ceiling above or on walls adjacent to infant care areas to determine the sound levels that are transmitted to the infant (decibel monitoring system). These microphones are wired to a monitoring device that feeds a signal to a visual alarm if the sound level exceeds a predetermined level. This visual system helps alert staff and parents to sounds that exceed a reasonable level and provides a gentle reminder to lower the sound level in order to provide a quietly healing environment for NICU infants, staff, and families.

Light/Vision. Protecting the development of the visual system is important because visual problems continue to be common among NICU graduates who were born prematurely. Visual stimulation is not required at any point before term gestation, since the visual system is the last sensory system to develop functionally at term. The eyelids and iris control the amount of light entering the eye. Infants at or before 32 weeks' gestation have thin eyelids and little or no pupillary constriction, thus allowing light to reach the retina much easier than more mature infants, children, and adults (Graven, 2011; LeVay, Wiesel, & Hubel, 1980). At 29 to 30 weeks' gestation, sleep partitions into rapid eye movement (REM) and non-REM (NREM; slow-wave) sleep. Transition to regular sleep occurs around 30 to 34 weeks' gestation (Graven, 2011). Protecting sleep cycles, and especially REM sleep periods, is critical for healthy visual development as any event or drug that disrupts REM sleep can impact visual development.

Endogenous brain activity stimulation (activity-independent) is created by spontaneous firing of neural cells in the retina, lateral geniculate nucleus (LGN), spinal cord, hippocampus, pons, cerebellum, cerebral cortex, and auditory systems, which occurs at a particular time in their development. The endogenous stimulation of the visual system prepares the retina, LGN, and visual cortex for exogenous or outside stimulation (Graven, 2006).

At 40 weeks' gestation, the human visual system has intact retinal development and pathways to the visual cortex. It is at this time that the visual system must have regular visual stimulation. Visual experiences for healthy visual development require ambient light (not direct light), focus, attention, novelty, movement, and, after 2 to 3 months, color (Graven, 2006). The visual system develops in utero in the total absence of light, and therefore the visual system is not developmentally ready for external visual stimuli until birth at term. Three main areas of care in the NICU that can adversely affect visual development are interference with endogenous brain cell activity, sleep deprivation, and intense light exposure.

Lighting in the NICU should be adjusted to support each infant's best sleep and awake organization and to deliver care without impinging on the development, comfort, and care of other infants (Lawhon & Als, 2010). Lighting in the NICU needs to be adjustable to the infant's developmental stage with a balance between dimmed ambient lighting, natural lighting, and brighter task lighting. A preterm infant should never be positioned facing directly into a light source. Only indirect ambient lighting should be utilized for preterm infants who cannot block out light through their thin eyelids, may not be able to turn away from light, and cannot communicate their needs (Rodríguez & Pattini, 2016; White et al., 2013). The focus of care for preterm infants of 22 to 28 weeks' gestation and/or VLBW infants should be on protecting the eyes from direct light and keeping ambient light exposure to low levels. Care of the 28 to 36 weeks' gestation preterm infants should focus on protecting sleep cycles, especially REM sleep. During this time, intense stimulation from NICU noises, vibrations, and other disturbing stimuli of other sensory systems can greatly interfere with the processes of visual system development (Lickliter, 2011).

Ambient lighting levels in the infant care spaces shall be adjustable through a range of at least 10 to no more than 600 Lux (the international symbol unit of illuminance), with a color rendering index (CRI) greater than 80 and a gamut area index (GAI) greater than 80 and less than 100. Both natural and electric light sources need to have controls that allow immediate, sufficient darkening of any bed space for transillumination when necessary. No direct view of the electric light source or sun shall be permitted in the

infant space. Use of multiple switches with individual dimmers to allow different levels of illumination is helpful. Procedural lighting should be available at each bedside to allow caregivers to evaluate a baby or to perform a procedure. This increased illumination should not increase light levels of adjacent babies. Illumination of support areas such as charting areas, medication preparation areas, and reception areas should be adequate to allow important or critical tasks to be performed. This light level should conform to Illuminating Engineering Society specifications (www.iesna.org). When possible, independent controls should be used to accommodate sleeping infants and working staff (Rea & Figueiro, 2016; White et al., 2013).

Each infant room, care area, or adjacent staff work area should have at least one source of daylight visible. Windows provide a psychological benefit to NICU staff as well as families. Day lighting is desirable for charting as well as the evaluation of infant skin tone. Exterior windows provide the recommended natural light and assist with diurnal cycling. However, serious problems with radiant heat loss or gain and glare can occur if infants are placed too close to external windows. External windows should be at least 2 feet away from the infant's bed and may be placed away from direct patient areas—for example, high up on the walls, as skylights, or in other locations that provide indirect light to the patient area. The latter might be a window in a hallway that secondarily allows light to pass into the NICU. All windows, including skylights, should have retractable covers for times when light is not desired. These windows should be insulated and have shading devices in a neutral color to minimize color distortion from transmitted light. Significant flexibility in lighting levels is required to accommodate the disparate needs of infants at various stages of development and at various times of the day, as well as the needs of caregivers.

Safeguarding Sleep

Sleep is a crucial human physiological need, which is beneficial to the maturation of the central nervous system memory consolidation, secretion of growth hormone (Als et al., 1994; Bonan, Pimentel Filho, Tristão, Jesus, & Campos Junior, 2015), energy storage, and illness recovery (Mahmoodi, Arbabisarjou, Rezaeipoor, & Pishkar Mofrad, 2015). The disruption of sleep experienced by preterm infants in the NICU may influence brain development and result in negative neurobehavioral outcomes, especially in learning and memory (Bonan et al., 2015; Valeri, Holsti, & Linhares, 2015). The chaotic environment of the NICU can interfere with infants' ability to modulate their sleep–wake states (Als, 1986). Preterm infants need caregivers' assistance in regulating their sleep–wake states by reducing environmental stress and adjusting nursing care activities (Als, 1986). Therefore, it is important to develop supportive interventions to facilitate infants' sleep in order to mitigate the negative influences of sleep disruption in the NICU.

Sleep organization begins during fetal life, at which time it is influenced by multiple maternal zeitgebers (White, 2018). Preterm infants are deprived of these maternal factors, so they develop a sleep structure based on the environment of the NICU. Preterm infants typically sleep less and have seriously disrupted and fragmented patterns of sleep (Levy et al., 2017).

In neonates, the sleep cycle is frequently categorized into three stages: active, quiet, and indeterminate sleep. Quiet sleep plays a role in energy restoration and cerebral maturation, in particular in the development of thalamocortical and cortical pathways and synaptogenesis. It allows stabilization of neuronal connections, increases protein synthesis, and releases growth hormones. Active sleep is characterized by a high level of endogenous neuronal activity. It contributes to the maturation of the central nervous system and the consolidation of memory and axonal connections, especially between the retina and the brain, and is accompanied by REM (Graven, 2006; Tarullo, Balsam, & Fifer, 2011).

Zores et al. (2018) found that small light-level increases led to sleep disruption in very preterm infants. Combined with our previous results, which documented the physiologic responses of very preterm infants to changes in light levels, these findings clearly demonstrate that very preterm infants are visually sensitive to small changes in light levels. Notably, these behavioral and physiologic responses occurred when there were small light-level changes that were within the light-level range recommended by the American Academy of Pediatrics. The main determinant of awakening was the initial light level. The physiologic and behavioral responses were greater, and awakening events were more common under medium light protection rather than high light protection conditions. Thus, very preterm infants reacted more strongly to a small change in light level when the baseline light level was greater. Further studies are needed to more precisely determine the mechanism by which the properties of the visual stimulus influence the reactivity of infants (Zores et al., 2018). Additionally, the Cochrane review on cycled lighting included randomized controlled trials that further demonstrated improved outcomes for infants in a cycled lighting environment (Morag & Ohlsson, 2016).

At approximately 28 weeks' gestation, individual sleep patterns begin to emerge characterized by REM and NREM sleep periods. These periods become constant by 36 to 38 weeks' gestational age. REM sleep dominates in the initial sleep cycles; REM and NREM are nearly equal as the infant approaches term, and by 8 months of age NREM sleep occupies nearly 80% of sleep time (Hobson, 1995). REM and NREM sleep cycling are essential for early neurosensory development, learning and memory, and preservation of brain plasticity for the life of the individual (Graven, 2006). For the visual system, the need for visual experiences does not occur until near term or 40 weeks' gestational age. The environment of the fetus in utero and the preterm infant in the NICU require appropriate levels of specific types of neurosensory stimuli for healthy early brain development (Graven, 2006; Graven & Browne, 2008).

Preservation of "brain plasticity," the ability of the brain to constantly change its structure and function in response to environmental changes, is an essential process throughout childhood and adult life. Sleep deprivation (both REM and NREM) results in a loss of brain plasticity, which is manifested by smaller brains, altered subsequent learning, and long-term effect on behavior and brain function. Facilitation and protection of sleep and sleep cycles are essential to long-term learning and continuing brain development through the preservation of brain plasticity (Graven & Browne, 2008).

Because REM sleep is essential for neurosensory as well as visual development, neuroprotective strategies for the NICU infant include the following:

- Protect the eyes from direct light exposure and maintain low levels of ambient light when not needed for care and procedures
- Provide some daily exposure to light, preferably including shorter wavelengths, for entrainment of the circadian rhythm (after 28 weeks' gestation; Rivkees, Mayes, Jacobs, & Gross, 2004)
- Protect sleep cycles, and especially REM sleep; avoid sleep interruptions, bright lights, loud noises, and unnecessary physical disturbing activities
- Avoid high doses of sedative and depressing drugs, which can depress the endogenous firing of cells, thus interfering with visual development, REM, and NREM sleep cycles
- Provide developmental care appropriate for the age and maturation of the infant (Graven, 2011).

Continuous bright lights in the NICU can disrupt sleep–wake states. Patients of any age who are trying to sleep find direct light unpleasant. Premature infants are photophobic; however, they will open their eyes with dim lights. If the light levels never change, infants never experience the diurnal rhythm necessary for development. Reducing light levels may facilitate rest and subsequent energy conservation and promote organization and growth.

Special attention should be given to lighting as it relates to caregivers who work night shifts. Visual and circadian needs of staff are quite different from those of patients. Five characteristics of light important for both human visual and circadian systems are quantity, spectrum, timing, duration, and distribution. The visual system responds well to a light stimulus at any time of the day or night and does not depend on the timing of light. Timing of the light exposure, however, is critical for circadian development. The visual system responds to a light stimulus in milliseconds; yet, the duration of light exposure necessary to stimulate the circadian system can take minutes (Figueiro & White, 2013).

Most babies should remain in a dimly lit environment at night, yet some staff may have difficulty staying alert, which could cause safety concerns. Shift-work disorder, a circadian sleep dis-order characterized by sleepiness and/or insomnia, is associated with decreased productivity, impaired safety, diminished quality of life, and adverse effects on health, such as increased risk for metabolic syndrome, diabetes, cardiovascular disease, ischemic stroke, depression, obesity, gastrointestinal dysfunction, reproductive problems, and cancer (Antunes, Levandovski, Dantas, Caumo, & Hidalgo, 2010; Figueiro & White, 2013). Both the health of caregivers and the safety of infants need to be considered with all unit designs.

Light levels should be regularly monitored and reported to staff for self-assessment and to provide interventions and opportunities for improvement. Both intensity and duration of light exposure should be considered when evaluating the light levels in a NICU. Some units are placing visual sensors in the ceiling above or on walls adjacent to infant care areas to determine the light levels that are transmitted to the infant. This can help alert staff and parents to light levels that exceed a reasonable level and provides a gentle reminder to lower the light level in order to provide a dimmed healing environment for NICU infants, staff, and families.

Positioning and Handling

Even as we focus on the macroenvironment in most of this chapter, we cannot forget about the microenvironment. Positioning (or nesting) the neonate in midline, flexion, and containment is one of the most important NPIs that minimizes the effect of environmental stimuli from the NICU, thereby promoting comfort and sleep. Nesting facilitates transformation of the sleep pattern from erratic disturbed spells to deep peaceful periods of sleep, which has shown to conserve energy and minimize weight loss. A study by Mony, Selvam, Diwakar, and Raghavan (2018) observed the effect of nesting on sleep pattern among preterm infants admitted in NICUs.

Results demonstrated a significantly higher (113 minutes) total duration of sleep time among infants with nesting as compared to routine care (86 minutes), which is highly significant ($t = 4.930$, $p < .001$; Mony et al., 2018).

Minimizing Stress and Pain

Preterm infants typically cared for in NICUs undergo repeated invasive procedures, which can result in pain and stress, and, in turn, disturb infants' sleep cycles and sleep quality, all of which influence their growth and overall health (Bonan et al., 2015; Lan et al., 2018; Liaw et al., 2013; Ranger & Grunau, 2014; Valeri et al., 2015).

Greater numbers of painful procedures in preterm infants (gestational age ≤29 weeks) are associated with delayed postnatal growth, poor early neurodevelopment, high cortical activation, long-term abnormalities in white matter microstructure, brain development, and lower IQ in toddlers born very preterm (gestational age ≤32 weeks; Valeri et al., 2015). Furthermore, greater numbers of painful neonatal experiences cumulatively have been associated with a poor quality of cognitive and motor developments at 1 year of age and changes in cortical rhythmicity and cortical thickness in children at 7 years of age (Valeri et al., 2015). The utilization of supportive care bundles (modulation of the infants' states, nonnutritive sucking, facilitated tucking, and oral sucrose) during intrusive procedures not only significantly increases sleep efficiency and total sleep time, but also significantly decreases duration of sleep latency and frequency of wake bouts (Lan et al., 2018).

The Social Environment—Staff and Family Partnerships

The admission of an infant to the NICU is frequently a crisis for the family. The delivery is usually unexpected, and the family unit is often separated. Their infant is attached to wires, cables, and equipment in a harsh NICU environment that is far different from the newly decorated home nursery they had planned. The environment can become comforting and inviting with attentive and compassionate caregivers who provide a welcoming environment to initiate effective partnerships with parents.

The concept of partnering with families in the NICU offers a philosophy of care acknowledging that, over time, the family has the greatest influence over an infant's health and well-being. Creating an effective partnership between professionals and families has shown benefits such as decreased length of stay (LOS), increased satisfaction for both staff and parents, and enhanced neurodevelopmental out comes for infants (Segers, Ockhuijsen, Baarendse, van Eerden, & van den Hoogen, 2019). A recent study by Welch et al. (2017) strengthened the conclusion that family-nurturing interventions (FNI) promote cerebral cortical development of preterm infants.

Establishing family–professional partnerships in the NICU environment can be challenging; yet, because families are the constant in the infant's life, helping families achieve a positive outcome from their NICU experience should be a priority while providing care. The family is integral to developmental care, and NICU design should include accommodations and considerations for the comfort and support of families. Parents must be viewed as partners in the care of their infant, rather than visitors to the NICU, and spaces should be created in the NICU environment that are welcoming and encourage their presence in the NICU and participation in their baby's care. Consideration should be given to attractive and clear signage in the primary languages spoken by the populations served by the hospital. Adequate and convenient storage of personal belongings should be made available to parents who will spend considerable time in the NICU. Comfortable chairs should be present at every bedside to facilitate prolonged SSC between parents and infants as early SSC is associated with a reduced risk of bronchopulmonary dysplasia (BPD) development, cholestasis, and nosocomial infections (Casper, Sarapuk, & Pavlyshyn, 2018). Providing parents with computer and Internet access and educational materials as well as space for parents to socialize supports the emotional and psychosocial needs of NICU parents. It is ideal to have spaces with equipment for parents to make meals, wash clothes, shower, and sleep in close proximity to their NICU baby. Private spaces for therapeutic interactions with

NICU mental health providers will facilitate psychosocial supportt for NICU parents who are at significantly increased risk for postpartum depression, anxiety disorders, and posttraumatic stress disorder.

The well-being of NICU staff is equally important. NICU staff often suffer from caregiving fatigue and secondary posttraumatic stress. Prioritizing equipment and workspace in the NICU design that optimizes staff workflows will support NICU staff in providing the best care with the greatest efficiency. NICU design that includes spaces for rest and relaxation in a pleasant environment during work breaks will give NICU staff tangible evidence of the value placed on their well-being.

Promoting a healing social environment requires a NICU design that prioritizes the need to support all members of the multidisciplinary team involved in caring for preterm and sick infants in the NICU, including medical, nursing, therapy staff, and parents. Equilateral respect and support among all members involved in this partnership will promote optimal patient care, enhance family satisfaction, and engage the healthcare team.

THE FUTURISTIC NICU

Premature and ill full-term infants require complex, real-time, clinical decision support correlating medical data from multiple sources as there are many potential complications of prematurity.

Neonatal intensive care is a complex environment that must support collaborative decision making among various care providers. Clinical decision support utilizing "Big Data" in the NICU can benefit from online health analytics platforms that leverage high-speed physiologic data together with other electronic health record data (McGregor, 2013).

Infants in the NICU are frequently attached to many different medical devices, such as cardiorespiratory monitors, mechanical ventilators, temperature probes via incubators, smart infusion pumps, and neurologic monitors, all of which display constantly changing sensed data, usually at second-by-second intervals, generating over a billion data points per patient per day. Caregivers, typically NICU nurses, must translate this data into actionable information.

Recent and upcoming technologies are changing how we deliver neonatal intensive care and how we support babies and their parents through their NICU journey. Technology has long been the backbone of modern neonatal intensive care, yet with the overwhelming amount of data generated by technology and electronic medical records, there is a need to view the infant and infant parameters more holistically in order to support clinical decision making. Clinical rule-based engines and deep learning combined with comprehensive integrated platforms can address current issues of NICUs, such as tedious workflows and the integration of big data generated by multiple devices at once.

SUMMARY

The NICU is where an extraordinary period of growth and development will take place for premature infants. Because the preterm infants are no longer protected in the uterus, their physiologic and neuroprotective needs have dramatically changed. In order to meet the unique developmental needs of preterm and sick neonates, efforts must be made to modify the usual hospital environment to create a specialized healing environment that supports their ongoing neurosensory and neurobehavioral development. Whenever possible, the optimal healing environment for infants in the NICU is in SSC with their mothers (or other primary caregivers), but also encompasses the physical environment (space, privacy, and safety), the sensory environment (touch, temperature, tastes, smells, noise, and light), as well as the social environment (families and staff). While aiming for a gentler approach, we should always assess and reevaluate our treatments and routines, because sometimes "less" is best, while at other times, "less" might not be enough.

CASE STUDY

■ Identification of the Problem

- 24-week gestational age newly born premature infant girl weighing 650 g

■ Assessment: History and Physical Examination

Upon delivery, the infant was limp, cyanotic/pale, and apneic. The infant was successfully resuscitated following Neonatal Resuscitation Program© (NRP) guidelines; required 2 minutes positive pressure ventilation by T-piece resuscitator to initiate effective ventilation when spontaneous respirations were noted; infant received 10 minutes of continuous positive airway pressure (CPAP) via the T-piece resuscitator, prior to being transferred to the NICU.

■ Physical Examination on Admission to the NICU

- TEMPERATURE: 35.7°C, axillary HR 180 beats/min; RR: 56, shallow; saturations 88% to 92% in room air
- HEENT: WNL
- RESPIRATORY: lung fields bilaterally clear and equal to bases; grunting
- CARDIOVASCULAR: rate regular with no murmur noted; good peripheral perfusion, capillary blood refill less than 3 seconds, and strong peripheral pulses noted
- ABDOMEN: abdomen soft, flat, and nontender with no masses palpable; three-vessel cord; the anus appeared patent
- GENITOURINARY: normal female infant genitalia
- NEUROLOGIC: appropriate responses, eyes open and infant blinks; extremities well formed; decreased muscle tone
- SKIN: pale pink, thin, transparent, yet intact skin
- EXTREMITIES: well formed; 10 digits per extremity; low tone
- Umbilical arterial and venous catheters were placed for fluid management and laboratory specimen draws

■ Differential Diagnoses. The differential diagnosis includes the following:

1. Prematurity
2. Perinatal hypoxic-ischemic injury
3. Shock
4. Congestive heart failure
5. Sepsis screen

■ Diagnostic Tests. Head ultrasound at 24 hours of age

■ Working Diagnosis. Extreme prematurity

■ Development of Management Plan

- Place infant in 80% humidified incubator
- Position infant in midline, flexed, and contained position utilizing positioning aids (e.g., Snuggle Up, bendy)
- Continuously monitor vital signs (VS), every 2 to 4 hours

- Maintain fluid support; TPN (total parenteral nutrition) within 24 hours of life
- Provide respiratory support with CPAP as needed
- Administer antibiotics until cultures negative for 72 hours

■ Implementation and Evaluation of Effectiveness

Implementation of Management Plan (Immediately After Initial Assessment in the NICU)

- Mother was transferred with infant to a Couplet Care Room for her care as well as the care of her infant with father assisting
- Infant was placed on CPAP of 5 within the first half hour of life

■ Effectiveness of Management Plan

- Temperature was 36.7 at 1 hour of life
- Respiratory status was stable by 2 hours of life
- Blood pressure was normal within 2 hours of life

■ Outcome

Extremely premature white female infant with stable VS. Anticipate lengthy NICU stay. Neuroprotective family-centered developmental care will be individualized to meet the infant's and family's needs at each developmental stage. Exogenous stimuli will be limited, with positive neuroprotective strategies introduced as tolerated and warranted.

EVIDENCE-BASED PRACTICE BOX

The design and operation of NICUs have evolved from the 1960s to the 2000s to support and accommodate the changes in technology involved in meeting the physical and caregiving needs of preterm infants and their families. The equipment has changed, the space has enlarged, and caregiving practices have changed. Units historically were designed as large, open areas with visibility for the caregivers. Infants were in rows, close to each other, with open space between bays. Technology has advanced with the ability to keep smaller and smaller infants alive. Small infants, less than 1,500 g, occupy most patient days, with many stays being 3 months and longer. Although the survival rate has improved, the number of infants with evidence of neurologic and learning problems continues to increase.

The focus on the environment of preterm infants and young neonates began in the 1970s but made little progress in changing the environment of the fetus or infant until the 1990s. Even in 2019, it is estimated that less than half of the more than 1,500 NICUs in the United States and even fewer in Europe and Asia are able to maintain an environment and care practices that are supportive of early neurosensory and neuromotor brain development. These units support the physiology of care, but many fail to support the needs for healthy brain development.

Although preterm birth accelerates the maturation of the lungs, kidneys, and gastrointestinal tract, it does not accelerate neuroprocesses, and under most conditions of care, it can seriously alter these processes. Processes under genetic control are thought to be important but not altered by the environment. With the studies of epigenetics, it is now clear that environmental factors can alter the expression of genes related to brain development without altering the DNA structure or code for the gene.

Alterations in the sensory environment including excess noise, bright lights, sleep deprivation, and poorly timed caregiving all affect neurosensory development in the preterm infant. The physical environment, the nutritional environment, and the social/emotional environment also influence the processes involved in the early development of the neurosensory systems. Neuroprotective family-centered developmental care provided in an environment that supports early brain development is essential for optimal outcomes and the best possible long-term development. It is essential that NICUs make changes necessary to have a healing environment along with care practices that support and protect the processes of early brain development (Altimier & White, 2014; White, 2013).

CHAPTER 33

The NICU—Through a Mother's Eyes

Kelley Benham French and Leslie B. Altimier

INTRODUCTION

The birth of a baby is a milestone event for a family and is typically a joyous occasion. When a baby arrives much too early, or complications arise, and a neonatal intensive care unit (NICU) stay is required, this typically joyous occasion turns into a stressful, anxiety-filled nightmare for families. Parents are immediately separated from their newly born infant and, depending on the unit, it can take days, weeks, or months before they are "allowed" to hold and care for their new infant. Parents are frequently treated as visitors in the NICU, only able to visit their infant during certain times of the day and all the basic caregiving roles (e.g., changing diapers, taking temperatures) are fulfilled by nurses. Parents frequently feel like outsiders, that they don't fully understand what is going on, and that they are not included in decisions regarding their infant's health. Parents may experience feelings of disempowerment and doubt about their parenting abilities, which may lead to a lack of confidence, anxiety, and subsequent posttraumatic stress (Varghese, 2015). From these experiences, NICU parents have high levels of stress and anxiety, and frequently have trouble connecting with their new infant, leading to parental (mothers and fathers) psychological distress even 9 months postpartum (Carson, Redshaw, Gray, & Quigley, 2015).

Most NICUs claim to provide "family-centered care" or "family-integrated care"; yet, of the 100 NICUs that I consulted or toured for 20 years (from 1999 to 2019), over 80% had written family "visitation policies" that indeed stated the importance of the family, EXCEPT for during shift change, clinical rounds, procedures, admissions of other infants, and the list goes on.

Simply put, is this really family-centered care? A policy that includes the words "visitation" or "allowed" sends a clear message that the family are visitors and are not all that important, or as important as the NICU staff. NICU staff verbalize acceptance of families being involved in patient care, but their actions do not always reflect their words. Many units provide opportunities for parents to engage and provide care (or at a minimum, participate in care) of their hospitalized infant. However, these opportunities are sometimes offered to parents inconsistently based on the experience, confidence, and tenure of the nurses.

As caregivers, once we really listen to parents and their stories, we can begin to understand the parent experience and really support parents in the way they need support. To get honest and transparent feedback about different components of family-centered care, an author, professor, and, most importantly, parent (Kelley French) was asked a series of questions by Leslie Brinley Altimier, RN. Here are Kelley's stories illustrating her NICU experience through a mother's eyes.

1. ***Leslie Brinley Altimier (LBA), RN: Kelley, were you always welcomed by name and treated with courtesy and respect by the healthcare team staff? What actions by the healthcare team were welcoming, courteous, and demonstrated respect?***

   Kelley Benham French, (KBF) [Mother]: We were always made to feel like we mattered and that our presence was important to our baby. Everything—from the design of the unit, with private rooms and comfy chairs, to the obvious training and philosophy of the hospital staff—was designed to include us. Yet I really struggled in the beginning to feel like I could contribute. If not for the insistence of the nurses and nurse practitioner, I'm not sure I would have bonded in the NICU with our daughter like I did. I'm not sure if anyone used my name, especially at first, but that didn't bother me. Being called "Mom" was a new and thrilling experience that I cherished.

   I was blessed with a supportive and involved husband, and he was in a better place mentally to participate in the first few days. The nurses lavished attention and praise on him; I suppose it was because seeing a dad so involved was an anomaly, and probably because he baked them cookies. But, it did grate on me that he got so much attention when I could slip through the NICU in my rumpled pajamas practically unnoticed. It made me resent him for being the better parent. I often wondered if the staff would have treated us differently had we not been older, white, and middle class. I hope not. But, our advantages were clear. We had more support and resources than most of the other families, and we got a lot of attention from the nurses.

2. ***LBA: Did you always feel "listened" to? What are some things that the healthcare team did that made you feel they were listening and hearing what you were saying?***

   KBF: For the most part, I felt listened to, but less so when we had an unfamiliar nurse. We built trust and respect with our primary nurses over time, one long afternoon together after another. Still, we really struggled to know when to object or complain. For the most part, we are pleasers and we respect authority, and we frankly wanted the nurses to like us, because we firmly believed that if they liked us, they'd be

more responsive to our daughter. Again, there's a question of class here. If I'd been 17, homeless, or if I'd spoken another language, would anyone have taken my concerns seriously? I have no idea.

3. ***LBA: Is there an example of an action or comment that demonstrated staff were not really listening or hearing what you were saying?***

KBF: When we had a new nurse one day, several months into our stay, our daughter had an elevated temperature in the crib. The nurse requested a urine catheter culture to check for infection. I remembered the previous attempt to catheterize our baby and how she had screamed. I noted that our particular baby was difficult to "cath" and that she had been sleeping under a pile of blankets, which was unusual for her. I asked the nurse to hold off for half an hour, take away the blankets, and take her temperature again. The nurse pushed back, which seemed silly. It got tense, and I flatly refused to allow the catheter, and within a few minutes Juniper's temperature returned to normal.

Later, after discharge, Juniper had to be catheterized again, and I requested it be scheduled in conjunction with another procedure that required anesthesia. They had such a hard time with the catheter they had to call a urologist, who found scarring from the first NICU catheterization. Reflexively ordering a urine "cath" for a fever without thinking through other causes would have been unnecessary torture for my baby.

I'm not a medical expert, but what I can offer is continuity. I know if the routine has changed. I know what has worked in the past, and I know what has not worked. Continuity is the weak link in the NICU.

4. ***LBA: Do you feel that the healthcare team members could recognize parents' psychological challenges (anxiety, depression, frustration)?***

KBF: Some of the healthcare team seemed to be able to tell I was struggling. A note in our daughter's chart noted that "Mom is stressed." A very nice social worker checked in on us, but we were the least of her problems. So many families needed translation services, bus passes, a place to stay. We would never try to claim resources that should go to people who needed them more. And I would never add the burden of my mental health onto the already overloaded plates of the medical staff. I want them focused on my baby, not me.

A few weeks into our stay, I drove the 45 minutes across town to a counselor I used to see. I spewed my story and my anxiety at her for an hour and a half, and she could do little more than absorb it. I paid the $90 and drove back to the hospital. This counselor had helped me through some garden-variety stressors in my previous life, before my entire world turned inside out and all the things I used to care about fell away, to be replaced with only my tiny daughter and my overpowering terror and love. My therapist didn't know what NEC was, or what it felt like to pump 12 hours a day, or what a 1-lb baby feels like in your hands.

Surely, I thought, there are enough mothers in this hospital dealing with grief, anxiety, and PTSD to keep a whole unit of psychologists busy. Why not bring specially trained therapists right into the hospital, to the epicenter of the need?

5. ***LBA: What were the top three stressors/anxieties/frustrations you experienced as a parent in the NICU (Box 33.1)? Could something or someone have helped to decrease this stressor?***

KBF: Yes, I KNOW that anything can happen, I KNOW you don't have a crystal ball, and I KNOW that you're superstitious, but we made it 5 months before anyone suggested our daughter might live.

Pessimism

A little hope is okay too. Along with all the statistics about disability and death, what about some studies that help parents see how important their role is? What about some stats that validate how far we've already come?

We get a bunch of statistics on the first day, thanks to the NICHD neonatal outcomes estimator, but those odds were never updated as milestones passed. Most babies who die do so in the first week. How about a sit-down check-in after the first brain ultrasound with some new numbers and a new outlook? How about a sit-down check-in every 2 weeks? Every month? Every time a new doctor comes on scene?

The number of times a doctor sat down in a chair and talked to us in our 197 days in the NICU?

TWO.

Lack of Continuity

This was the hardest part of the whole experience. From day to day, our understanding of our baby's condition and forecast cascaded wildly depending on the perspective and tone of the nurse *du jour*.

After our baby took a turn for the better, a nurse gave us an extended lecture on all the ways she could still suffer and die. "Kids like her are scary kids," she told us, shaking her head. When she teetered on the brink, a doctor found a way to offer hope.

When we were with our primary care team, we learned to calibrate our expectations. We knew to ask harder questions of Dr. Sunshine and to take what Dr. Doom said with a grain of salt. That was a gift that experience brought us. Parents who don't have 6 months to adjust might not have the advantage of perspective that we developed.

When we had an unfamiliar doctor or nurse, we could not read the tea leaves, and were nearly as lost as we had been on our first day. We held our breath for days until our primary nurse returned. We prayed our primary nurse practitioner would return from vacation. Nights and weekends were hell.

We understood that everyone needed time off, and that keeping the staff rested was good for everyone, including our daughter. But our 1-lb baby didn't understand day or night, and her body did not respect vacation schedules. Why should the staffing be thinner after dark? Why should we have to deal with a whole new team on the weekend? This would not be such an issue over on the feeder-and-grower side of the NICU, but on the critical side in our tertiary care center, it was a huge issue for us.

Jargon

I teach and study language, but I've never felt the power of language as acutely as I did in the NICU. Every profession has its jargon, its code, and medicine is no exception. Jargon makes us feel like part of a tribe. And people who work in high-stress environments especially need to feel the support and camaraderie of the tribe.

Box 33.1

TOP THREE STRESSORS/ANXIETIES/FRUSTRATIONS PARENTS EXPERIENCED IN THE NICU

1. Pessimism
2. Lack of continuity
3. Medical jargon

But the problem with jargon in the NICU is that it sends an equally powerful message to newcomers. New parents—dazed, disoriented, depressed, sleep-deprived—are already baffled by the foreign landscape of machinery and the metric system. So, when the humans in the room speak about morbidities and trials of life, the gulf between the parent and child yawns wider.

How can a parent feel close to a baby encased in plexiglas, ensnared by wires, and guarded by uniformed people who speak in code? When a neonatologist said our daughter was likely to develop a number of "morbidities," I didn't know that could mean anything as mild as nearsightedness, because the word "morbid," for nonscientists, conjures all sorts of gruesome imagery. All I saw were coffins.

When he asked, "Do you want everything done?" I had no understanding of what he meant by "everything." I pictured cracking her ribs during futile CPR.

I met a father this year who, 2 years after the death of his son, was still angry to the point of tears over the phrase "incompatible with life." In his fear and grief, he simply could not process what the term meant.

The people who made us feel steady on our feet used words that can be hard to say and hard to hear, but whose meaning was clear. Death. Die. Disabled. Blind.

Jargon offers us an emotional shield. It distances us from the things that are hard to say and feel. But, in the NICU, what parents need is someone who can speak across the divide.

6. ***LBA: What made you feel most like a mom to your baby and who had an impact on you feeling like a mom/dad to your baby?***

KBF: Nurses! When I met my daughter, I was afraid. I was afraid that she'd be so alien and incomplete that I wouldn't recognize her. I was afraid that I'd love her, and that would only make losing her harder. I had convinced myself that God, or the universe, or whoever, was punishing me for defying nature in conceiving her through IVF. I had convinced myself that God wouldn't kill her unless I was there to watch. If I stayed away, she would be safe. None of those feelings was rational, but who is rational at such a time?

It started with a little bow on our baby's head. A tiny thing, but it did send a message. This is your daughter. Get to know her.

7. ***LBA: What would be the most valuable feedback you could give a nurse or doctor to help them support parents in feeling more like a real "mom or dad"?***

KBF: I teach storytelling. A story needs a central character, and the most important quality of that character is that they have power over their situation. That's why Sleeping Beauty sucks and Moana is amazing.

A parent feels like he or she has no power. Imagine being trapped in the most important story of your life, watching your baby die, and being powerless to help. Imagine that your baby is dead, and all you did was watch. Why wouldn't you run?

Without those nurses, would I have become one of those parents who disappeared? I would not have stopped coming entirely, but I might have said I had to work, or pump, or come up with a million excuses not to engage. It's easy to look around the NICU and see the empty chairs and judge the parents who are not there. I don't judge them anymore. I could have been one of them. I was carrying an impossible amount of guilt over my body ejecting my daughter at 23 weeks. I couldn't hold her, couldn't feed her, couldn't do any of the things that mothers are supposed to do.

I conceived with an egg donor, so I didn't even share her DNA. When I signed consent forms, I wrote "Mom" next to my name. But in what way was I her mother? I became her mother, truly, thanks to the actions and the insistence of the NICU nurses.

8. ***LBA: When and how did you first touch your baby in the NICU?***

KBF: The first time I held her was a Tuesday, and on Tuesdays they clean the incubators. So, while they had the baby out, why not hold her? She was 2 weeks old.

Later, we would learn that a young nurse named Courtney talked the doctor into allowing it because she'd recently trained in developmental care. The doctor allowed it because she thought the baby would die anyway, and every mom should hold their baby once while it is still alive. It seems like simple compassion, letting a baby and a mom be together. But we know this is actually a crucial moment. Clinically, this is what she needed. She breathed better and held her temperature better when she was skin to skin.

But the moment might have been even more important in my life. Even when babies do die, the doctors and nurses are helping the parents write the story of their short lives, and of our lives as their parents. The story has to be one that we can live with for the rest of our lives. It might be the only story we will ever have of who we were in that moment and how we formed a family.

My daughter lived. And now, the nurses and family and even strangers like to tell my husband and me that she lived in part because we were such great parents to her. Because we were there for her, reading, singing, and holding her hand. Some of that is true. But I could not have been that parent without those nurses.

People say, "She's a miracle." I believe that's true. But as my friend Stephen told me, "Love is the miracle." The miracle was that those nurses loved her, and they made me feel safe enough that I could love her too.

9. ***LBA: Did the healthcare team encourage you to participate and take over parts of your baby's care?***

KBF: Nurses pulled me out of my fog and told me to put my hands into the incubator and touch her. I am certain that if the nurses had not forced me to engage, my daughter would not be alive.

- Here. Change her diaper.
- Here. Swab her mouth.
- Here. Lift her so I can weigh her.

10. ***LBA: Is there an example of something a healthcare team member said or did that discouraged you from participating in the care of your baby?***

KBF: Once, when our baby swelled beyond recognition and began to leak fluid through her pores, the medical team was stumped at how to make it stop. I blurted out something at rounds that probably felt absurd to the medical team. "When my iPhone gets wet, everyone tells me to put it in a bag of rice," I said. "Should we set the baby on a bag of rice?" Someone smiled condescendingly, and I was embarrassed and that was the end of it. That nonverbal "look" discouraged me from speaking up. It sounds dumb even as I type it. But there has always been a little part of my brain that has nagged at me asking, "*What would it have hurt?*"

11. ***LBA: Did you provide input during multidisciplinary daily rounds on your baby?***

    KBF: We always tried to be there for rounds, because often our observations didn't mesh with whatever had been charted or documented, or with the recollections or understanding of the team that rounded 12 hours or 3 days later. Details get lost over time. When did that darkness on her belly first appear? Did her head swell first or her chest? What percentage of the time does she recover from a drop in her saturations on her own? Those are the kinds of details that we seemed to hold on to.

    Only once during rounds did a doctor ever ask us what we thought. When it happened, it came as a shock. Why was the doctor asking us? Why was everyone looking at us now? But, in retrospect, we should have been asked more often. We **DID** have something to contribute.

12. ***LBA: Did you consistently attend nurse hand-offs/shift changes while your baby was in the NICU?***

    KBF: We were not allowed to be present at shift change, and I never understood why. I think it had to do with HIPPA and possibly overhearing something being discussed nearby about another patient.

13. ***LBA: Did you complete any "charting/documentation" of your baby's activities, feedings, output, etc.?***

    KBF: We were never asked to chart or document, although we would have liked to have some input, especially when our assessment and/or views did not mesh with what had been stated or documented.

14. ***LBA: Did you consistently read the healthcare team's documentation (in the EMR) about your baby's conditions, results, and care?***

    KBF: I tried to read the chart once, but was told that if I wanted to do so I needed to make an appointment to do it with a doctor present, so the doctor could explain anything confusing. I understand the reason for that policy, but I didn't like it, and I never asked again.

    After discharge, I ordered the entire 7,000-page chart, and I saw many things I hadn't known at the time and things that I would have liked the opportunity to clarify or expand on in the moment. I also saw a general over-focus on detail and a lack of synthesis or attitude. Detail matters, but so does the narrative, the arc. The charting system did not seem to leave space for meaning.

15. ***LBA: Did you feel prepared and ready for the discharge of your baby from the NICU?***

    KBF: You might think that after 197 days, we'd feel prepared for discharge. But we were terrified. I cried.

    What would I do without the nurses who had held my hand, translated for me, supported me? What would my daughter do without the people who knew how to get her to eat, calm her cries, settle her to sleep?

    When my husband and I walked her out of the hospital, our primary nurse, Tracy, walked beside us. "She's not going to know which one of us is her mother until we get to the car," I said. I was not kidding.

    My daughter had heard Tracy's voice from her first days, had felt Tracy's hands, smelled Tracy's smell. Tracy had played her favorite music for her when we weren't around, had changed the batteries on her mobile, and kept her in fashionable outfits and fancy homemade hats. Thanks to Tracy, the love our daughter had known had been multiplied. So, when we walked out, the car seat bumping against my knee, it felt wrong—cruel even—to leave Tracy behind. She never treated our daughter like a patient, only like a little girl.

16. ***LBA: What were your biggest "aha" moments in the years after your baby was discharged that could have been* stressed *more during the NICU stay, or could have prepared you more for your baby's future?***

    KBF: I wish someone had told me that:

    - There's so much more hope in the research;
    - Babies with involved parents have as big an advantage as not getting a brain bleed;
    - I mattered, and that the idea that I mattered was supported by science. These studies do exist, so why share statistics about nearsightedness, but not share statistics about parental engagement?
    - It would be terrifying, yes, but
    - It would also be exhilarating, fascinating, boring, funny, and transformative, and that when it was over, I would not give up that time in my life—I would not go back to the person I had been before—for anything in the world.
    - Before she was born, when we were asked to decide whether to "do everything" to save her or let her die at birth, I wish someone had told me that I was trying to make a decision as a person I had not yet become. The things that mattered to me in that moment were not the same things that would matter to me 6 months later.
    - It was OK to be afraid (Box 33.2).

    There are studies on this too, though. People who come out the other side of these things with disabilities rate their quality of life pretty high.

    - Our daughter came home on no oxygen, no monitors, and no meds of any kind.

    By some standards, though, she was an "unfavorable outcome." She battled NEC, ROP, CLD—so many acronyms that statisticians and researchers used to measure outcomes. But, every one of those "morbidities" resolved on its own before discharge.

    - She came home. She rolled over, sat up, walked, talked, sang, ran.
    - She dances. She reads. She rides horses. She writes songs for her little sisters.

    Every day in the NICU, there is suffering, there are heartaches, and there are goodbyes. Those stories surely weigh on the hearts and consciences of the nurses and doctors who knew, loved, and lost those kids. But, every day there is also invention, surprise, and wonder. And, so many kids thrive after discharge in so many astonishing and ordinary ways. They sell Girl Scout cookies, climb trees, dance in the Nutcracker,

Box 33.2

WE WERE AFRAID

- Of disability
- That we were too old
- That we couldn't handle it
- That our daughter would hate her life, and that she would blame us

swim in the deep end, and read their first chapter books. They don't visit the NICU nearly often enough, but their successes are still your successes. So, as you guard against the terrible things that can happen, I challenge you to kick out a window for hope. For the things you can't see and wouldn't predict. Because those stories are happening every day, too. And the lessons of those stories are just as important as the harder ones, probably more.

17. ***LBA: Kelley, thank you so much for your open and transparent discussion about the NICU experience through your eyes—a mom's eyes.***

    As NICUs strive to create partnerships with parents and families, we need to move from words and theories to actions and reality. Building family partnerships begins with trust from all involved. To build a trusting relationship, difficult questions need to be asked and answered in an open and transparent just culture. Understanding needs and wants from a family's perspective can only be met by listening: listening to parents and meeting their needs at their level of understanding. We cannot assume that every parent wants the same information, which is why listening and asking about their needs and wants is vitally important.

References related to the content of the questions asked of Kelley are listed in the text that follows.

To find out more about the family experience through a mother and father's set of eyes, I ask you to join me in reading an amazing book by both Kelley Benham French and her husband, Thomas French (2016). Kelley and Thomas French chose to fight for their daughter, Juniper's life, and this is their incredible tale.

> Juniper French was born 4 months early, at 23 weeks' gestation. She weighed 1 lb, 4 ounces, and her twiggy body was the length of a Barbie doll. Her head was smaller than a tennis ball, her skin was nearly translucent, and through her chest you could see her flickering heart. Premature babies like Juniper, born at the edge of viability, trigger the question, "Which is the greater act of love—to save her, or to let her go?" Kelley and Thomas French chose to fight for Juniper's life, and this is their tale. In one memoir, the authors explore the border between what is possible and what is right. They marvel at the science that conceived and sustained their daughter and the love that made the difference. They probe the bond between a mother and a baby, between a husband and a wife. They trace the journey of their family from its fragile beginning to the miraculous survival of their now thriving daughter.

CHAPTER 34

Touch a Life, Impact a Lifetime: Trauma-Informed Care in the NICU

Mary E. Couglin McNeil and Amy D'Agata

INTRODUCTION

The scenario in Exhibit 34.1 is fictitious, yet events like this happen far too often and change the course of a family's pregnancy expectations and their lives forever. As we know, maternal and/or fetal complications affect about 10% of births in the United States (Harrison & Goodman, 2015). When complications occur, families are typically grateful for the advancing technology available in neonatal intensive care units (NICU); however, admission to the NICU is rarely a benign event. One unintended consequence of NICU care is the pervasive suffering experienced by the infant, the family, and the clinicians (D'Agata, Coughlin, & Sanders, 2018). In this chapter, we uncover the suffering of infants, parents, and clinicians, which will provide the framework for why NICU practice is ripe for a paradigm shift. A shift that acknowledges the traumatic nature of NICU care, both for care recipients and care practitioners, and actively seeks to reduce the experience of toxic stress and mitigate the associated trauma. We also provide tools

EXHIBIT 34.1

HIGH SCHOOL GRADUATION!

Tracy, Shannon, and Erin are NICU nurses at Elmwood Medical Center. Seventeen years ago, they were part of the team of nurses who cared for Katie Walsh. Katie was memorable to these nurses for several reasons. First, the circumstances of her birth were tragic. Second, her family has maintained contact with the NICU by visiting each year around Katie's birthday. Finally, for years the NICU team has supported Katie's interest to one day herself become a NICU nurse. Next week, Katie will graduate high school and many of her former nurses will be at her graduation party. In the fall, Katie will be attending college in Pennsylvania as a nursing major, just like her mom. This accomplishment is relished by all who know Katie because of the many hurdles she has faced.

Since Katie entered elementary school, her former nurses have been aware of Katie's learning and sensory processing challenges. Her sensory processing issues cause her to be sensitive to noise and touch. Early on, Katie was diagnosed with attention deficit and executive function disorders. Katie received individualized educational support for the last 10 years to help ensure her academic success.

Most recently, Katie has shared with the nurses her struggles with anxiety and depression. Katie was diagnosed last year with major depressive disorder. Following her most recent crisis, Katie tried to describe to Tracy, Shannon, and Erin the storm of emotions that flood her mind during an "event," as she calls it. Katie not only suffers mentally when a crisis occurs but also physically, so much so that some days she cannot get out of bed because of the pain she feels. Katie says the treatment she has been receiving for her depression has been really helpful, and it has been 6 months since her last "event."

Katie learned the circumstances of her birth at an early age. Her family shared that she was born at 23 weeks' gestation following her mother's brain aneurysm, an event that her mom did not survive. As Katie was growing up, her dad and grandparents surrounded her with love and made sure she received all the help possible to overcome being born so early. In fact, as far back as she can remember, her teachers and therapists have told her that many of her challenges are probably linked to her premature birth. They have explained that lots of painful procedures are done to premature babies during the weeks and months they are in the hospital, and that these experiences can affect how the brain develops.

Tracy, Shannon, and Erin are excited to share in Katie's graduation celebration. They feel proud to have been part of her life since birth. Over the years, the nurses have talked together about Katie's challenges. They know premature birth increases the risk for suboptimal outcomes, yet have wondered to what extent their care may have played a role in Katie's outcomes. Fortunately, Katie escaped major complications, but they have seen the toll her learning, sensory, and mental health issues have taken on Katie, her dad, and her grandparents. The nurses wonder if there are practice changes they could make to decrease the risk for outcomes like these.

Clinician Questions:

1. *How does this scenario make you feel?*
2. *Have you cared for infants and families that you have maintained a relationship with beyond the NICU?*
3. *Do you ever wonder how the care you provide affects infants?*

EXHIBIT 34.2

KATIE WALSH'S PRETERM BIRTH

Jake and Kimberly Walsh met in college. Jake was from Seattle and Kimberly from a small town outside of Atlanta. They met during an undergraduate English class and discovered they both had a love of running. After graduating from college and completing their first marathon, they both began their careers in Philadelphia, Jake as a middle school teacher and Kimberly as a staff nurse in the cardiac ICU of a trauma center. They were very much in love and began planning their wedding and life together. They were married 4 years after finishing college and found out they were pregnant with their first baby 1 year later. At the age of 27, they were both the epitome of health and thrilled about their uneventful pregnancy.

At 23 weeks, Kimberly continued working 12-hour shifts and picking up extra shifts here and there. After finishing her week, Kimberly was looking forward to her 4-day weekend with Jake. On Friday morning, Kimberly began her day at yoga, stopped for brunch with her best friend, and then went grocery shopping before heading home. Once at home, she put the groceries away and started a load of laundry when she noticed a headache coming on. Kimberly decided she would rest on the sofa before Jake arrived home in half an hour. Her headache quickly changed from tolerable to blinding in minutes.

Kimberly began sweating and sensed she was going to vomit. She made her way to the bathroom, which is where Jake found her moments later. Kimberly was barely responsive and Jake immediately called 911. He cradled his wife and told her over and over again everything was going to be okay, help was on the way for her and the baby. By the time emergency medical services arrived, Kimberly had become unresponsive and was intubated on the bathroom floor. In the emergency room, Jake was told the horrific news that it appeared Kimberly may have suffered a brain aneurysm; her condition was grave and the baby needed to be delivered immediately.

Kimberly was transported to the main operating room. Due to the urgency of the situation, Jake was not allowed to attend the birth. A labor and delivery nurse escorted Jake to the waiting area and remained with him. When the surgery was complete, the surgeon congratulated Jake on the birth of his baby girl. The baby had been stabilized and transferred to the NICU. His wife, Kimberly, had suffered a massive brain aneurysm. The surgeons tried desperately to save her but were unable.

for how clinicians can begin to incorporate trauma-informed care into their practice. First, let us look back at the events that resulted in Katie Walsh's preterm birth (Exhibit 34.2).

WHY DID YOU CHOOSE TO PRACTICE IN THE NICU?

We all choose to practice in the NICU for different reasons; however, often a common denominator is a desire to make a difference in the lives of vulnerable newborns and their families. Despite the difficulties NICU clinicians face in their day-to-day role responsibilities, compassion and the desire to help others are typically what drive our commitment to this fragile patient population. In an effort to develop trust and partnership between the healthcare team and families, clinicians work hard to create relationships with parents and families. As demonstrated in the opening scenario, a strong bond was developed in the NICU between the nurses and Katie's family. Therapeutic relationships are a cornerstone of nursing, deepening our connection with the people we serve and providing us with insights that enhance our ability to meet their needs. However we must be aware that bearing witness to the suffering of others may come at a cost; stories like the Walshs', and those of every family we care for, affect us deeply.

For years, NICU clinicians have primarily viewed the importance of their role and their impact on outcomes specifically related to the neonatal period. Our focus has been the provision of life-sustaining care, birth to discharge. Ideally, the NICU team is present at delivery to provide life-saving care and then infants are transferred to the NICU for ongoing care until discharge. Given the increasing rates of survival reported, neonatal medicine is succeeding with this goal. While medicine continues to fine-tune treatment protocols, attention now must pivot toward improving *quality* of life for those infants who survive the NICU (Exhibit 34.3). Care provided by NICU nurses requires awareness that every care encounter has implications not just in the moment of care, but also for the developmental trajectory of the infant–family dyad across the life span (Shonkoff et al., 2012).

Intensive care nursing is challenging on many fronts to include competing priorities, complex patient assignments and a myriad of mission critical tasks. A focus on the psycho-socio-emotional dimensions of NICU nursing often takes a back seat to life-saving care for the infant. Accordingly, as we care for multiple patients, our work can become very task-oriented and we can inadvertently lose sight of the bigger picture. For many of us, this is through no fault of our own as we were never trained to understand just how critical our immediate actions may be to future outcomes. We were trained to be focused in the moment to be able to recognize and anticipate clinical complications and plan for proper, immediate treatment interventions.

As to the lack of nursing training, we are not suggesting ill intent. Rather, neonatology is a medical specialty in its own infancy, and as the specialty grows, we all need to broaden our focus to include quality care measures that support infant brain development and social–emotional health. To do so, we need a common understanding of the infant experience, and that of the family and clinician.

WHAT IS TRAUMA?

Trauma has traditionally been a word to describe physical injuries or wounds. During the 19th century, *trauma* evolved to include psychological phenomenon. The Substance Abuse and Mental Health Services Administration (SAMHSA) of the United States defines individual trauma as the result of "an event, series of events, or set of circumstances that is experienced as physically or emotionally harmful or life threatening and that has lasting adverse effects on the individual's functioning and mental, physical, social, emotional, or spiritual well-being" (SAMHSA, 2014). The current symptomatology of trauma includes intrusive re-experiencing, avoidance behavior, alterations in cognition and mood, and hyperarousal (American Psychiatric Association, 2013).

EXHIBIT 34.3

KATIE'S CARE IN THE NICU

As soon as Katie was delivered from her mother, the blue and limp baby was placed on a warmer and the NICU team began providing neonatal resuscitation. She was quickly placed into a thermoregulation bag, suctioned orally and nasally five times, successfully intubated on the third attempt, and an umbilical line was placed. Once stabilized, the baby was transported from the main OR to the NICU, which was several long corridors and five floors away. During the transport, a nurse manually bagged the baby while navigating the transport isolette and monitoring vital signs.

During the course of Katie's care in the NICU, she was intubated and extubated several times, experienced a number of feeding intolerance episodes, "NEC scares," and sepsis. Katie was eventually discharged from the NICU at 39 weeks into the care of her father.

Information about Katie's course of NICU care was captured using the Neonatal Infant Stessor Scale (NISS), see Box 34.1. The NISS allows clinicians to see the quantity of painful and stressful interventions infants have experienced during care. Data are organized into categories of intensity: *extremely stressful*, *very stressful*, *moderately stressful,* and *a little stressful*.

The following are the weekly quantities of pain and stress events Katie experienced in the first 4 weeks of life:

	Katie's Total
Week 1	345
Week 2	483
Week 3	396
Week 4	409

According to data collected in the first 4 weeks of life, Katie's extremely preterm brain was exposed to **1,633** stressful events. This exposure is in contrast with a healthy term infant who typically is suctioned multiple times at delivery, receives a couple of injections, and has heelsticks for newborn screening. Comparing these pain and stress exposures, Katie experienced almost **200 times** the number of adverse exposures in just the first month of life, as compared to a healthy term infant.

Box 34.1

NEONATAL INFANT STRESSOR SCALE

The Neonatal Infant Stressor Scale instrument categorizes interventions and procedures according to clinician-assumed severity of pain or stress. The categories are *extremely stressful, very stressful, moderately stressful,* and *a little stressful.* Examples of interventions included in each category are as follows:

- *Extremely stressful:* multiple IV, intra-arterial, and umbilical venous catheter/umbilical arterial catheter attempts, intubation, chest tube insertion, eye examination
- *Very stressful:* nasal, oral, and endotracheal tube suctioning, heelsticks, single IV insertion, lumbar puncture
- *Moderately stressful:* diaper change, position change, gavage feeding, x-ray, receiving continuous positive airway pressure
- *A little stressful:* mouth care, IV flushing, stomach aspiration via nasogastric tube, application of body cream

IV, intravenous.

Source: From Newnham, C. A., Inder, T. E., & Milgrom, J. (2009). Measuring preterm cumulative stressors within the NICU: The neonatal infant stressor scale. *Early Human Development, 85*(9), 549–555. doi:10.1016/j.earlhumdev.2009.05.002

Within the context of the NICU, trauma has been recognized for years as a critical psychological experience. Interestingly though, this traumatic experience has primarily been described from the parental perspective, and not the infant or clinician's perspective (Lasiuk, Comeau, & Newburn-Cook, 2013; Lefkowitz, Baxt, & Evans, 2010). Our intention is not to compare severity of experience, as many parents suffer greatly from their experience of premature birth and separation from their baby. Rather, we believe it is critically important to also include the infant experience into these discussions, the individual to whom direct physical trauma and social–emotional trauma may occur as a result of his or her medical experience. Acknowledging that NICU clinicians may also be traumatized by their burden of care experience is very important. Caregivers, albeit parents and/or clinicians, cannot provide high-quality, empathetic care when they themselves are suffering under the weight of unresolved trauma exposure.

Infants

Infants of all gestational ages requiring NICU care are potentially vulnerable to a traumatic experience. The degree of prematurity or illness at birth, due to the duration of medical care and frequency of interventions, may indicate the most vulnerable infants. While there are some factors critically important to infant development that are beyond the control of NICU clinicians (e.g., prenatal factors, birth immaturity, and state of health or illness), protective opportunities exist in other areas. The risk factors of NICU care are the basis of the *Infant Medical Trauma in the NICU* (IMTN) conceptual model, Figure 34.1 (D'Agata, Young, Cong, Grasso, & McGrath, 2016). IMTN suggests that infant exposure to repeated and intense pain and stress, within the context of limited parental protection, may lead to poor neurodevelopmental outcomes. Active clinician protection to modify and minimize infant exposure to pain and stress experiences and parental-infant separation will enhance neuroprotection.

Life-saving care after birth inherently includes medical interventions and procedures to provide systemic monitoring and treatment. A side effect of many interventions and procedures, however, is pain and/or stress.

As we observed in the case of Katie Walsh, during the first 4 weeks of her life she experienced 1,633 stressful and painful events. When infants are extremely preterm and ill, parents are often unable to hold them. During this period of prolonged separation, infants experience repeated and intense pain and stress without the protective physical comfort only a parent can provide. Research has yet to identify how this lack of protective care influences brain development. Based on the scientific evidence we do have though, clinicians should seek opportunities to place infants in skin-to-skin

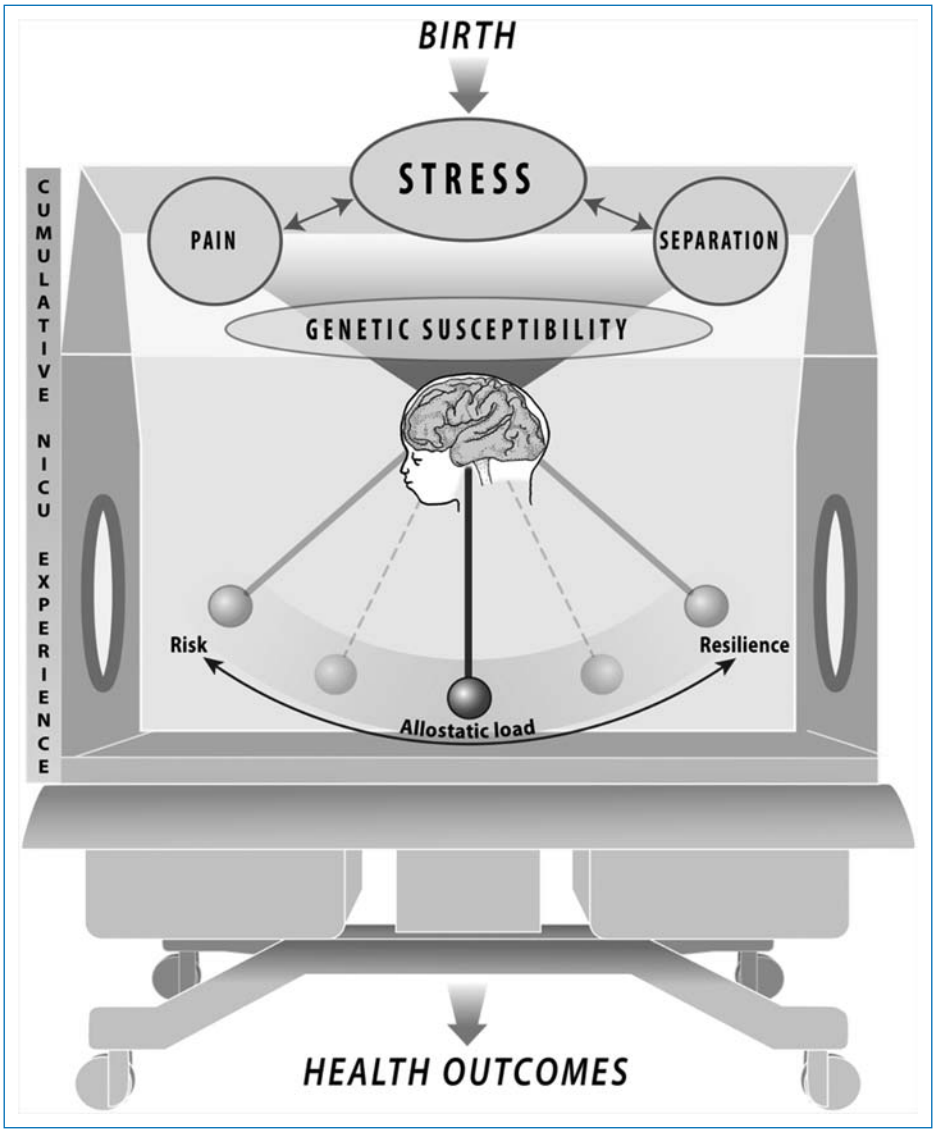

FIGURE 34.1 Infant medical trauma in the neonatal intensive care unit.

Source: D'Agata, A. L., Young, E. E., Cong, X., Grasso, D. J., & McGrath, J. M. (2016). Infant medical trauma in the neonatal intensive care unit (IMTN): A proposed concept for science and practice. *Advances in Neonatal Care, 16*(4), 289–297. doi:10.1097/ANC.0000000000000309

contact with parents as a stress reduction intervention. The potential for NICU trauma exists not only for infants but also for parents and clinicians.

Parents

Preterm birth has been described as a "traumatic event that shattered parents' taken-for-granted expectations of parenthood" (Lasiuk et al., 2013). Interestingly, the authors reported that these parents believe "stress" does not adequately describe their experience, while the term *trauma* does (Lasiuk et al., 2013). Mothers of NICU infants have been reported to experience acute stress disorder and posttraumatic stress disorder (PTSD) more frequently than mothers of full-term infants. Acute stress disorder was identified in 18% of mothers during their NICU stay, and at one month follow-up 30% of these mothers experienced PTSD (Shaw et al., 2009). At 14 months postpartum, mothers of preterm infants experienced higher rates of depression, anxiety, and traumatic symptoms (Kersting et al., 2004). Similarly, Cheng, Kotelchuck, Gerstein, Taveras, and Poehlmann-Tynan (2016) reported a higher incidence of postpartum depression in fathers of preterm infants than fathers of term infants.

From the parent perspective, preterm birth has been described as having "invisible effects" that are very difficult and involve expected milestones, connection of preterm birth to later-life consequences, relationship issues, and feelings of isolation (Graham's Foundation, 2017). The developmental milestones expected of healthy, full-term infants are often unattainable at the same age by former sick or preterm infants. For this reason, parents learn to support their child along a different chronologic continuum. As children age, it can become more difficult to distinguish a former sick or preterm infant from a healthy infant, which may or may not be beneficial. Anxiety disorders and sensory issues may also be invisible; difficulties with weight and/or growth and behavioral issues may be interpreted as bad parenting. When leg braces, a feeding tube, or thick glasses are not present, others may have difficulty recognizing correlates to preterm birth. As such, while a child's delays in meeting milestones or academic achievement may be rooted in early birth, it may not be obvious at a glance. These examples and others may ultimately lead to misunderstandings and be damaging to relationships.

Clinicians

Research has shown that clinicians who are repeatedly exposed to the suffering of others can themselves be vulnerable to compassion fatigue, secondary trauma, and PTSD. Interestingly, clinicians may not recognize their own trauma symptoms, which in turn can have significant implications in their patient care practice (D'Agata et al., 2018). Specifically, the degree to which clinicians are able to extend the qualities of compassion and empathy to others when they themselves are suffering is strained. Because patients and families rely so deeply on clinicians for compassionate, empathetic, and supportive care, when it is not received, the expectations of all parties are not met. The most important consequences of unmet expectations are the effects it can have on infants.

The demands placed on NICU clinicians to provide life-saving care can result in difficulties processing or dealing with clinical experiences of loss. Both primary and secondary traumatic stresses are recognized as adverse outcomes of providing intensive care services in healthcare providers, discussed more in depth later. A survey of NICU and pediatric intensive care providers suggested that up to 17% of participants had diagnosable PTSD and 66% had concerns that were worrisome but did not reach PTSD diagnostic criteria. Provider resilience was inversely related with clinician PTSD symptoms (Welch et al., 2016).

In a recent focus group study, more than 80% of clinicians reported having experienced a traumatic event (D'Agata et al., 2018). Participants stated they learned to "detach," suggesting that one response to vicarious traumatization in the NICU may be withdrawal of emotional responsiveness. Strategies to consider for providing protective care for the neonatal clinician include debriefings, involvement of chaplain, and training in peer support programs (Dalia, Abbas, Colville, & Brierley, 2013; Keene, Hutton, Hall, & Rushton, 2010; Welch et al., 2015). Acknowledging the nature of workplace traumatic experience for neonatal clinicians may assist in developing strategies to reduce clinician traumatization and retraumatization while promoting effective caregiver–patient and family empathy.

TRAUMA STEWARDSHIP

The Merriam Webster dictionary defines *stewardship* as "the conducting, supervising, or managing of something; especially the careful and responsible management of something entrusted to one's care." Trauma stewardship, a term coined by social worker Laura van Dernoot Lipsky, is the careful and responsible management of the trauma exposure caring professionals experience in the course of their work (Lipsky, 2009). Caring professionals include social workers, first responders, firefighters, police officers, public defenders, military persons, family caretakers, doctors, nurses, teachers, and other service providers, to name a few. Bearing witness to human suffering touches us and changes us in subtle and insidious ways that alter how we engage in our caring work. "The expectation that we can be immersed in suffering and loss daily and not be touched by it is as unrealistic as expecting to be able to walk through water without getting wet" (Remen, 1996).

The terms *burnout*, *secondary trauma*, *vicarious trauma*, and *compassion fatigue* have been used to describe the impact of trauma exposure on the professional. Burnout is usually the result of prolonged stress or frustration resulting in physical and emotional exhaustion and is usually associated with the workplace. Burnout is usually the result of prolonged stress or frustration resulting in physical and emotional exhaustion and is usually associated with unsupportive management and a compromised professional practice environment; burnout is not the result of trauma exposure. Secondary trauma occurs when the traumatizing event experienced by the patient becomes a traumatizing event for the professional with trauma exposure symptoms presenting suddenly and with little warning (Centre, 2012). Vicarious trauma and compassion fatigue are terms that have been used interchangeably to describe the impact of a specific experience and outcome (i.e., the NICU). Vicarious trauma is a permanent and pervasive change in the professional as a result of his or her empathic engagement with a patient's traumatic experience and impacts all facets of the professional's life including body, mind, character, and belief systems (Centre, 2012). For more information, see Laura Lipsky's TEDx talk entitled "Beyond the Cliff."

TABLE 34.1

TRAUMA EXPOSURE RESPONSES

Minimizing reality	Chronic fatigue and/or physical ailments
Feelings of helplessness and hopelessness	A sense that one cannot do enough
Hypervigilance	Decreased creativity
An inability to grasp complexity	An inability to listen and/or deliberate avoidance
Disconnected/dissociative moments	A sense of persecution
Feelings of guilt	Feelings of fear/fearfulness
Anger and cynicism	An inability to empathize/feeling numb
Addictions	A grandiose perception of self/an inflated sense of self-importance related to one's work

In her book *Trauma Stewardship*, Laura van Dernoot Lipsky describes 16 trauma exposure responses associated with bearing witness to and walking with victims of trauma (see Table 34.1; Lipsky, 2009). As you review the descriptions of each trauma exposure response, take note of how each description makes you feel. Embrace the opportunity this chapter provides you to cultivate trauma stewardship and take steps to restore and rejuvenate the caring-healer within. ". . . how one is with oneself affects how one is with others and, in turn, . . . how one is with others affects how one is with oneself . . ." (Watson, 2018).

Minimizing

Minimizing is about losing our compassion and our capacity to empathize with others. It is when we compare suffering or organize it into some kind of hierarchy. An example of minimizing is when we judge the degree of distress expressed by a mother based on her baby's diagnosis: "he/she just has a little TTN, what's that mother crying for, it's not like he's/she's a 24 weeker." Minimizing occurs when we are so saturated with trauma exposure we minimize trauma in order to protect ourselves from reaching our breaking point. Often, this behavior contributes to a negative organizational culture. Comparing leads to competition where we exaggerate the intensity of a given situation to make our issue more legitimate. Minimizing does not only occur at work; it can spill over into our personal lives as well, when your child comes

crying to you because she or he fell down and the response is "Stop being so dramatic, it's not like you're dying." Trauma exposure responses permeate every aspect of our lives. Minimizing the lived experience of others distances us from our shared humanity and undermines our capacity to heal. Have you noticed you or your colleagues minimizing the experience of others?

Chronic Exhaustion/Physical Ailments

The tiredness that emerges from trauma exposure induces a level of fatigue that permeates every cell of your being, a bone-tired, soul-tired, heart-tired kind of exhaustion that cannot be relieved by a good night's sleep, or a series of good night sleeps (Lipsky, 2009). This severity of exhaustion is observed in people who feel completely overwhelmed by the urgency of their work and the belief they have no choice about the work they do. "The fresh-scrubbed and hopeful idealism of the new [nurse] starting out may gradually give way to a thrashed, haggard, martyred persona" (Lipsky, 2009).

In *The Body Keeps the Score*, Bessel Van Der Kolk (2014), the author, reveals the internal toll trauma has on how we think, feel, and respond to everyday situations as a result of our trauma exposure (Van Der Kolk, 2014). Trauma produces actual physiologic changes, including a recalibration of our hypothalamic-pituitary-adrenal (HPA) axis (our internal alarm system), an increase in stress hormones, and alterations in the systems that filter relevant information from irrelevant information. These physiologic changes impact our health and wellness and manifest in not only chronic fatigue, but also chronic pain and body aches, migraines, hypertension, obesity, and other chronic morbidities. What types of restorative self-care practices do you or could you employ on a regular basis to shield yourself from chronic exhaustion?

Feelings of Helplessness and Hopelessness

Feelings of helplessness and hopelessness are experienced when the positive aspects of work are eclipsed by the negative (Lipsky, 2009). It may be that feeling of successfully resuscitating an infant at the cusp of viability but knowing that the next few days will likely be filled with uncertainty. Garber and Seligman (1980) identified three perceptions that contribute to feelings of helplessness: (1) the perception of being personally responsible for a bad outcome even when this is unreasonable; (2) the perception that there is no relief from the current reality of the traumatic event/crisis; and (3) the perception that you are likely to repeat your current struggle in another time and place; there is no escape. Do any of these perceptions resonate with you?

A Sense That One Can Never Do Enough

"If I don't do it, it's not going to get done, and if it doesn't get done, babies will die. I can never do enough." How many times have you made or heard that statement? The belief that no matter what you do, it will not be enough wreaks havoc in our lives and instills a powerful sense of inadequacy. This sense of inadequacy plays itself out in organizational cultures that perpetuate a culture of scarcity: "We don't have enough staff, we don't have enough money, you need to work harder, you need to work more, and it still won't be enough." These negative, oppressive messages undermine our ability to recognize our self-worth and feel validated about the good work we do, leaving us dissatisfied in our work and maybe in our life. What would it look like for you to be satisfied in your work, in your life? How can you create that?

Hypervigilance

Hypervigilance creates a dynamic where we are so focused on the work we are unable to be present for anything else in our life; it is an attempt to restore a sense of safety and control by anticipating everything as a possible threat, waiting for the other shoe to fall, so to speak. In the NICU, the ever-present potential for life threat can cultivate hypervigilance. Individual experiences with different clinical scenarios may create a state of hyperarousal, which can include hypervigilance and heightened anxiety. Remember, the first thing to do in a code is to take your own pulse. Taking your own pulse brings you back to center, brings you to the present. Being present allows you to regulate your autonomic nervous system, which then enables you to act instead of react. Joan Halifax, an American Zen Buddhist teacher, worked with palliative care and end-of-life nurses and introduced G.R.A.C.E. as an intervention to reduce compassion fatigue among this unique group of health professionals. The "G" stands for *gather your attention*; the "R" invites you to *recall your intention*; the "A" is *attune* to the individual or situation; "C" means to *consider* what you should do, based on your attunement; and the "E" is to *engage and then end* the encounter (Halifax, 2014). Practicing G.R.A.C.E. takes just a few minutes but creates the opportunity for you to center yourself and be present. Try G.R.A.C.E. during your next shift and see if anything changes within you.

Diminished Creativity

"The deeper we sink into a culture of trauma, the less flexible and original our thinking becomes." (Lipsky, 2009). Change requires creativity, and with creativity comes a certain amount of chaos or uncertainty that may feel threatening. When we experience trauma exposure, we find ourselves thirsty for structure and stability and become resistant to change, even if the change is evidence-based. Is it possible that a culture of trauma may be a contributing factor to a knowledge–practice gap as we resist change to create a false sense of control? What could you do to cultivate creativity in your unit?

Inability to Grasp Complexity

A strong indicator of the inability to grasp complexity is when we look for clear signs of good or bad, right or wrong, yes or no. It is when we are unable to grasp the entirety of a given situation that we take sides, internalizing a binary structure to help us cope with the complexities inherent in healthcare. The toll of bearing witness reduces our capacity to engage with the nuances and gray areas of the human experience of crisis. We all know the importance of the family to our fragile patients, yet what the family brings to our work can be too overwhelming to integrate into our workflow. As a result, we create rules, guidelines, and policies to restrict and define when, where, and how family is allowed to engage and parent their hospitalized infant. Life is messy, but it is the messiness that becomes cognitively impossible to grasp when we are exposed to trauma day after day (Lipsky, 2009). Practicing personal wholeness enables us to make room within ourselves to embrace the complexity of the human condition. How do you practice personal wholeness?

Inability to Listen/Deliberate Avoidance

Avoidance may be seen as quickly finishing up your hands-on care to avoid facilitating a parenting moment when the family comes in "a little too late" (according to you) to provide skin-to-skin care with their baby. It is finishing up all your tasks so you can sit in the rocking chair and wait for the next round of caregiving. The inability to listen (a form of avoiding engagement with others) can be observed when someone may be speaking to you, but the only thing going on in your head is what your next task is and you shut down the "conversation" with a swift and often curt retort.

As avoidance shows up in your personal life, you may go out less and less or if you do go out, it is with people who are as avoidant as you are, people who "get it" (Lipsky, 2009). Has avoidance crept into your daily routine?

Dissociative Moments

A dissociative moment is the experience of being engaged in your work and then, for whatever reason, suddenly something inside you becomes unhinged (Lipsky, 2009). You realize you have disconnected with what is happening right in front of you. A NICU example could be you are running a code, and all of a sudden you remember the last infant you unsuccessfully resuscitated. These moments are common and only become problematic when we try and "tough it out" by pretending not to feel. No matter what role you play in the NICU, when you are exposed to the suffering of others, you can expect these moments to occur. Notice them, avoid isolation, and seek out the support you need to stay whole and healthy. How does your unit support staff who have experienced the loss of a patient? Do you routinely debrief after critical events?

Sense of Persecution

Feelings of persecution arise from a profound lack of self-efficacy in one's life and we become convinced that we are unable to change our circumstances (Lipsky, 2009). When we succumb to the belief that we cannot change our situation, we consent to suffer and relinquish our power to an outside force (Lipsky, 2009). This is the "martyr mentality." Sometimes we can feel persecuted by our own patients and their families: "Why does this kid always need a new IV when I am on?"; "Why does this family always want to kangaroo when I have a busy assignment?" Quickly and insidiously, we can forget how tragic it must be to require neonatal intensive care, to have your baby fighting for his or her life, to be confused, frightened, and alone being cared for by strangers. Uncovering persecution as a trauma-exposure response often shows up in the language we use to describe our circumstances. What language is used in your NICU that may suggest you or your colleagues are experiencing a sense of persecution?

Guilt

Bearing witness to the suffering of the infants and families we serve in the NICU can sometimes make us feel guilty that our life is pretty good, maybe our family is healthy, we have a great support network, or simply that we can leave the hospital at the end of our shift. One of the bad things about guilt is that it undermines our ability for authentic connection with others (Lipsky, 2009). We may find ourselves not wanting to share information about our vacation or time off with our patient's family because we do not want to make them feel bad. However, purposefully diminishing ourselves will not help us make the connections that are so important in the work we do. Being honest, not pretentious, about our privilege allows us to be present and experience our shared humanity with others (Lipsky, 2009). This simple act can actually provide comfort and connection, which is what we all need, especially when we are in crisis. How do you create authentic connection with the infants and families you care for?

Fear

Fear is a natural response to much of what we witness in our work: fear of intense feelings, personal vulnerability, or potential victimization (Lipsky, 2009). In our opening scenario, I am sure the clinicians in Katie's delivery room experienced some degree of fear as she emerged blue and limp and required resuscitation. When feelings of fear (which are perfectly healthy) are not addressed, discussed, and released, they can turn into anger and prejudice (think of perinatal substance use and neonatal abstinence syndrome). These prejudices quickly morph into stereotypes and lead to generalizations about cultures and socioeconomic groups (Lipsky, 2009). These generalizations undermine our ability to serve. Fear makes us feel vulnerable, which is uncomfortable, and so quite often we distance ourselves from those feelings. However, when we are able to acknowledge our fear, it deepens our capacity for compassion, for ourselves and others. Have you experienced fear in the course of your work? How have you worked through your fear?

Anger and Cynicism

"Anger is a common feeling among those trying to do right in the world" (Lipsky, 2009, p. 101). Whether your anger is a flash of rage or a slow boil, it is important to understand what your anger looks like so that you can learn to manage it. When we are not connected to what our anger looks like, we can often direct it to people and situations unrelated to why we are angry. In the clinical setting, an example may be how we behave with certain families or diagnoses that spark our anger, but really are not the root of our anger. Cynicism, on the other hand, has been described as a sophisticated coping mechanism for dealing with anger and is often witty and easy to laugh at (Lipsky, 2009). Cynical humor is a way to avoid dealing with our feelings of anger; although alluring, it can warp our sense of the world around us. We may get angry when our patients exhibit physiologic instability while providing hands on care but then glibly comment that they "tried to die on us." That kind of cynical response reflects a complete absence of empathy fueled by a failure to address our underlying feelings of anger. Have you experienced anger in the course of your work? What does your anger look like?

Inability to Empathize/Numbing

The inability to empathize is the result of a system that is completely overwhelmed with constant input. Likened to a sponge, when we have reached the point of saturation we are unable to take in any more input and we become numb (Lipsky, 2009). We become afraid to feel, as if the feelings will come in torrents that we will not be able to control. Sometimes we become so used to not feeling that when we are removed from our day-to-day routine, for example on vacation, we may struggle to really enjoy ourselves (Lipsky, 2009). Have you experienced an inability to empathize with your patients and their families? What would help you reconnect with your feelings in a way that did not overwhelm you?

Addictions

"An addiction is an attachment so strong that it persists despite our understanding of its potentially destructive nature" (Lipsky, 2009, p. 109). Often when we think of addiction, we think of the usual suspects (alcohol, drugs, food, and sex), but many of us may also have an addiction to the rush of adrenaline we experience in our work. Overwork is an example of addiction that keeps us from feeling and being with the world around us. However, at some point, our efforts to escape the intense feelings associated with our work are unable to be held back by our addiction. What are you most attached to? How does this attachment serve you and others?

Grandiosity: An Inflated Sense of Importance Related to One's Work

"When work becomes the center of our identity, it may be because it feeds our sense of grandiosity" (Lipsky, 2009, p. 111). We must approach with caution our reliance on work for our sense of

self-esteem. This certainly may be a challenge in the United States where our work is a cornerstone of our self-image, especially when we do such important work as seen in the NICU. Losing ourselves to our work means we have truly lost our self. We are more than nurses; we may be mothers, fathers, friends, brothers, sisters, joggers, swimmers, artists; we may be many of these things and often more. Maintaining a sense of balance between all the facets of who we are enables us to preserve our wholeness and our integrity. What you do is not who you are (Lipsky, 2009). How do you stay grounded in the larger reality of your life?

Recap

The onset of trauma exposure responses is often insidious and even invisible in settings that lack awareness about the physiologic and psychologic sequelae of bearing witness to suffering on a regular basis. Mediated by the HPA axis, chronic exposure to toxic stress has a cumulative negative effect on health and wellness across the life span. Trauma stewardship and the concept of trauma-informed care in the NICU have implications for mitigating these deleterious effects on the infant, the family, and ourselves. While bearing witness is a moral way of engaging with our patients and their families (Naef, 2006), we must be cognizant of the toll it takes on us and adopt self-care practices that help us find balance, create a sense of personal control, make healthy lifestyle choices, and ensure a supportive social network (Lipsky, 2009).

WHY IS IT IMPORTANT TO REDUCE THE TOXIC STRESS ASSOCIATED WITH TRAUMA?

Stress is a word many of us commonly use to describe physically and emotionally taxing experiences (McEwen, 2007). In our culture today, we often use the word *stress* as a descriptor of all different types of events in our daily lives. This common and varied usage of the word has the potential to perhaps desensitize us to important effects of this brain–body reaction to stimuli.

Stress can be differentiated into "good or positive" and "bad or negative" stress, indicating the benefit or burden of the experience. As we discuss later, the duration of stress exposure is another important differentiator between acute and chronic stress. Despite the quality of the stress experience, the same physiologic activation occurs in our bodies—activation that includes reactivity of the autonomic nervous system and HPA axis. The physiologic response to stress exposure is a highly complex process that is not covered in detail here. In turn, we refer interested readers to literature by Dr. Bruce McEwen (McEwen, 2004, 2007).

In response to stress, hormones, inflammatory mediators, and neurotransmitters are released to support our *fight or flight* response and eventual decay of the chemical response. There are critical factors of the stress response that include inadequate or excessive responsivity, as well as the frequency of response activation. If one's physiologic response to stress is blunted, there is an inability to mount an appropriate response. Conversely, for some people, stress exposure produces a physiologic response that is in excess of what would normally be expected. The reason for inappropriate responses may be due to the frequency of activation. When we encounter chronic stress, it may affect how we respond to future stress. The stress event initiates a hormone, neurotransmitter, and autonomic response. As the event resolves, the chemical response decreases and the body begins to return to baseline. When one encounters repeated events or "hits," the stress response system is in constant activation, allowing for little recovery. Figure 34.2 demonstrates normal and abnormal stress responses.

This background information on how our bodies respond to stress is important when we consider NICU infants and trauma. The literature reports a range of daily stressful and painful events for infants cared for in the NICU. Carbajal et al. (2008) reported that in an Italian cohort of 430 NICU infants with a mean gestational age of 33 weeks, infants experienced an average of 141 procedures during their NICU stay, 78 of which were painful. Additionally, these infants experienced an average of 16 procedures per day, 12 of which were painful. In a small cohort, D'Agata et al. (2017) combined stressful and painful procedures and reported NICU infants, with a mean gestational age of 30 weeks, experienced an average of 46 events per day. Variability among reports of NICU infant painful and stressful events is often related to clinical practice of units, the country where the study was conducted, and the types and quantity of procedures included in the data collection. Regardless, these reports demonstrate chronic stress experiences that occur to infants simultaneously during key critical and sensitive periods of brain development and maturation, placing infants in very vulnerable situations (Exhibit 34.4).

For preterm infants who experience repeated NICU stress exposure, functional and structural changes to their brain may occur. Smith et al. (2011) examined NICU infant stress exposure and found frontal and parietal regions of the brain to be decreased in size (Smith et al., 2011). Furthermore, alterations in the microstructure were noted. When neurobehavior was evaluated at term age, infants demonstrated at-risk behaviors, consistent with early life stress exposure (Smith et al., 2011). Using MRI at term-equivalent, Chau et al. (2013) found abnormal brain development with infants born at 24 to 32 weeks' gestation. When these infants were 18 months old, abnormal brain development was associated with adverse neurodevelopmental outcomes (Chau et al., 2013). The complex relationship of early life medical care and stress exposure reflect an environmental burden that may influence health and neurodevelopmental outcomes.

Sullivan and her colleagues have followed a cohort of preterm infants from birth to 23 years of age. During their early school age years, as expected, preterm survivors with neurologic compromise demonstrated increased impairment and poorer cognitive performance (McGrath, Sullivan, Lester, & Oh, 2000). At 12 years of age, neonatal morbidities continued to impact the health of survivors (Miller, Sullivan, Hawes, & Marks, 2009). As adolescents, high rates of depression, anxiety, and attention problems were identified (Sullivan, Msall, & Miller, 2012). At 23 years of age, young adults who were born preterm and experienced neonatal illness demonstrated distinctly different cortisol patterns from term-born peers (Winchester, Sullivan, Roberts, & Granger, 2016). Interestingly, preterm infants considered "healthy" demonstrated a most unique cortisol pattern. The health trajectory of this former preterm cohort supports the theory that early life stress disrupts the developing brain and HPA axis, resulting in later life dysregulation. Dysfunction and dysregulation during the neonatal period place these individuals at increased risk for issues later in life with cognition, mental health, and other stress-related diseases.

In 1998, Felitti et al. published a landmark study describing the long-term health effects of adverse childhood exposures. Adverse childhood experiences (ACE) are events of abuse and environmental exposures that have associations to adult mental health and disease risks (see Box 34.2). Using adult self-reports of childhood abuse, researchers asked participants about occurrences of neglect, parent mental illness, parent substance abuse, and witness to domestic violence and found a strong dose response with multiple adult health risks. These health risks included heart disease, cancer, and chronic lung disease. Interestingly, of the greater than 50% of adults who reported a history of childhood exposure, they also reported

EXHIBIT 34.4

COMMON INTERVENTIONS AND PROCEDURES FOR PRETERM INFANTS

You may be asking yourself what about the NICU experience is so stressful that it would cause brain changes. Let us think about Baby Walsh in our opening scenario. A baby born at 23 weeks will most likely receive this type of immediate life-saving care following delivery:

- Transfer to a far different environment than the uterus.
- Bright lights, loud voices and commotion, cool temperatures, touching, and repeated movement of a fragile body
- Intubation at birth, success on third attempt
- Repeated oral and nasal suctioning
- Umbilical line placement
- Transport through hallways and elevators to NICU with often unsteady control of endotracheal tube
- Positioning and repositioning for x-rays
- Frequent interruption of rest for assessments
- Heelsticks for glucose testing

These interventions and procedures are commonplace to NICU clinicians and reflect lifesaving procedural practices we have been trained to perform. In addition, we typically complete these initial procedures as quickly as are tolerable to the infant. A momentary pause to consider how stressful and painful this series of clinical interventions likely is to a fragile 23-week infant is a simple first step to practicing trauma-informed care.

more than one type of abuse. This demonstrates that as exposures increased, the risk for obesity, depression, and suicide attempt also increased. The more exposures a child has to adverse events, the greater the possibility of developing adult physical and mental health sequelae.

While the Felitti et al. study was not conducted with former preterm infants, this type of research demonstrates the risks posed to one's health when children are exposed to adverse events at a critical stage of development. As previously discussed, preterm infants are exposed to prolonged and intense pain and stress events during NICU care. They have few coping mechanisms, minimal maternal contact, and no agency; all of this coupled with their immature brain development suggests that these infants are at significant risk for toxic stress. The major concern from toxic stress exposure for preterm infants is the developmental implication. Former very preterm infants subject to greater invasive and painful procedures evaluated at age 7 demonstrated decreased cerebellar volume and poorer cognition (Ranger et al., 2015).

Molecular evidence is also beginning to emerge that suggests various preterm infant systems may be impacted by early life experience. In particular, DNA methylation changes (Giarraputo et al., 2017; Montirosso, Provenzi, et al., 2016), dysbiosis of the gut microbiome (Chernikova et al., 2018; D'Agata, Wu, et al., 2019; Dahl et al., 2018), and cortisol reactivity (D'Agata, Roberts, et al., 2019; Grunau, 2013; Vittner et al., 2017), to name a few, generally confer early life exposures leading to short-term alterations. What has yet to be determined are the mechanisms by which these changes may influence longer-term outcomes (Figure 34.3; Johnson, Riley, Granger, & Riis, 2013).

These findings are compelling not only to health professionals but also to parents. As evidence continues to be elucidated as to the impact of early life experience of preterm infants, and how environmental exposures influence neurobiology, the NICU will be confronted with how to improve practice to better support infants. If clinicians do not demand re-evaluation of practice norms and

standards of care, parents will likely demand it of us. Thus, the implications for advancing practice affects not only nursing but also all those who care for vulnerable preterm infants. To help meet the expectations of the patients and families we serve, we must begin to look at the NICU through their lens and consider how we might modify practice to be more neuroprotective.

TRAUMA-INFORMED NEUROPROTECTIVE CARE

Trauma-informed neuroprotective care (TINC): (a) ***realizes*** that traumatic experiences change our biology; (b) ***recognizes*** the signs and symptoms of trauma in patients, families, colleagues, and others involved in caregiving; (c) ***responds*** by fully integrating knowledge about trauma into policies, procedures, and practices; (d) actively seeks to ***resist retraumatization*** (SAMHSA, 2014). Retraumatization is a conscious or unconscious reminder of past trauma resulting in a re-experiencing of the initial trauma event that can be triggered by an action, attitude, or expression that makes one feel powerless and compromises a felt sense of safety (Exhibit 34.5).

Realization that Trauma Changes our Biology

Our opening story about Katie Walsh exemplifies the how the trauma experienced in the NICU changed Katie's biology: "*Early on, Katie was diagnosed with learning and sensory processing challenges, attention deficit disorder, and executive function disorder. Most recently, Katie has shared with the nurses her struggles with anxiety and depression and was diagnosed with major depressive disorder last year.*"

Recognizing Signs and Symptoms of Trauma

Signs and symptoms of toxic stress and trauma experienced by NICU infants and families are shown in Table 34.2. For signs and symptoms of toxic stress and trauma experienced by the clinician, see Table 34.1.

While the list in Table 34.2 is far from exhaustive, it highlights signs and symptoms of infant and parent traumatic stress that are often misinterpreted in the setting of the NICU. Our own trauma exposure increases our vulnerability to minimizing the lived experience of the families we serve as we become numb and less capable of empathizing with others.

Response to Trauma

The response to trauma in the NICU (under a TINC paradigm) is the adoption and integration of evidence-based best practices in TINC aimed at managing, mitigating, and minimizing the trauma experience of the infant, the family, and the clinician (Coughlin, 2016). These best practices must be reflected in policies, procedures, practice guidelines, documentation requirements, and ongoing staff education and new hire orientation curriculum.

Resisting Retraumatization

Infants and neonates are capable of experiencing intense pain and show signs of traumatization (Coates, 2016). The memories of these events are stored in such a way that affect learning and behavior later in life, consequently adopting a trauma-informed approach to care in the NICU is paramount (Coates, 2016).

Of critical importance, once a trauma-informed care paradigm is established, there must be a commitment to sustain this new culture of care over time. Sustaining the gains in transforming the culture of care is achieved through clear accountability metrics, ongoing practice audits, and integrating the principles and values of TINC into daily practices across all disciplines that interface with the NICU patient and family population.

Quality Core Measures for Trauma-Informed Neuroprotective Care

Inconsistent definition, application, and evaluation of developmentally supportive care prompted the development of core measures for developmentally supportive care in the NICU (Coughlin, Gibbins, & Hoath, 2009). Coughlin et al. (2009) adopted The Joint

EXHIBIT 34.5

Retraumatization in the NICU

Jake Walsh brought Katie back to the NICU when she had just turned 1 to visit Tracy, Shannon, and Erin. The minute the elevator doors opened on the second floor, where the NICU was located, Katie's demeanor changed and she began fidgeting and fussing. The closer they got to the NICU reception area, the more agitated and distressed Katie became.

TABLE 34.2

SIGNS AND SYMPTOMS OF TOXIC STRESS AND TRAUMA

Infants	Families
Exaggerated responses to acute stress; intense fight or flight responses (Holsti, Grunau, Whitfiled, Oberlander, & Lindh, 2006; Vinall & Grunau, 2014; Whitfield & Grunau, 2000)	Feelings of guilt and inadequacy in parental role (Lasiuk, 2013; Roque, Lasiuk, Radunz, & Hegadoren, 2017)
Hyporeactivity and/or immobilization to increasing stress; fright and freeze responses (Whitfield & Grunau, 2000)	Less affectionate and less responsive to their infant; withdrawn, flat affect, and/or hostility or intrusiveness with their infant (Tahirkheli, Cherry, Tackett, McCaffree, & Gillaspy, 2014)
Feeding intolerance (Moore & Pickler, 2017; Moore et al., 2013)	Fatigue and sleep disruptions (Busse, Stromgren, Thorngate, & Thomas, 2013)
Sympathetic nervous system arousal (Holsti, Gruanu, Oberlander, & Whitfield, 2005)	Protracted sadness and worry (Greene et al., 2015)
Autonomic dysregulation (Grunau et al., 2005)	Hypervigilance and avoidance behaviors (Greene et al., 2015)
Poor weight gain (Godoy, Rossignoli, Delfino-Pereira, Garcia-Cairasco, & de Lima Umeoka, 2018)	Physical and emotional withdrawal (Flacking et al., 2012)

Commission framework of core measures to establish disease-independent, minimum, evidence-based best practice standards that would offer an objective basis for cross-institutional comparison of developmentally supportive care practices. In 2011, these core measures became the National Association of Neonatal Nurses' (NANN) *Age-Appropriate Care of the Premature and Critically Ill Hospitalized Infant: Guideline for Practice* (Coughlin, 2011) and have been recognized internationally as best practice standards for developmentally supportive neuroprotective care in the NICU (Milette, Martel, da Silva, & Coughlin McNeil, 2017a, 2017b). The concept of trauma-informed care for hospitalized infants resonates with neonatal clinicians and researchers around the globe (Coughlin, 2014; Montirosso et al., 2012; Torowicz, Lisanti, Rim, & Medoff-Cooper, 2012). In 2016, NANN endorsed *Trauma-Informed Care in the NICU: Evidence-Based Practice Guidelines for Neonatal Clinicians* (Coughlin, 2016).

There are five core measure sets for trauma-informed care. These categories of quality caring have remained consistent since their inception in 2009; however, the attributes and specific criteria for each core measure set have evolved as more and more evidence has been brought to bear on what constitutes best practice in (a) the healing environment; (b) protected sleep; (c) pain and stress prevention, assessment and management, and the role of the family; (d) activities of daily living: posture and mobility, eating experiences, skin care, and hygiene; and (e) family collaborative care (see Figure 34.4 and Table 34.3).

In a large, multicenter, longitudinal study on the quality of developmentally supportive, neuroprotective care, Montirosso, Tronick, and Borgatti (2016) demonstrated both short- and long-term implications of high-quality developmentally supportive neuroprotective care (see Table 34.4). These findings highlight the importance of quality and consistency in improving outcomes.

Nursing in the NICU

While it is clear that a cultural shift must occur to achieve the best results from a trauma-informed care paradigm, a change of attitude and mindset that supports and ensures a holistic, person-centered approach to caring must be embraced by all who work in the NICU. For nursing, this shift restores the primacy of nursing care—to support and manage the human experience of disease. Watson (2018) urges nursing to move beyond "practice-for-institutional-practice's sake to praxis – an informed moral practice guided by our timeless values . . . and love of humanity . . . and all its complexities and unknowns." If we fail to do this, we

TABLE 34.3

QUALITY CORE MEASURE SETS AND ATTRIBUTES FOR TRAUMA-INFORMED NEUROPROTECTIVE CARE IN THE NICU

Healing environment	• The physical environment is conducive to rest, healing, and establishing relationships that confer a sense of safety and connectedness. • The healthcare team is collaborative, respectful, mindful, and caring. • The Organizational Environment reflects a just culture committed to quality and safety.
Pain and stress	• Prevention of pain and stress is a daily expressed goal. • Continuous and procedural pain and stress are routinely assessed, managed, and reassessed to ensure maximum infant comfort. • Family is informed and involved in managing and mitigating the pain and stress of their infant(s).
Protected sleep	• Infant sleep and diurnal rhythmicity are protected and supported. • Sleep protective strategies are implemented in partnership with parents and family. • Staff role-model compliance with safe sleep practices for eligible infants.
Activities of daily living	• Postural alignment and spontaneous movement are supported for optimal comfort, safety, and neuromotor development. • Infant eating experiences are nurturing, individualized, infant-driven, and pain and stress free. • Skin care routines preserve barrier function and ensure tissue integrity.
Family collaborative care	• Parents and family, integral to quality care, have unrestricted access to their infant(s). • Emotional well-being of parents and families is routinely assessed and supported with access to appropriate, culturally sensitive resources. • Parenting skills are mentored, supported, and validated throughout the hospital experience.

may lose our identity as caring healers and become very good technicians subsumed by other disciplines (Watson, 2018).

The seductive lure of a technologically advanced environment juxtaposed with the ever-present threat of death and dying can make us lose sight of our purpose and our passion—to be the difference in the life of another. Several of the trauma-exposure responses (Table 34.1) gain traction when we lose ourselves in a complex web of the suffering savior. In order to be the best version of ourselves and fully operationalize our purpose and passion, we must be present in every human encounter. Embracing the quality core measures for TINC creates opportunities for us to be present and to transform the experience of care for each baby and family we serve.

The Healing Environment		
Attribute	**Criteria**	**Nursing Actions**
Physical environment	• Sensory input (e.g. light, sound, touch etc.) is age-appropriate; dose and duration of sensory input is guided by the infant's behavioral and physiologic responses. • Space safely accommodates the provision of quality clinical care, 24-hour parental presence, and privacy. • The design of the space honors the holistic and human dimensions of those that inhabit it, integrates stress-reducing strategies, and facilitates social and therapeutic interactions for patients, families, and professionals.	• Use a speaking voice in the infant care area that aligns with AAP sound level recommendations (e.g., use your library voice or your church voice) • Invite parents to decorate their baby's bedspace • Explore the availability of stress-reducing resources for families and staff—music therapists, quiet rooms for meditation, outdoor gardens, etc.
Human environment	• The interprofessional team exhibits shared responsibility in problem solving and decision making to formulate holistic plans for patient care; team members assume complementary roles that facilitate cooperation. • Team members support each other in "always doing the right thing" for the patient, the family, and staff. • All verbal, written, and behavioral communication is respectful, complete, and patient-centered; there is zero tolerance for behaviors that compromise safety and/or undermine respectful relationships.	• Practice mindful presence • Ask for help—for the sake of the patient • Provide help, even when not asked • Consider incorporating G.R.A.C.E. into your caregiving routine

(*continued*)

TABLE 34.5

THE CLINICIAN'S TOOLBOX FOR TRAUMA-INFORMED CARE PROVIDES THE READER WITH QUALITY CORE MEASURES, ATTRIBUTES, AND SUGGESTED NURSING ACTIONS (*continued*)

The Healing Environment		
Attribute	**Criteria**	**Nursing Actions**
Organizational environment	• Core measures for age-appropriate care provide the standard of care for all patient care encounters and are reviewed/revised annually to reflect the latest evidence-based best practices. • Practice standards are integrated into the annual performance evaluation across all disciplines and professionals who interface with the neonatal/infant population. • A just culture framework ensures balanced accountability at the individual and organizational levels for continuous learning, quality improvement, and patient safety.	• Join your unit/hospital practice council • Take ownership for the professional practice in your setting • Be a mentor to your colleagues, both new and legacy
Protected Sleep		
Protect sleep integrity	• Scheduled, nonemergent caregiving is contingent on the infant's sleep–wake state and adapted accordingly. • Cycled lighting is provided to support circadian rhythms. • Staff and family are competent in the assessment of infant sleep–wake states.	• Change your mindset from technician to healer and use the scheduled caregiving times as a lattice to your caring encounters instead of a prescription • Educate yourself about sleep and wake behaviors and use this new knowledge to guide your caring encounters
Support sleep	• Skin-to-skin care is an integral part of the daily care of eligible infants; length of sessions are documented in the medical record. • An individualized sleep hygiene routine is an integral part of daily care. • Supportive sleep routines are developed in partnership with family and documented to ensure consistency.	• Gain confidence and competence in facilitating skin-to-skin experiences • Offer skin-to-skin care *always* for eligible infants • Support parent confidence in providing skin-to-skin care • Collaborate with parents to create daily routines that facilitate transition to home
Safe sleep	• All staff are competent in the most current "back to sleep" recommendations from the AAP; competency is documented. • There is a clear protocol and/or algorithm for the transition and initiation of "back to sleep" practices. • Parents demonstrate competency in safe sleep practices before their infant is discharged home.	• Role model safe sleep practices for parents and colleagues • Ask questions when safe sleep practice is not adopted for eligible infants • Support parent confidence in safe sleep practices
Pain and Stress		
Prevention	• Painful and/or stressful daily activities are critically reviewed, revised, and modified based on the infant's current health status. • Each infant will have an individualized pain and stress prevention care plan that will be reviewed daily with the interprofessional team. • A unit-specific pain and stress prevention policy will address strategies to manage disease-specific pain (abdominal, pulmonary, neurologic, etc.) as well as pain and/or distress associated with hunger, gas, pruritus, and other discomforts experienced during hospitalization and critical illness.	• Ask if the painful procedures that are scheduled for any given day are actually necessary; if so, coordinate with parents to provide comfort during the procedure(s) • Draft a pain and stress prevention policy for your unit, engage your colleagues to join the initiative; gain buy-in from key stakeholders—test, refine, implement, and measure
Assessment and management	• A valid, age-appropriate, contextually accurate pain assessment tool is used for all patient care encounters throughout the hospital stay. • Pain and stress assessments guide all caregiving activities; caregiving activities are adapted and modified based on infant physiologic and biobehavioral expressions.	• Know your unit's pain assessment tool; truly assess the infant during its experience of pain/distress and respond accordingly

(*continued*)

TABLE 34.5

THE CLINICIAN'S TOOLBOX FOR TRAUMA-INFORMED CARE PROVIDES THE READER WITH QUALITY CORE MEASURES, ATTRIBUTES, AND SUGGESTED NURSING ACTIONS (*continued*)

Pain and Stress		
Attribute	**Criteria**	**Nursing Actions**
Assessment and management (*cont.*)	• Nonpharmacologic and/or pharmacologic pain and/or stress-relieving strategies are consistently and reliably provided for *all* painful and/or stressful procedures (this is documented).	• Obtaining a pain score before the infant has been prepared for the procedure does not give you the information you need: REASSESS—REASSESS—REASSESS
Role of the family	• Parent education regarding infant pain and stress is provided within the first week of hospital admission; learning is validated. • Parents are partners in pain and stress prevention, assessment, and management for their infant(s). • Parents are encouraged, empowered, and supported to advocate for and provide comfort to their hospitalized infant(s).	• Share your knowledge of pain and stress behaviors with parents—educate and empower them • Schedule painful procedures when the parents are present (all laboratories do not need to be drawn at 0400)
Activities of Daily Living		
Posture and mobility	• Optimal postural alignment that supports spontaneous movement during caregiving and at rest is a standard of care. • Infants receive appropriate therapeutic interventions aimed at optimizing neuromotor and neurobehavioral performance for improved short- and long-term outcomes. • Skin-to-skin care is the position of choice for eligible infants.	• Know how to effectively use your unit's postural aids and also when to remove them; they are not accessories to the infant's bed but are therapeutic supports • Support the infant's posture during all movements and caregiving (weights, transfer to a different bed, etc.)
Eating experiences	• Breast milk is actively recommended as the preferred diet for hospitalized infants. • Skin-to-skin care and prefeeding activities at the breast are actively encouraged and supported. • Bottle-feeding encounters are introduced no sooner than 34 weeks' gestational age based on the infant's feeding readiness behaviors; these behaviors direct all bottle-feeding experiences.	• Educate yourself on the current best practices in infant feeding • Be an advocate for improved eating experiences for the patients you serve—role-model infant-driven feeding • Ensure the first oral feeding for breastfeeding dyads occurs at the breast
Skin Care and Hygiene	• Skin and mucous membrane integrity is routinely assessed (at least daily) using a validated, reliable tool • Recommended bathing frequency (sponge, tub, swaddled) is no more than 3 times/week for the purpose of removing debris and general hygiene • Skin and mucous membranes are protected from potential secondary injury, transepidermal water losses and perturbations to the surface microbiome	• Know your unit's skin assessment tool and assess the entire surface of the skin and mucous membranes ensuring accurate documentation and the prompt reporting of abnormal findings • Remember that tub bathing is a parent activity; ensure that parents are confident and competent to perform this parenting activity • Protect infant skin from pressure points and adhesives; remove adhesives gently with non-toxic substances. Promote skin-to-skin care to stabilize the infant's microbiome
Family Collaborative Care		
Presence and partnership	• Parents have unrestricted access to their infant(s). • Parents are invited and encouraged to be present and participate in bedside rounds. • Supportive spaces and resources are readily available to include restrooms, comfortable seating, designated space for personal belongings, and other comfort resources that support parental presence.	• Parents are not visitors—be the champion who changes the language in your NICU • Authentically advocate for and encourage parents to participate in rounds and change of shift • Assess the resources available in your unit that can optimize the parent's experience and the parent's presence with the baby

(*continued*)

TABLE 34.5

THE CLINICIAN'S TOOLBOX FOR TRAUMA-INFORMED CARE PROVIDES THE READER WITH QUALITY CORE MEASURES, ATTRIBUTES, AND SUGGESTED NURSING ACTIONS (*continued*)

Family Collaborative Care		
Attribute	**Criteria**	**Nursing Actions**
Emotional well-being	• The unit has appropriate staffing ratios of licensed mental health professionals. • Parents are assessed/reassessed routinely for postpartum depression and acute stress disorder; all staff are competent and responsible for this assessment. • Appropriate, effective therapeutic interventions and additional crisis support resources are available to families and staff, including family support groups, a peer-to-peer support network, and other support resources (e.g., spiritual, financial).	• Talk with your unit-based social workers about how they support the family in crisis; brainstorm about additional resources to optimize parent emotional well-being • Start a family support group; connect with March of Dimes
Competence and confidence	• Competency-based education is provided to all parents across all facets of the core measures for age-appropriate care to include (but not limited to) breastfeeding skills, skin-to-skin care, safe sleep, bathing and hygiene practices, infant communication, nonpharmacologic pain and stress strategies, and so on. • All staff are culturally competent to support the parenting needs of their unique patient demographics. • Parents are empowered and supported in relationship building and role-validating activities with their infant(s) such as the provision of routine infant caregiving, feeding activities, supporting their infant during painful/stressful procedures, advocating for their infant(s), and so on.	• Develop a parent competency-based education program • Engage former NICU parents for input and assistance • Create a fun way of recognizing parent skill building

SAFETY AND QUALITY IN THE NICU—A CALL TO ACTION

"It is easier to build strong children than to repair broken men."
—Frederick Douglass (Rowland, 2014)

Quality and safety in the NICU begin with *you* choosing courage over comfort in your daily practice as a neonatal nursing professional—the courage to lead from the frontline and be the change you want to see in your NICU. It takes courage to resist and change the status quo, but that is what is needed to improve outcomes across the continuum of care for infants, families, and clinicians. The 2012 policy statement from the American Academy of Pediatrics (AAP; reaffirmed in 2016) urges all pediatric healthcare professionals to adopt an eco-biodevelopmental (EBD) framework as a means of understanding the determinants of lifelong health and wellness (Garner et al., 2012). The EBD framework explains how the social and physical environment of the developing individual impacts his or her biology and subsequently influences the developmental trajectory for health and wellness, both physically and mentally, over the life span (Shonkoff et al., 2012). The AAP urges educational institutions to prepare pediatric professionals to incorporate the growing body of knowledge regarding toxic stress and its deleterious effects on development into their curriculum (Garner et al., 2012). Finally, the AAP admonishes pediatric professionals (of which neonatology is a subspecialty) to be proactive educators of parents and families about toxic stress and the associated consequences. Being vocal advocates for the development and implementation of evidence-based interventions that reduce toxic stress and mitigate the adverse effects of early life adversity is crucial (Garner et al., 2012).

In advocating for the implementation of evidence-based best practices that reduce and mitigate toxic stress in the NICU, it is important to understand the environment of care and the complex dynamics that influence trauma-informed neuroprotective nursing. Workforce shortages, staffing levels, work intensification, and "bottom line" hospital cultures have been linked to an emerging epidemic of missed or unfinished nursing care (Ball, Murrells, Rafferty, Morrow, & Griffiths, 2014; Harvey et al., 2015; Harvey et al., 2016; Willis et al., 2015). Missed care or rationed care, defined as a failure to carry out necessary tasks due to inadequate time, staffing level, and/or skill mix, has been associated with deficiencies in the work environment and is a predictor of nursing job satisfaction, patient satisfaction, and patient outcomes (Ball et al., 2014; Kalisch, Landstrom, & Hinshaw, 2009; Papastavrou, Andreou, & Efstathiou, 2014; Papastavrou, Andreou, Tsangari, & Merkouris, 2014; Rochefort & Clarke, 2010). Physicians have also described the phenomenon of care rationing at the bedside and it creates a moral dilemma for many (Strech, Persad, Marckmann, & Danis, 2009).

In a comprehensive literature review of unfinished nursing care, missed care, and implicitly rationed care, Jones, Hamilton, and Murry (2015) uncover that between 55% and 95% of international nurses in acute care hospitals report leaving at least one task undone on their last shift worked and these errors by omission have a cumulative effect and leave vulnerable patients with unmet educational, emotional, physical and psychological needs. Tubbs-Cooley, Pickler, Younger, and Mark (2015) invited a random sample of regionally diverse certified neonatal nurses

TABLE 34.6

MISSED NICU NURSING CARES

1. Attendance at daily rounds	2. All vital information communicated to other staff during handoffs	3. Feedings offered when baby exhibits cues of hunger	4. Parents prepared for discharge	5. Baby repositioned at least once q2h
6. Oral care for ventilated babies provided per protocol	7. Emotional support provided to parents/ family	8. PRN meds given per order	9. Oxygen titrated per protocol/order	10. Pain managed using pharmacologic or supportive care approaches
11. Baby bathed routinely and/ or as needed	12. Baby received developmentally supportive care (skin-to-skin, nesting)	13. Central line site care and assessments per protocol	14. Documentation completed as care is provided	15. Peripheral intravenous site care and assessments per protocol
16. Parents included in baby's care	17. Critical laboratories/ vital sign values communicated to team per protocol	18. Intake and output monitored hourly or per protocol	19. Infection control precautions followed per protocol	20. Alarms responded to in a timely manner
21. Parents educated about home management of illness, including devices, medications, and general care of preterm infant	22. Skin and wound care provided routinely and/ or as needed	23. Pain assessed according to protocol	24. Laboratories/ specimens obtained as ordered	25. Hand hygiene per protocol
26. Medication effectiveness assessed in 30–60 minutes of administration or per protocol	27. Safety checks of bedside equipment completed once per shift or per protocol	28. Medications administered in 30 minutes of scheduled time	29. Vital signs assessed per protocol	30. Focused reassessments according to the baby's condition
31. Oral feed offered at each feeding opportunity (when infant cleared for PO)	32. Code readiness data assessed once per shift or per protocol	33. "6 rights" of medication administration adhered to each time a medication is given	34. Comprehensive physical assessments per protocol	35. High-risk medications verified per protocol

who provided direct patient care in the NICU to participate in a descriptive study of missed care in the NICU using the MISSCARE Survey (Kalisch & Williams, 2009) adapted for use in neonatal intensive care. Of the nurses reporting, 52% missed at least 1 of 35 nursing care items on their last shift worked (Table 34.6).

Nursing care with the highest missed frequency included attendance in daily rounds, medication effectiveness reassessment, and oral feedings offered to infants who exhibited feeding readiness behaviors (Tubbs-Cooley et al., 2015). Rochefort and Clarke (2010) describe care activities most frequently rationed in the NICU to include discharge planning, parental support and teaching, and infant comfort care. Missed care creates a moral conundrum for the neonatal clinician who feels forced to prioritize and rationalize what is and is not completed during any given shift, minimizing the implications of the missed care, and adding a layer of professional frustration and disappointment in abandoning moral integrity and accountability.

> Missed care may not necessarily be an indicator of poor-quality nursing, but rather a by-product of rational nurse decision-making in the midst of competing priorities. (Tubbs-Cooley et al., 2015, p. 821)

The reported reasons for missed nursing care in the NICU included frequent interruptions, unexpected increase in patient volume or acuity, medications not available when needed, supplies/equipment not available, inadequate number of nurses, lack of protected time, lack of clerical/assistive personnel, inadequate handoff, and tension/communication breakdown across physicians, nurses, and/or other departments (Tubbs-Cooley et al., 2015). Other reasons for missed nursing care include multitasking, task switching, fatigue and physical exhaustion, moral distress and compassion fatigue, leadership issues, and complacency (Kalisch, 2015). Looking at missed nursing care through a trauma lens, we might conclude that many of these "reasons" for missed care may actually be linked to trauma exposure responses and a healthcare culture designed in the early 1900s where nursing was bundled into the cost of the bed and the board for any given hospital stay (Welton & Harper, 2016). This approach to quantifying and qualifying the value of nursing monumentally fails the patient and fails our profession. We are more than skilled technicians: we are healers who bear witness to the suffering of others. We walk with our patients when they

are most vulnerable, honoring their journey, comforting them, advocating for them.

Critically ill infants and their families are profoundly vulnerable to poor outcomes that negatively impact their short- and long-term health; reducing missed care for this unique patient population by improving care environments for patients and the professional practice milieu for clinicians is feasible and necessary (Lake et al., 2017). We know the quality of nursing makes a difference, but if we fail to capture and quantify it, then we will continue to fail our patients, be frustrated in our work, experience compassion fatigue, burn out, and leave the profession. The adage "if it is not documented, it is not done" rings true with the missed care phenomenon. If I am not required to document certain caregiving activities, then maybe they are not really that important and missing them frees me up to do other "higher priority" caregiving. But, this approach invalidates that part of nursing which is the heart and soul of caring for others. Using value-based metrics, Welton and Harper (2016) suggest focusing on the individual nurse as a provider of care and identifying the interaction or encounter of a nurse and a patient, family, or community. Value-oriented care metrics for the NICU must reflect a commitment to trauma-informed, patient- and family-centered care.

> "We can't keep adding to the nurse's workload and expect that everything will get done. Nurses are going to make decisions about what they can and can't accomplish, and this will often depend on what hospitals are holding them accountable for." . . . Do we want checks in all the right boxes, or do we want nurses to provide the care that patients need? (Stokowski, 2015, Viewpoint)

SUMMARY

Decisions about what can and cannot be accomplished are informed by the organizational and unit culture. If the culture is one that does not recognize the impact of trauma on the caregiver, not much will change. However, if we truly embrace the tenets of nursing it becomes incumbent on us, as nurses, to stand in our power, and change the current paradigm to one that is trauma-informed and neuroprotective of our patients, their families, and ourselves.

> Nursing is the protection, promotion, and optimization of health and abilities, prevention of illness and injury, facilitation of healing, alleviation of suffering through the diagnosis and treatment of human response, and advocacy in the care of individuals, families, groups, communities, and populations. (American Nurses Association, 2016)

CHAPTER 35

Family: Essential Partner in Care

Jacqueline M. McGrath and Dorothy Vittner

INTRODUCTION

Parents are essential caregivers for their infants. While admission to the NICU may temporarily shift some of those caregiving responsibilities, it does not negate the importance of a parent's life-long role in their child's overall health and development (Niela-Vilén, Feeley, & Axelin, 2017). Current evidence is increasingly providing direction for how best to fully engage parents in the NICU. These opportunities include increasing both physical and emotional closeness within parent–infant interactions and caregiving activities as well as within caregiving, decision making, and management (Dykes, Thompson, Gardner, Moran, & Flacking, 2016; Flacking, Thomson, & Axelin, 2016; Niela-Vilén et al., 2017). Parent engagement is defined as a dynamic process focused on enhancing and supporting the parent–infant experience, specifically enhancing the acquisition of skills for problem-solving and provision of appropriate infant care based on the infant's unique needs at a particular point in time (Drenkard, 2014; Samra et al., 2013, 2015).

The premise of this concept is that with support from the nursing and medical team and through a parent's self-motivation to set goals and to utilize informational resources about the unique care necessary for their child, parents can increase their engagement while simultaneously improving the progression of their infant's health (Makris, Vittner, Samra, & McGrath, 2019; Provenzi, Barello, & Graffigna, 2015). Defining parent engagement facilitates identification of parent risks and needs for intervention to optimize outcomes for premature infants (Vittner et al., 2019). In the adult literature, patient activation is an evidence-based outcome of increased involvement in care (Greene & Hibbard, 2012; Hibbard & Greene, 2013). Supporting and facilitating parent engagement is one means of decreasing what has been recently documented as posttraumatic stress disorder (PTSD) experienced by parents who must traverse the unfamiliar and chaotic NICU environment in partnership with their high-risk infant (Garfield, Simon, Rutsohn, & Lee, 2018; Karatzias, Chouliara, Maxton, Freer, & Power, 2007; Santos, Yang, Docherty, White-Traut, & Holditch-Davis, 2016). The NICU environment has been repeatedly documented as traumatic to parents, and parents need increasing support depending on their reactions to the environment. Increasing parent engagement has the potential to enhance parent confidence, competence, and self-efficacy, which ultimately has potential to increase their ability to self-manage their child's care after discharge to optimize the health and developmental outcomes for the child (Amin, Tam, & Shorey, 2018; Vance & Brandon, 2017; Wittkowski, Garrett, Calam, & Weisberg, 2017). Even more importantly, the unique needs of the infant's developing brain demand that caregiving delivered by both parents and health providers be neuroprotective, matching the "expectations" for experiences that "nurture" their short- and long-term neurocognitive development (Bonnier, 2008; McGrath, 2008, 2013; McGrath, Cone, & Samra, 2011; Samra, McGrath, Wehbe, & Clapper, 2012). Trauma-informed care has been increasingly implicated in caregiving in the NICU, and we as caregivers need to continue to acknowledge that care is traumatic to all involved (D'Agata, Coughlin, & Sanders, 2018; Sanders & Hall, 2017).

Baum et al. reported how mothers who gave birth prematurely felt "somewhere between being pregnant and being a mother" and that this disconnect further added to their inability to reconnect and attach to their infant in the unfamiliar environment of the NICU (Baum, Weidberg, Osher, & Kohelet, 2012). These ambivalent feelings decrease the mother's ability to be appropriately responsive and sensitive to her infant's needs and potentially leads to dyssynchrony within mother–infant interactions and overall poorer attachment (Baker & McGrath, 2011; Flacking et al., 2016; Green, Darbyshire, Adams, & Jackson, 2015). Sometimes prenatal diagnosis provides the opportunity to enter and learn about the environment of the NICU prior to the birth of a high-risk infant. Although providing this information to families is helpful, if the birth is traumatic the context for what information the parents were provided prior to the birth may be lost (Beck, 2011).

Regardless of how a family enters the NICU, it is important to remember at that initial moment a partnership must be formed between the family and professionals providing care for the infant (Johnson et al., 2008; Reis, Rempel, Scott, Brady-Fryer, & van Aerde, 2010). This relationship must continue as a true collaborative partnership for as long as it is in the best interest of the child (Boykova & Kenner, 2010; Johnson et al., 2008). Even with the added focus on the integration of family-centered care (FCC) that is prevalent in most NICUs today, families continue to report being extremely distressed by the environment and their inability to parent their child in the way they had planned or the way they would at home (Baum et al., 2012; Santos et al., 2016; Stremler, Haddad, Pullenayegum, & Parshuram, 2017).

Partnerships exist when there is a relationship between two or more parties with a shared goal. Effective partnerships between

professionals and families are based on mutual respect, valuing of family expertise, fully shared information, and joint decision making (Johnson et al., 2008). When parents are consistently well informed and involved as partners within the NICU team, ethical dilemmas can be potentially lessened and care decisions optimized in the best interest of the infant and the family (Boykova & Kenner, 2010; Institute for Patient- and Family-Centered Care [IPFCC], 2013b). Partnership and true collaboration between families and health professionals are essential and form the crux of caregiving interventions discussed within this chapter.

Change is the most certain event throughout a person's life. A family experiencing the birth of an infant faces many changes. Some variations in lifestyle occur in the areas of employment, financial security, daily activities, relationships with others, and roles within the family. These changes have a major impact on each parent, family member, and on the family as a whole. When medical needs require admission of the infant to an intensive care nursery, the changes become even more significant because, for the most part, the complex needs of this unique infant or complicated birth have not been planned for or expected (Baum et al., 2012). For the family, these changes can be devastating and challenging. The more fully integrated the family is within the NICU caregiving team, the more unlikely will events be challenging. During this difficult time parents need more than support; they need to be true partners and an integral part of the process of caring for and parenting their child (Boykova & Kenner, 2010; Johnson et al., 2008; McGrath, 2007a). In the environment of the NICU, it is wholly impossible to provide excellent care to the infant without partnering with the parents or family, or preferably both, in every aspect of care (Agency for Healthcare Research and Quality, 2013; Boykova & Kenner, 2010; Stevens, Helseth, & Kurtz, 2010).

Families provide the foundation for health concepts and are the child's portal to the healthcare system. Family beliefs and individual health values are highly correlated. Families are the constant for the child. The provision of individualized developmental care (IDC), of which FCC is a core principle, is pivotal to optimize long-term medical and developmental outcomes for the child (Craig et al., 2015; Montirosso et al., 2012). The effects of IDC are documented into school age, adolescence, and young adulthood (Ekeus, Lindström, Lindblad, Rasmussen, & Hjern, 2010; McAnulty et al., 2013). For these reasons, understanding the many influences of the context of family on the mental health status of each of its members is important for those caring for infants and children (Beck, 2011; D'Agata et al., 2017; Garfield et al., 2018; Hall et al., 2015; Szaniecki & Barnes, 2016; Box 35.1). Most professionals collaborating with children and families believe that a family-centered approach is the best option, because this type of care supports optimal outcomes for the child in concert with those derived from high-quality professional and technical care (Craig et al., 2015; Institute for Patient and Family Centered Care [IPFCC], 2010b; Kersten-Alvarez, Hossman, Riksen-Walraven, Van Doesum, & Hoefnagels, 2011). Fundamental to the infant's developmental trajectory is early parent–infant contact. Parental–infant contact through nurturing touch, especially during skin-to-skin contact (SSC), has the potential to reduce the adverse consequences of critically ill infants (Kamphorst et al., 2018; Olsson, Eriksson, & Anderzen-Carlsson, 2017). These benefits are thought to occur though physiological changes in the infant and parents which facilitate increased feelings of comfort, attachment, and physiological stability (Campbell-Yeo et al., 2017; Casio, Moore, & McGlone, 2018; Mori, Khanna, Pledge, & Nakayama, 2010). SSC is an evidence-based holding strategy that increases the opportunity for parental proximity and provides a continuous interactive environment known to enhance infant physiological stability and affective closeness within the parent–infant dyad (Boundy et al., 2016; Cho et al., 2016; Feeley, Genest, Niela-Vilén, Charbonneau, & Axelin, 2016; Ludington-Hoe, 2011; Mori et al., 2010; Vittner et al., 2018, 2019).

Clear definitions of family and the philosophy of FCC are critical to the foundation of the concepts presented in this chapter. Role theory is used to explain the issues families face during this challenging time. Factors that influence parenting behaviors include personal experiences, medical and nursing staff expectations, environmental conditions, and peer relationships. These factors can either promote or interfere with the development of an intact family unit (Morey & Gregory, 2012; Reis et al., 2010). The birth of a critically ill newborn complicates the attachment process (Brooks, Rowley, Broadbent, & Petrie, 2012; Udry-Jørgennsen et al., 2011) as well as the learning of parenting skills, and thus, an evidence-based framework is provided for understanding what

Box 35.1

FUNDAMENTAL CHARACTERISTICS OF FAMILY-CENTERED CARE

The practice of FCC involves the following:

1. Recognizing the family as the constant in a child's life, whereas the service systems and those who work within each are always changing.
2. Facilitating family–professional partnerships and collaborations at all levels of healthcare provision.
3. Providing care for the individual child and his or her unique characteristics.
4. Families partnering and participating in program development, implementation, and evaluation.
5. Collaboration with families to contribute to policy formation.
6. Honoring the racial, ethnic, cultural, religious, and socioeconomic diversity of families.
7. Recognizing family strengths and individuality and celebrating those differences as valuable.
8. Respecting and supporting different methods of family coping with difficult situations and information.
9. Partnering and sharing with families, on a continuing basis and in a supportive manner, complete and unbiased information.
10. Encouraging and facilitating family-to-family support and networking.
11. Understanding and incorporating the developmental needs of infants, children, and their families into healthcare systems.
12. Implementing comprehensive policies and programs that provide emotional and financial support to meet the unique needs of families.
13. Designing accessible healthcare systems that are flexible, culturally competent, and responsive to family-identified needs.

families need in terms of true support in the neonatal setting. Several different models of family-centered care are presented. The chapter concludes with evidence-based FCC strategies that support optimal family functioning during the NICU experience and promote the discharge of intact families as the crisis of newborn intensive care begins to resolve. These strategies also include issues related to sibling adaptation and involvement of extended family members in the care and decision making related to the infant.

FAMILY-CENTERED CARE

FCC is a philosophy of care in which the pivotal role of the family in the lives of children is recognized and respected (IPFCC, 2017; Johnson et al., 2008). According to this philosophy, families are supported in their natural caregiving and decision-making roles by building on their unique strengths as persons and then extending this same examination of strengths to the family unit. FCC recognizes and promotes the normal patterns of a family's life at home and in the community. Rather than expecting the family to take on the medical culture of the institution, healthcare professionals recognize and reinforce the family's culture through a partnership formed in the best interests of the child. Parents and professionals are equals in a partnership committed to the child and to the development of optimum quality in the delivery of all levels of healthcare (IPFCC, 2013b, 2017). FCC strengthens the family unit through empowerment and advocacy by enabling the family to nurture and support their child's development (IPFCC, 2013b; Lee, Carter, Stevenson, & Harrison, 2014; Box 35.2).

From the child's perspective, FCC is safe and familiar; the infant/child is first and foremost a member of a family and care that is individualized to the family is also individualized to the infant (Hill, Knafl, & Santacroce, 2018). When the framework of FCC is the foundation for caregiving, the family is visible, available, and supportive of their infant's needs. They are an integral part of every decision that affects their child, even if they are not present at the bedside 24 hours a day like any other member of the health professional team (Craig et al., 2015; Miyagishima, Himuro, Kozuka, Mori, & Tsutsumi, 2017). Thus, their presence is noted in all aspects of care. The family members are empowered partners in the caregiving practices of their child within the healthcare setting (Johnson et al., 2008; McGrath, 2011). FCC begins wherever and whenever a family enters the healthcare system and continues throughout the hospitalization to discharge. Families should encounter this philosophy of care before birth in antenatal care, and continue it into the delivery room and beyond into the postpartum period (Hodnett, Gates, Hofmeyr, Sakala, & Weston, 2011; Lindner & McGrath, 2012). It is important to remember that families are not replaceable at any level in the overall development of the child. Within implementation of the philosophy of FCC, their impact always supersedes that of the healthcare system (Foster, Whitehead, Arabiat, & Frost, 2018; Gooding et al., 2011).

It is important to organize care to minimize the separation of parents and infant and to provide expertise in bonding and attachment theory that supports parents directly or indirectly. Nonseparation of infant and parents also has ethical and legal support. The United Nations Convention on the Rights of the Child from 1989 states in article 7: "The child . . . shall have the right from birth to . . . be cared for by his or her parents" and in article 9: "Parties shall ensure that a child shall not be separated from his or her parents against their will.. . ." Couplet care is an emerging concept within neonatal care that provides facilities for parents to live in the neonatal intensive care nursery along with their infants throughout the hospitalization by coupling the care of the infant with the care of the newly delivered mother. This model has been practiced in Sweden for over 10 years. It includes not only postpartum care after a normal delivery but also care of mothers with more advanced needs. After the immediate postpartum period, approximately half of all mothers with infants born prematurely have a prolonged need for medical care and would otherwise be separated from their infants during the very important first days of bonding and attachment (Westrup, 2015). When introducing couplet care, it is important to appropriately adjust the design and structure of the nursery. It is essential to build structures for a close collaboration with obstetrics since they must still have the medical responsibility for the mothers; for example, do rounds and prescribe medications and decide if the mother is receiving adequate care. FCC cannot happen in a vacuum; it must be supported by organizational policies and procedures that optimize the strengths of the family (Milette, Martel, Ribeiro da Silva, & Coughlin, 2017a, 2017b). Delivery requires a whole team approach where everyone has the same beliefs and attitudes toward the importance of families to ensure that *all* families receive this type of care.

Box 35.2

FOUNDATIONAL PRINCIPLES OF FAMILY-CENTERED CARE

- **Enabling:** Building on family strengths to create opportunities and ways for families to use the abilities and competencies they already have to learn new ones to meet child and family needs
- **Empowering:** Acknowledging and respecting the fact that families have existing strengths and capabilities and building on those strengths by supporting the family in meaningful decision making about issues that affect their welfare. Professionals who empower families interact and form partnerships with families in ways such that the family develops and maintains a sense of control over their own lives and are able to make positive changes to reinforce their own strengths, abilities, and actions.

DEFINITION OF FAMILY

The concept of who and what comprises a family in North America is defined best by each specific family unit. Families expand, contract, and realign at a rapid pace to keep up with the rapidly changing demands of our world. Today, dual-career families; single-parent households; unmarried couples; lesbian, gay, bisexual, queer, and transgender (LGBQT) couples; remarried couples; and sole-parent adoptions are all accepted models of family, in addition to the "traditional" family units common a century ago.

"Family" is a broad term that is best defined by the individual; however, in general, a family is made up of those people, both related and unrelated, who provide support, structure beliefs, and define values. Family has also been defined as a social system composed of two or more people who coexist in the context of expectations of reciprocal affection, mutual responsibility, and

temporal duration (Kaakinen, Gedaly-Duff, Hanson, & Coehlo, 2009). Families provide the framework through which individuals enter and interact with society at large. For infants and children, families are the means to resources, education, and society. Again, it is important to remember that families bring their children to the healthcare system for care. No matter how an infant comes to us, it comes with a family.

A family is defined by its members; "family" is an internal concept of how that particular group defines itself. It may be composed of blood relations or friends; it may not depend on a blood bond but on the emotional tie or closeness felt among its members. It also may be an extended family that includes parents, grandparents, other relatives, and friends. Families today are not necessarily defined as they have been in the past and not according to gender-specific roles. Families also can be defined by considering the degree to which the following five attributes are present (these attributes also depend on the family's societal and cultural orientation; Kaakinen et al., 2009).

1. A family is a social system or unit.
2. Family members may or may not be related by birth, adoption, or marriage.
3. A family may or may not include dependent children.
4. Families involve commitment and attachment.
5. Family members usually have roles and caregiving functions (e.g., protection, nourishment, and socialization).

ROLE THEORY

In the context of better understanding family dynamics, it is important to also review and examine role theory. Role theory, which first appeared in the literature in the 1930s, offers a framework for understanding families and identifying the roles that individuals play within the family. As a broad term, role theory represents a collection of concepts, subtheories, and research that address aspects of social behavior relevant to families. Roles are social contexts with patterned behaviors that develop over time and are predetermined by social forces. Roles are dynamic, interactional, and reciprocal relationships among individuals; therefore, values, attitudes, and behaviors influence these relationships. Each role has specific behaviors and expectations placed on it by society and these expectations guide individuals as to when, where, and in what manner they are to perform within the role.

Each role within a family has specific demands. An individual learns these demands by maturing and advancing through the middle to later stages of the life cycle: (a) adolescence, (b) adulthood, (c) marriage and parenthood, and (d) middle and old age. Individuals respond to the demands of a role differently based on their maturity and current developmental stage in the life cycle. For example, a single, adolescent girl would be expected to perform the maternal role differently from a married, adult woman.

Within role theory, seven areas of distress have been identified: (1) role ambiguity, (2) role conflict, (3) role incongruity, (4) role overload, (5) role underload, (6) role overqualification, and (7) role underqualification. These terms are defined in Table 35.1. Distress is often responsible for producing role stress and strain. Role stress is defined as either internal or external pressure that generates role strain. As a consequence, feelings of frustration, tension, or anxiety are produced in either the individual or the reciprocal partners. When problems occur within a role, or a person, the members of the group may need to modify or completely change roles. Changing roles can be stressful for the individual and the group. However, not changing roles can result in intrapersonal and interpersonal role conflict, which can lead to further stress and anxiety. Parenting in the NICU can lead to role conflict since parents may feel they are not the ones parenting their child (Curley, Hunsberger, & Harris, 2013; Treyvaud et al., 2011).

TABLE 35.1

POTENTIAL ROLE PROBLEMS

Role	Potential Problems
Ambiguity	Role expectations are vague or lack clarity.
Conflict	Role expectations are incompatible (conflicts exist between reality and expectations).
Incongruity	Self-identity and subjective values are grossly incompatible with role expectations.
Overload	Too much is expected in the time available.
Underload	Role expectations are minimal and underuse the role occupant's abilities.
Overqualification	Occupant's motivation, skills, and knowledge far exceed those required.
Underqualification	Incompetence; the role occupant lacks one or more of the necessary resources (commitment, skill, knowledge).

Source: Adapted from Lipson, J. G., & Dibble, S. L. (2005). *Culture and clinical care.* San Francisco, CA: USCF Nursing Press.

The working mother is an example of role conflict and role overload; she may struggle with her dual professional and maternal roles. A decision to quit work and devote all her time to mothering may contribute to a lack of self-worth or identity. A decision to continue both roles may generate feelings of guilt because the new mother feels she is neglecting her family's needs. Reducing her work hours is a behavioral change she may make to allow more time for her family. She thus receives the positive reinforcement of employment yet has more time for family and her maternal role. If she does not modify her roles, she may experience further stress and anxiety. To be effective, role change requires several steps. Such change develops through gradual, continuous, and dynamic processes based on the individual's needs and those of relevant others. The steps to successful role change include identifying the role of the relevant other (or others), identifying the expectations of the new role, developing the abilities for it, taking on the new role, and modifying it.

PARENTAL ROLE

Certain behaviors define the role of the parent. It is also important to remember that not all families today are composed of mothers and fathers, so identifying who is taking on the parenting role is important to understand how to best support families. Several factors influence these behaviors: cultural background, personality, previous parenting and life experiences, degree of attachment to the infant, and expectations that parents have of themselves and the infant or child. A child changes everything in the

close-knit relationship of the parents (Tryphopoulos, Letourneau, & Ditommaso, 2014). They must take on a new role; they are not just partners sharing a relationship, they are now mothers and/or fathers as well. Feelings of inadequacy, conflict, and fatigue are often apparent during the transition and may adversely affect both existing relationships and those just developing between parent and child (Brett, Staniszewska, Newburn, Jones, & Taylor, 2011). Parenting remains the only major role for which there is little systematic preparation in our society. Difficulties encountered in the early stages of parenting may adversely affect all relationships but most especially the relationship between partners (Jackson, Newsome, & Beaver, 2016). These difficulties can arise even if the new child is not the first child in the family unit; each additional member of the family brings unique joys and challenges.

The situation in which a person must parent also influences behaviors. Parents faced with a crisis must modify their roles and adapt to the necessary changes encountered with the crisis. Role and behavior changes can cause considerable stress, especially if these changes occur abruptly (Treyvaud et al., 2011). Maternal depression is a well-known phenomenon encountered by many mothers both during pregnancy and in the postpartum period. Mothers who must encounter the NICU are at particularly high risk for developing depression (Barnard et al., 2011; Beck, 2011; Rogers, Kidokoro, Wallendorf, & Inder, 2013). Parents suffering from mental or physical illness or those who are chemically dependent can have limited coping abilities and social support (Gray, Edwards, O'Callaghan, & Cuskelly, 2012). Screening at admission, and throughout the infant's stay in the NICU, is important so that support and treatment can be provided for at-risk mothers (Rogers et al., 2013). Other interventions might include enhancing the mother's ability to become more engaged in her infant's care, as well as helping her connect with other mothers in similar situations and finding resources for them in the community (Gray et al., 2012; Zelkowitz et al., 2011).

Single, adolescent, or first-time parents are also at a disadvantage. They may lack maturity and coping skills because of limited life experiences and unavailable or inappropriate social support systems. These disadvantaged situations may inhibit the development of the parent–infant relationship and thus impair parenting behaviors regardless of whether the infants are high-risk, preterm, or full term (Gray et al., 2012). In addition, people parent differently and take on roles differently (Boykova & Kenner, 2010). These differences are not wrong or right; they are just differences that need to be acknowledged and accepted. Parents who have experienced some type of loss through infertility may also have more difficulties parenting their infant in the NICU since their personal investment in having a child may be causing role strain accompanied by increased stress and anxiety (McGrath, Samra, Zukowsky, & Baker, 2010). Sensitivity to these experiences and previous losses is important in understanding how best to support these parents in the NICU. Lastly, in the NICU women are often the focus and men can be easily overlooked and not well understood or supported (Boykova & Kenner, 2010; Cleveland, 2008). Care of men in this high-risk situation is changing but it still is an area where we need to improve and provide optimal care and support (Kim, 2018).

Infant-related factors can also interfere with parental attachment and subsequent parenting behaviors. An example is an infant born with a congenital anomaly (Neel, Stark, & Maitre, 2018). Many of these infants may be mentally or physically disabled for a lifetime, which interferes with the parents' expectations of their infant (Brooks et al., 2012; Flacking et al., 2016; Watson, 2010). A visible anomaly is particularly difficult for parents because society places such emphasis on appearance. An infant with an easily correctable anomaly is tentatively unacceptable to society, until the anomaly has been corrected. A visible, noncorrectable anomaly has a greater impact on the parents and other family members. This stigma may include preterm infants who have deficits related to their untimely birth, such as blindness, deafness, or severe respiratory compromise. These parents may suffer from chronic sorrow and the child may grow up hindered by the expression of the "vulnerable child syndrome" (Samra & McGrath, 2009; Coughlin & Sethares, 2017). It may be helpful to connect these families with support groups or other families with children with similar disabilities or diagnoses (Al Maghaireh, Abdullah, Chan, Piaw, & Al Kawafha, 2016; Liu, Chao, Haung, Wei, & Chien, 2010; Stefana & Lavelli, 2017).

A life-threatening or terminal illness in a child is another situation that may interfere with parenting attachment and behaviors (Pelentsov, Fiedler, & Esterman, 2016). Parents may hold back their feelings for the child to try to protect themselves from loss and pain if the child dies (Currie et al., 2016). This inability to attach to their infant interferes with the parenting experience and may affect the child's development if the child lives past the previously expected life span.

At any birth or other interaction between a parent and his or her child, the nurse must identify adaptive and maladaptive parenting behaviors. Adaptive behaviors indicate that both the infant's and parent's needs are met and the parent–child relationship can be established. Parents have different ways of expressing their parental roles based on gender differences alone (Boykova & Kenner, 2010; Mundy, 2010). Table 35.2 identifies parenting behaviors the nurse can use as a foundation for assessing adaptive or maladaptive behaviors. It is important to remember that these are guidelines and must be adapted individually to each parent based on his or her personality and the specific situation.

PARENTING DURING CRISIS

Taking on the parenting role is a major life task for a couple. The crisis of having a critically ill newborn in the NICU compounds the stress of that task. Whether the family unit attains growth from a positive resolution of this crisis or splinters because of a maladaptive adjustment largely depends on the partnership formed with caregiving and the quality of support provided (Aronson, Yau, Helfaer, & Morrison, 2009; Beck, 2011). The memory of what happens in the first days after a traumatic birth often stays with a family forever. Just ask a mother to describe her birth experience, and she will talk for hours, explaining every detail (Beck, 2011). Consequently, the relationships formed and interventions provided during the initial trauma can be critical to the adjustment and continued growth of the family unit (Barnard et al., 2011; Cleveland, 2008).

Parent Responses

Crisis can be defined as an upset of a steady state; that is, a period of disequilibrium precipitated by an inescapable demand to which the person is temporarily unable to respond adequately. The birth of a critically ill infant represents two types of crises for parents. The birth of any infant is a developmental crisis, a natural transitional phase in the lives of parents. When the infant is premature or ill, parents also experience an accidental and unexpected crisis. The meaning of the event for the family and the resources available to deal with the event are variables that determine the scope of the crisis. With the technological advances in medicine, some families are now able to better prepare for and make decisions about their child's prognosis and medical needs before birth. For example, many infants with gastroschisis or other anomalies are diagnosed during a prenatal ultrasound examination. In such cases, families have the opportunity to better plan for the birth and to make decisions with the healthcare team in a more conducive

TABLE 35.2

GUIDELINES FOR ASSESSING ADAPTIVE AND MALADAPTIVE PARENTING BEHAVIORS

Adaptive Behavior	Maladaptive Behavior
Delivery	
Attempts to position head to see infant as soon as delivered and while infant is on warming table	Does not position head to see baby
When shown infant: • Smiles • Keeps eyes on infant, looking at all parts exposed • Attempts a face-to-face position • Uses fingertip touch on face and extremities • Asks to hold baby • Partly opens blanket to see more of infant • Talks to baby • Asks questions about baby	When shown infant: • Frowns • Stares at ceiling • May not look at infant • Stares at baby without expression • Does not assume *en face* position • Does not touch baby • Does not ask to hold baby • Declines offer to hold baby • If infant is placed in her arms, lies still, and does not touch or stroke baby's face or extremities • Does not talk to baby • Asks few or no questions
Makes positive statements about baby: "She's so cute!" "He's so soft!"	Makes no comments or makes only negative statements: "She looks awful." "He's ugly."
May cry out of joy or relief that infant is normal or of desired sex	May cry, appearing unhappy or depressed
May smile and cry at the same time (to differentiate from crying out of disappointment, note facial expressions and verbal statements)	When asked why she is crying, states she is disappointed in baby
Expresses satisfaction with or acceptance of infant's gender: "We really wanted a girl, but it's more important that he's healthy." "I can't believe it's a boy, at last!"	Expresses dissatisfaction with baby's gender: "Not another girl. I should have known better than to try again for a boy." "I don't even want to see him." May use profanity when told gender
Predominant affect: appears pleased and happy	Predominant affect: appears sad, angry, or expressionless
Suddenly decides she wants to breastfeed	Suddenly decides against breastfeeding
First Week	
Initially uses fingertips on head and extremities; progresses to using fingers and palm on infant's trunk; eventually draws infant toward her, holding infant against her body	Uses fingertip touch without progressing to palm on trunk or drawing infant toward her body
Snuggles infant to neck and face	Does not hold infant to neck or face
Makes spontaneous movements, kissing, stroking, and rocking	Makes few or no spontaneous movements with infant
Talks to infant with positive manner and tone, uses appropriate language, speech, and content	Uses curt language or content
Attempts to establish eye contact by moving infant, assuming *en face* position, or shielding infant's eyes from light	Does not use *en face* position or attempt to establish eye-to-eye contact
Handles and holds baby at times other than when giving direct care	Handles baby only as necessary to feed or change diapers

(*continued*)

TABLE 35.2

GUIDELINES FOR ASSESSING ADAPTIVE AND MALADAPTIVE PARENTING BEHAVIORS (*continued*)

Adaptive Behavior	Maladaptive Behavior
Relaxed with child; relaxed posture, muscle tone	Rigid posture, tension, fidgeting, seems somewhat agitated
Smiles at baby frequently; changes affect appropriately, such as when infant cries	Rarely smiles at baby or smiles all the time without change in affect
Makes many specific observations of infant: "Her eyes look like they might turn brown." "One foot turns in just a bit."	Makes no observations or makes few observations that are either general or negative
Discusses infant's characteristics, attempting to relate them to others in the family: "He has my ears but his daddy's chin." "She really doesn't look like either of us, she just looks like herself."	Does not discuss infant's characteristics in relation to characteristics of family members
With a positive manner, uses animal characteristics to describe baby: "She's just like a cuddly little kitten." "His hair feels like down."	In a negative or hostile manner, uses animal characteristics to describe: "She looks awful, just like a drowned rat." "He looks like an ape to me."
Asks questions about caring for infant discharge	Asks no questions about care
Seeks information about the child; asks appropriate questions	Does not ask questions or questions are not appropriate
First Few Weeks **(if infant remains hospitalized after mother has been discharged)**	
Calls every day or every other day	Calls less frequently than every other day or not at all
Is present at bedside a minimum of twice a week	Is unable to be present at least twice a week, or is not present at all
Stays at bedside for a minimum of 30 minutes	Stays at bedside for <30 minutes
Asks specific questions about infant's condition	Asks no specific questions
Asks appropriate questions frequently	Asks inappropriate questions
Spends most of the time at bedside participation in care while looking at and handling infant	Spends most of the time at bedside observing unit activities and other infants (this may be normal behavior for the first few times the parent is in the NICU); has little or no interaction with infant even though she/he does participate in caregiving with encouragement
Becomes involved with care when encouraged and supported by staff	When encouraged by staff to participate in care, refuses, or decides to leave the NICU, or performs only minimal care
Although the parent is not able to be at the bedside often, when is able to be present the time at the bedside lasts longer than 30 minutes, makes statements about missing infant (e.g., says that she misses infant at home or that she/he wishes she/he could be present more often and stay longer)	Makes no statements about missing infant, or states that she/he misses infant at home and wishes she could be present more often, but comments are not validated by frequent or lengthy time spent at bedside with infant
Expresses reluctance to terminate time at the bedside; is reluctant to leave	Leaves nursery with little hesitation
Waits until infant is asleep before leaving; touches or talks to baby just before leaving; may stand outside window and look at baby before leaving unit	Frequently asks nurse to complete feeding or to change and settle infant
Expresses a desire to participate in holding the infant	Seems afraid to hold infant or participate in care
Expresses a desire to participate in skin-to-skin holding	Finds it difficult to participate in skin-to-skin holding

(*continued*)

TABLE 35.2

GUIDELINES FOR ASSESSING ADAPTIVE AND MALADAPTIVE PARENTING BEHAVIORS (*continued*)

Adaptive Behavior	Maladaptive Behavior
Expresses desire to protect the child, aware of environmental hazards, actively protects	Protective behaviors not exhibited
Is available and willing to learn new things to better care for the child	Is unwilling to learn caregiving skills
Supportive of partner in caring for the child and participating in caregiving, holding, etc.	Communication between partners is distant or nonexistent
First Months	
Holds infant close to her/his body	Does not hold infant securely against body
Supports infant's trunk and head in position of comfort	Head and body of infant are not well supported
Muscles in her/his arms and hands are relaxed and conform to curvature of infant's body	Shoulder, arm, and hand muscles appear tense; hands and fingers do not conform to infant's body
During feedings, holds infant in well-supported position against her body	Holds infant away from her body during feedings or props infant or bottle
Positions during feeding so eye-to-eye contact can occur	Position during feeding prevents eye-to-eye contact
Minimizes talking to infant while baby is sucking	Continues talking to infant during feeding even though infant is distracted and stops sucking
Refers to infant using given or affectionate name	Refers to infant in impersonal way (e.g., "the baby," "she," or "it")
Plays with infant at times unrelated to direct care	Handles infant mainly during caretaking activities
When infant is in infant seat, playpen, or crib, frequently interacts with baby	Leaves infant for long periods in infant seat, playpen, or crib, interacting only after infant becomes fussy
Places infant, when awake, in an area where baby can observe and interact with others	Leaves infant, when awake, alone for long periods in bedroom or isolated area
Occasionally leaves infant with someone else	Frequently leaves baby with someone else or refuses to leave baby with someone else
Uses discretion in selecting babysitter and provides instructions on baby's routines, likes, and dislikes	Does not use good judgment in selecting babysitter; provides inadequate or no instructions for care
Provides infant with routine well-baby care; carries out medical plan for management of specific problems or conditions (e.g., thrush, anemia, or ear infection); makes additional phone calls or additional visits to physician	Fails to provide infant with well-baby care, seeking medical assistance only after problems, or keeps all appointments and makes emergency room visits for imagined or insignificant problems
Remains close to infant during physical examinations and attempts to soothe baby if infant becomes distressed	Remains seated at a distance from the examination table; does not soothe infant during examination; frequently arranges for someone else to take infant for medical appointments
Makes positive statements about parenting role	Makes negative statements about parenting role

Source: Modified from Hall-Johnson, S. (1986). *Nursing assessment and strategies for the family at risk* (2nd ed.). Philadelphia, PA: Lippincott William & Wilkins.

and supportive environment. The ability to anticipate the needs of the child reduces the sense of crisis for these families with the birth of the child.

Families of a premature or sick newborn react in different and individual ways. Some common responses are anxiety, guilt, fear, resentment, and anger. During the illness of a newborn, the parents must face many issues; two important ones are the loss of the perfect child they have anticipated and a fear that their infant may die (Beck, 2011; Cleveland, 2008). In general, excitement and a flurry of preparation surround the birth of a child. Family celebrations help parents share the anticipation of a new infant with friends and extended family members. Parents spend much time imagining what this child will look like and dreaming about the joys of parenting. The parents experience disappointment when the infant or pregnancy is not as anticipated. They may feel a sense of isolation from other parents who have a normal pregnancy or infant. They may even have feelings of isolation from each other or from close family members. The inability to produce a healthy infant or to protect the infant from the invasive and painful environment necessary to sustain the child's life may cause feelings of inadequacy. For some parents, the role they believed they would assume seems impossible to attain in the environment of the NICU, where often it seems everyone else is making decisions about the fate of their infant (Cleveland, 2008; McGrath, 2007b). Parents seldom have had experience with the NICU before and the intensity of the situation is heightened even more by the fact that they and their infant are center stage.

To move forward with the attachment process, parents must reconcile their idealized image of the child with the actual infant. They mourn the loss of the perfect child that was expected and encounter anticipatory grief for the infant whose life may now be in jeopardy (Caeymaex et al., 2012; Currie et al., 2016; Shah, Clements, & Poehlmann, 2011). The birth of an ill or a premature infant often places parents in a state of disequilibrium; nothing is as it was before. For many parents, hope is an important emotional concept during this time of crisis (Ingram et al., 2017). Hope provides some equilibrium that things will get better for their infant and for themselves. However, hope can also lead parents to develop high expectations for their child that may be in conflict with the expectations of the healthcare team (Nordheim, Rustøen, Solevåg, Småstuen, & Nakstad, 2018). These different expectations can lead to more conflict and role strain as families are trying to maneuver the difficult situation of the NICU and understand how to assume their parenting role and best support their child (Roscigno et al., 2012).

Mothers of premature infants have had the emotional work of pregnancy cut short and thus are often psychologically unprepared for the birth (Beck, 2011; Caeymaex et al., 2012). If the mother had felt ambivalent about the pregnancy, she may believe that the infant's illness is somehow punishment for those emotions. A mother may also feel guilty that she could not carry the infant to term, even if no reason can be found for the baby's premature birth.

Many parents of sick newborns go through identifiable stages of grief and loss with very emotional reactions (Currie et al., 2016). The initial response usually is one of overwhelming shock, characterized by irrational behavior, crying, and feelings of helplessness and despair. Families at this stage have difficulty with organization because their lives have been disrupted by the unexpected birth. They may feel as if everything is in chaos and the situation is out of their control. Substance abuse, adolescent pregnancy, clinical depression, and domestic violence can increase the chaos and vulnerability of these families (Cleveland, 2008). Parents also may feel guilt over the premature delivery or the infant's illness. Self-blame often characterizes these feelings ("If only I had stayed home the day I noticed the spotting"). Parents may try to escape the situation by using denial ("Everything will be fine in just a few days"). At the bedside in these initial days, parents may focus on facts they can understand and avoid issues they do not. To healthcare providers, this may seem as if the parents aren't listening or that they are unwilling to hear the information provided, yet the parents are trying to cope with what to them is an overwhelming situation (Hardy & McGrath, 2008; McGrath, 2007b).

Intense feelings of resentment and anger follow denial. Parents may direct these feelings at themselves, the infant, members of the healthcare team, God, or even each other as parents. They may also experience feelings of ambiguity and may fear the infant's physical and mental outcome. For these reasons, they may avoid emotional involvement with the infant to protect themselves from the pain of possible loss. A lessening of the intense emotional reactions and an increased ability to begin caring for their infant's emotional and physical needs are characteristic of adaptation and of taking on the parenting role. Reorganization is the final stage; at this point, parents come to terms with their infant's problems. This can take from a few days to several months. In some cases, these feelings of loss and grief may never be resolved (Caeymaex et al., 2012; Currie et al., 2016). Throughout these stages, often it is hope that helps parents to move forward and believe that a new day will bring better outcomes for their child (Nordheim, Rustøen, et al., 2018).

Factors That Affect Parenting Skills

Certain factors affect a person's ability to acquire parenting skills during the NICU experience (Box 35.3). Parents are unable to attach and detach at the same time; these two tasks are incongruent. Parents need time to detach or grieve for the lost perfect child before they can begin to attach to the ill infant. This adjustment may take days or even weeks and for some parents attachment may never occur (Shah et al., 2011).

Parents in the NICU environment face physical, mechanical, psychological, and emotional obstacles during this difficult time. In this chapter, we refer mostly to the psychosocial behaviors of parenting and becoming a family, but it is important to note that these behaviors also have implications for the parent's health and personal well-being (Howland, Pickler, McCain, Glaser, & Lewis, 2011). These physiological issues cannot be ignored since parents who do not attend to their personal and physical needs are not as able to attend to the needs of their child (Turner, Winefield, & Chur-Hansen, 2013). Evidence supports that an infant's appearance and experience of painful procedures, as well as the perceived

Box 35.3

FACTORS THAT INFLUENCE FAMILY REACTIONS TO A CHILD'S HOSPITALIZATION OR ILLNESS

- Severity of the illness and the threat to the child
- Previous experience with illness or hospitalization (or both)
- Familiarity with the medical procedures involved in diagnosis and treatment
- Available support systems
- Available coping strategies of family members
- Number and degree of other family stresses
- Cultural or religious beliefs
- Communication patterns of family members

severity of the child's illness, all contribute to the degree of stress experienced by parents (Heidari, Hasanpour, Fooladi, & Awat, 2015). A nurse who can properly identify the specific stressors with each parent or family has the opportunity to assist them in reducing those stressors and promoting adaptation for the family unit (Beck, 2011; Craig et al., 2015).

The nurse is potentially the principal barrier to parenting in the NICU because the nurse can be seen as the gatekeeper of the infant (Latour, Hazelzet, Duivenvoorden, & van Goudoever, 2010). In reality, the infant belongs to the family and not to the medical team. For parents to attach to their infant, a welcoming, calming environment in which they feel comfortable is essential in the NICU (Venkataraman, Kamaluddeen, Amin, & Lodha 2018; Box 35.4). This kind of environment encourages parents to grow in their primary caregiver role so they can develop skills needed to be advocates for their child. This advocacy is essential for the infant's continuing development, especially if the child has special needs (Franck & Axelin, 2013). Meiers, Tomlinson, and Peden-McAlpine (2007) developed the Family Nurse Caring Belief Scale to examine nurses' beliefs about FCC activities. This instrument can be used to understand how nursing staff perceive their own delivery of FCC and as a means to examine changes in FCC in a particular NICU environment over time.

Parents react to stress and grief in different ways (Cleveland, 2008). A man may isolate himself and become engrossed in his work and may not share his feelings with a woman. A man often tries to be strong for the woman and may become protective, sometimes choosing to shield her from painful information (Hardy & McGrath, 2008). A wife may view her husband's stoic behavior as cold and unfeeling. Both may have difficulty discussing the child because of their own grief or guilt feelings. Normal postpartum blues can increase the mother's sensitivity to this situation and lead to further depression (Beck, 2011). She may cry for no real reason and feel embarrassed about irrational behavior. Existing weaknesses in their relationship are often magnified. Parents are often separated in their feelings at this time and fears may arise that their relationship is falling apart at a time when they each need the other. Lack of communication can lead to isolation and feelings of resentment in each of the partners. Each may make assumptions about the other's feelings, resulting in misconceptions. The need to communicate and share in each other's experiences is especially true if the child has special needs or a developmental disability. These misconceptions, along with gender differences in coping, may continue for a lifetime if they are not recognized and shared during the neonatal period (Poehlmann, Miller Schwichtenberg, Bolt, Dilworth-Bart, 2009). Helping parents understand that their feelings are not unusual is important to facilitate the sharing of these feelings with their partner. Some people may require counseling during this time.

Other stressors in the family, such as the needs of other children, financial concerns, illness of family members, or marital stress, can complicate the situation (Curtis, Foster, Mitchell, & Van, 2016). For example, factors that can influence the degree of stress perceived by the family include the availability of appropriate emotional and psychological support among family members and from friends and the availability and use of community resources (Curtis et al., 2016; Wang, He, & Fei, 2016). Maintaining a support system and using community resources and professional assistance are excellent coping strategies for dealing with the crisis. Coping abilities demonstrated during previous crises often can predict how parents will cope with the current crisis. In an acute crisis, the family may be unable to use the resources available adequately because of lowered self-esteem, reduced family cohesiveness, and impaired family communication. Interventions during this time should focus on helping parents recognize and use available coping strategies. Communication patterns could be impaired because of anger or emotion derived from the crisis situation (Curtis et al., 2016). Therefore, at times the family may require outside assistance; they may be unable to use or maintain the community resources required without this support (IPFCC, 2017).

A stressful situation has a specific meaning for each family and for each member of the family because of previous experiences and the family's perceptions of these demands and their personal capabilities. For example, a sepsis workup may not seem particularly stressful to the healthcare team but may be very stressful to parents and families (Newnam & McGrath, 2010). For some families, the least hint that their infant is sicker or more unstable can be devastating. Certain personality types thrive on stress and deal effectively with any crisis. Others are unable to deal with even the smallest crisis. For example, if a family acknowledges a stressor as a "challenge" or can bestow meaning on the situation, such as believing that "it is the Lord's will," adaptation will likely be more successful. Maladaptation results if the family interprets the stressor as threatening or undesirable. The family's expectations for themselves and this new child affect parenting skills (Giambra, Broome, Sabourin, Buelow, & Stiffler, 2017). Each partner draws on his or her own childhood experience for parenting role models. The meaning the stressor has to the family also depends on the family's identity, cultural beliefs, and worldview. The family's identity comprises the values of the family which are seen in the routines and rituals that develop in individual families. Stressors may disrupt these routines and rituals, threatening the development, maturation, and stability of the family system (Craig et al., 2015; IPFCC, 2017). The family's worldview is based on how the family interprets reality, its core belief system (religious and cultural beliefs), and its purpose in life. The way a family handles its problems or deals with change often is based on the family identity and worldview. The family worldview is the most stable of the three levels of meaning but even this can be shattered by a severe crisis (Craig et al., 2015).

The coping strategies are cognitive and behavioral components of the effort to handle the stressful event, that is, what

Box 35.4

CREATING A WELCOMING ENVIRONMENT IN THE HOSPITAL FOR FAMILIES

1. When the opportunity presents before the birth, prepare the family for the infant's admission to the NICU and hospital course.
2. Give a special orientation for families who have undergone an emergency admission.
3. Provide for the needs of families who have traveled long distances.
4. Make fathers as welcome as mothers.
5. Meet the needs of siblings and other family members.
6. Enable families to be together as much as possible; have open visiting hours 24 hours a day.
7. Encourage families to bring items from home to create a personalized environment that makes their child feel more at home.
8. Provide privacy for family when present at bedside.
9. Encourage family participation in the child's care.
10. Help the family stay in touch with extended family members and support-givers in the community.

Source: Adapted from Institute for Patient- and Family-Centered Care. (2017). *Advancing the practice of patient- and family-centered care in hospitals: How to get started*. Bethesda, MD: Author. Retrieved from http://www.ipfcc.org/resources/getting_started.pdf

the family "does" to handle the stress. These strategies can be emotion-focused (i.e., strategies for controlling the emotions the crisis has engendered, such as denial or anger) or problem-focused (i.e., action-oriented strategies to manage the crisis). Coping behaviors are learned, and families can use any or all of the major coping functions in a crisis situation. Emotion-focused strategies are used most often in the adjustment phase of a crisis and problem-focused strategies are used more in the adaptation phase (Foster et al., 2018).

CULTURAL PERSPECTIVES

Definitions

Some key definitions are important to an understanding of cultural perspectives.

- Ethnicity: a common ancestry through which individuals have evolved shared values and customs
- Culture: socially inherited characteristics, such as rituals, thoughts, beliefs, behavior patterns, and traits inherent within a certain racial, religious, or social group
- Acculturation: changing one's cultural patterns and assimilating behaviors consistent with those of the society in which one lives; this task can be done by learning the language, intermingling socially, or developing friendships, or through marriage or relationships formed in school or workplaces
- Religion: a belief in divine powers; a system of beliefs, practices, and rituals

The family has always been seen as the critical social unit for passing on beliefs and values in our society. Healthcare professionals must recognize and be sensitive to the influence of culture and ethnicity on a child's development and the family's response to illness or a chronic condition (Lipson & Dibble, 2005). The family's cultural ties provide support and a sense of stability during times of upheaval and stress.

The meaning of family varies with the ethnic or cultural background of the family (Lipson & Dibble, 2005). Differences exist across cultures and although there are similarities, it is important not to generalize across social groups. The examples provided here are just that, examples. It is important to work with each family as individuals who may or may not exhibit these characteristics. The concept of immediate family among Anglo-Americans often means the nuclear family of mother, father, and children, although this is changing as other definitions of family are becoming increasingly acceptable in our society. Lesbian, gay, and same-sex partners are now more common and they may be raising children who may need care in the NICU. Parents who are unmarried but living together are also becoming increasingly commonplace in our society.

For African American families, the definition of family often includes extended family members within the community. For Italians, family can often include a very strongly knit group of family and friends extending over three or four generations. The Chinese family can often be defined as all their ancestors and all their descendants. Mexican American families often include close-knit members that include supportive communities that are multigenerational. Differences in family hierarchy can both positively and negatively influence young parents (Al Maghaireh et al., 2016). Understanding and appreciating the uniqueness and differences in the meaning of family across cultures and ethnic groups can assist the healthcare professional in promoting the family's health and supporting the family in times of illness or debilitating conditions (Ardal, Sulman, & Fuller-Thomson, 2011). No judgments should be made and the parents of the child should be able to choose who they believe is their family and their support system, particularly in this time of stress.

Ethnic or cultural groups also differ in the meaning they give to illness and disability, and in when they seek healthcare (Lipson & Dibble, 2005). Although the nurse must recognize that each family and situation must be assessed individually, there are some general characteristics that may be helpful in understanding differences seen among ethnicities. For example, generally members of an Italian family rely on the family for help when ill and seek medical help only as a last resort. They use words and emotions to convey the meaning of an experience to others. The close-knit family is of vital importance, and the nurse must respect the family as a cohesive unit. In general, African Americans often have an underlying distrust of the healthcare system. To effectively work with African American families, the nurse must be supportive of the family or empower the family to solve their own problems, providing as much information as possible. Racism and oppression have left their marks on these families and healthcare providers must facilitate the family to be advocates for the ill child, to cope constructively with problems, and to deal with an unknown future if disabilities persist (Al Maghaireh et al., 2016). Members of some ethnic groups (e.g., Irish, African Americans, and Norwegians) consider illness to be the result of an individual's own sins, actions, or inadequacies. Native American Indians often consider illness or disability the result of misconduct, for which the family is punished (Lipson & Dibble, 2005). The illness is part of the whole person. Native American Hawaiians may view illness as an imbalance in the energy or harmony within the family. The illness is part of wellness and this disharmony is a normal part of life. Anglo-Americans may view illness as stemming from a scientific cause that is outside the family. The illness is foreign and intrusive to the individual and the family. Considering these traditional characteristics may be helpful in understanding the context of culture.

When a child is hospitalized, several important issues must be discussed with the family:

- What support the family wants
- Preferences regarding language, food, holidays, religion, and kinship
- Beliefs with regard to health, illness, and technological advances
- Health practices (e.g., immunizations, annual physical examinations)
- Habits, customs, and rituals which could affect health

An understanding of cultural differences can help the nurse provide care, determine the meaning of the illness or disability to the family, and assist the family in interventions appropriate to their culture (Brooks et al., 2012). This understanding also shapes parent and staff expectations of each other and of the ways in which care is provided. Taking the time to ask questions and understand the cultural influences on families cared for in the NICU can facilitate communication between families and healthcare providers (Ichijima, Kirk, & Hornblow, 2011). Language can often be a barrier to providing care and understanding the needs of families. Providing appropriately supportive interpreters to families in the NICU is extremely important to supporting families and helping them to understand the needs of their infant (Matsuda & McGrath, 2011).

PROMOTING PARENTING IN THE NICU

A major nursing goal in the NICU for care of the family is to optimize parenting skills and discharge an intact family unit (Boykova & Kenner, 2012; McGrath, 2012). There are different ways to ease parental anxiety during the NICU experience. Open visiting policies encouraging unrestricted parent presence throughout the

24-hour period provides parents more opportunities to be with their infant while allowing them to manage other responsibilities outside the NICU (Raiskila et al., 2017). Unrestricted access to the infant allows the attachment and parenting processes to be fostered (Baker & McGrath, 2011).

Facilitating the Attachment Process

The attachment process for most parents begins at birth, or perhaps before birth during the pregnancy process. With a sick or premature infant, this process can be delayed until the parents can establish eye contact with and begin touching and caring for their infant. Bonding and attachment are enhanced by supporting parents to touch and hold their infant as soon as the child's condition allows, especially SSC (D'Agata, Young, Cong, Grasso, & McGrath, 2016; Casio et al., 2018; Neu & Robinson, 2010). The preterm neonate's physical appearance, disorganized behavioral responses, and variable physiological response to touch can cause much anxiety in the parents as they attempt to interact with their infant. However, it is important that the bedside nurse, well versed in what the sick or premature infant will tolerate, explains those maturational limitations to the parents. It is vital that parents understand an infant's immaturity and inability to navigate often overwhelming sensory experiences; otherwise, parents may misinterpret the infant's behavioral cues or detach from their infant in an effort not to bother or overstimulate the infant. Interventions that focus on helping parents to understand and respond sensitively to infant cues have been found to facilitate both the infant and the family (Moradi, Arshdi-Bostanabad, Seyedrasooli, Tapak, & Valizadeh, 2018; Mortessen & Mastergeorge, 2014; Zelkowitz et al., 2011). It also is important for the nurse to work with the parents to help them recognize an infant's distress signals (e.g., hiccups, apnea, cyanosis, bradycardia, or mottling) so that parents can gauge their caregiving interactions by their infant's unique cues and behavior (Als & Gilkerson, 1997; Raines & Brustad, 2012; Zelkowitz et al., 2011).

Parent participation in caregiving must begin at admission (Raines & Brustad, 2012). Soothing touch, providing containment, gentle infant massage, holding the infant, bathing, and SSC, or "kangaroo care," are just a few of the "high-touch" avenues for promoting parenting in the NICU (Casio et al., 2018; Neu & Robinson, 2010). Each of these supportive strategies should be provided to all infants in the NICU and reserved for families to implement with their infant. When parents are providing these interventions, there are physiological and behavioral benefits for the infant as well as benefits to parents, including early bonding, increased confidence in parenting skills, and a sense of control (Nordheim, Anderzen-Carlsson, & Nakstad, 2018; Vance & Brandon, 2017). Parents who have the opportunity to participate in caregiving and get to know their infant begin to have a sense of confidence that their infant is well cared for and may survive (Amin et al., 2018; Pichler-Stachl et al., 2011; Reid, 2007). Nurses can use several key techniques to prepare parents for working with their infant and the technology in the NICU:

- Build on parents' strengths
- Provide encouragement and use constructive criticism only as necessary
- Encourage parents to discuss their concerns and emotions
- Provide parents with information specific to their infant's care or condition
- Clarify information that parents have received through other channels
- Draw the parents' attention to positive points about their infant, including how the child responds to the parents
- Keep the channels of communication open by remaining nonjudgmental

Interventions with families must acknowledge the individuality of each member and of the family as a unit. Understanding that the needs of the whole are not equal to, greater than, or less than those of the parts is often a difficult concept for the neonatal nurse, who sometimes sees his or her role as involved more specifically with the care of the high-risk infant. Researchers repeatedly have found that hospital-based neonatal nurses view caring for families as not within their realm of practice (and certainly not a priority in their practice), but as something extra they do "when there is time" (Meiers et al., 2007; Mosqueda et al., 2013). These views are not congruent with developmentally supportive FCC practices. Optimal care requires that healthcare providers adopt a family-centered philosophy (Cisneros Moore, Coker, DuBuisson, Swett, & Edwards 2003; Latour et al., 2010). Full implementation of a family-centered approach depends upon the support of the unit leadership and the institution (Milette et al., 2017a, 2017b). One way to facilitate greater involvement of families is to form parent advisory boards that guide implementation of practices in the NICU (IPFCC, 2018). Staffing plans that allow healthcare providers, especially nurses, time in their schedules to work collaboratively with families must be a priority if developmentally supportive family-centered practices are truly fundamental to the philosophy of care in the NICU (IPFCC, 2017).

Parents have repeatedly reported that they felt that healthcare professionals did not recognize them as the expert caregivers of their child and the constant in their child's life (DeMauro, Cairnie, D'Ilario, Kirpalani, & Schmidt, 2014; Zhang, Kurtz, Lee, & Lui, 2014). This perception may lead to mistrust in the developing partnership between the caregivers and the professionals and may intensify the stress for the parent and, ultimately, the child during the hospitalization (Aagaard, Lall, Ludvigsen, Uhrenfeldt, & Fegran, 2018). Acknowledging that parents are the experts and nurses are the consultants to whom parents come to for information or support is a shift that remains difficult for some professionals (IPFCC, 2017). Parents are empowered by nurses when they are respected, involved in the plan of care, provided with complete, unbiased information, and given a sense of control in the healthcare setting (IPFCC, 2017; Pichler-Stachl et al., 2011). To support full integration and implementation, see Table 35.3 for evidence-based strategies and interventions that empower and support families during newborn intensive care.

Caretaking is a normal part of parenting. However, parents of sick or premature infants are often deprived of the time to prepare psychologically for caring for a high-risk infant and to develop the caretaking skills to feel confident (Amin et al., 2018; Raines & Brustad, 2012). If nurses do not allow the family to become regularly involved in caretaking tasks, parents may feel inadequate or may resent the nurses. Positive reinforcement builds self-confidence in parenting abilities. Interventions that empower families are important to both short- and long-term outcomes for the infant and the family (Mortessen & Mastergeorge, 2014).

Providing Information

Throughout the infant's illness, parents need accurate, timely information about their child's condition (Box 35.5). If the information provided is not timely and does not anticipate the needs of the parents as related to their relationship with their infant, it may not be helpful and may actually hamper the care (Herd et al., 2014). Information should be direct and honest and should not be contradictory, so limiting the number of professionals providing information is often helpful. Parents also appreciate the use of drawings and diagrams when their infant's condition is explained to them, and they appreciate being encouraged by staff members to ask questions. Presenting this information with some optimism

Rating System for the Hierarchy of Evidence

Level I:	Evidence from a systematic review or meta-analysis of all relevant RCTs, or evidence-based clinical practice guidelines based on systematic reviews of RCTs
Level II:	Evidence obtained from at least one well-designed RCT
Level III:	Evidence obtained from well-designed controlled trials without randomization
Level IV:	Evidence from well-designed case-control and cohort studies
Level V:	Evidence from systematic reviews of descriptive and qualitative studies
Level VI:	Evidence from a single descriptive or qualitative study
Level VII:	Evidence from the opinion of authorities and/or reports of expert committees

RCT, randomized controlled trial.

Box 35.5

GUIDELINES FOR PROVIDING INFORMATION TO FAMILIES OF ILL INFANTS

Focus the teaching session so as to build confidence and foster independence in the family. Build from strengths of the parents; do not focus on weaknesses.

1. Begin by assessing what the family members already know.
2. Establish a working rapport with the family; work to ease their anxiety and fear and to convey confidence and assurance to family members.
3. Ask family members what they expect to learn from the session and provide information directed toward their concerns.
4. Initially, focus teaching on the diagnosis or current crisis.
5. Use language the family understands; avoid jargon.
6. Include the key characteristics of the plan of care and treatment.
7. Explain the ways in which the illness or medication regimen will affect daily life.
8. Use a variety of teaching materials and styles. All information should first be provided orally and reinforced with handouts to be taken home.
9. Keep the information simple and concrete; reinforce oral communication with handouts. Expect to repeat the information and do so readily.
10. Avoid fear tactics while providing information on both benefits and detrimental effects.
11. Use praise to instill confidence.
12. Include anticipatory guidance.

Box 35.6

PROVIDING DIFFICULT INFORMATION

Although difficult information is most often provided by physicians, nurses often are part of the team, especially if the information will be painful to the family. Nurses must know how to support families in these difficult situations. Unexpected news is sometimes considered bad news, yet our approach can change the perspective for the family receiving the news.

1. Whenever possible, difficult information should be delivered with both parents present and/or supportive family members as deemed by the family. Crafting the conversation as sharing "unexpected news" rather than bad news can shape what families hear and understand.
2. Remember the language you use will be how the family shares the news with others, so choose your words carefully. Provide unbiased information that is clear, direct, detailed, and understandable; get to the focus of the discussion quickly.
3. Provide the information with compassion and care in a gentle but confident style; a private, quiet place free of distractions should be used for the discussion.
4. Personalize the information to this baby or child and this family. Use the child's name whenever possible. Begin the conversation by sharing with the family what is going well and congratulating them on their child's successes or strengths.
5. Allow the family time to express feelings and ask questions. Provide support for those feelings and questions. Offer hope about the next phase of the child's journey.
6. Provide information about resources and anticipatory guidance. Speak with the family about what you expect will happen next.
7. Arrange an opportunity for the family to meet another family who has experienced a similar situation or crisis.
8. Follow up with the family after an appropriate time to answer any latent questions or provide further support.

Source: Adapted from Carroll, C., Carroll, C., Goloff, N., & Pitt, M. B. (2018). When bad news isn't necessarily bad: Recognizing provider bias when sharing unexpected news. *Pediatrics, 142*(1), e201–e204. doi:10.1542/peds.2018-0503

allows the family some hope and, as discussed earlier, hope is an important concept for coping with the NICU (Ingram et al., 2017; Nordheim, Rustøen, et al., 2018). Ideally, the information should be presented to both parents at the same time. It should be expressed in simple terms with short explanations. The parents are under much stress and this information may be unfamiliar (Brooks et al., 2012; Menghini, 2005). Facts may need to be repeated several times before they are absorbed. Parents need a clear understanding of the information provided to make informed decisions about their infant's care. Family-friendly language in understandable terms should be used when delivering care and information (Herd et al., 2014; Menghini, 2005). Medical information from a primary caregiver, such as a neonatal nurse practitioner or primary physician, provides consistency, especially when the news is difficult or "bad" (Box 35.6). Consistency in caregiving and information sharing is important so that families are not confused by the different information they receive, adding to their distress and sense of distrust of healthcare providers (Carroll, Carroll, Goloff, & Pitt, 2018; DeMauro et al., 2014; Epstein et al., 2013). Families also need information about when they can be at the bedside, unit policies, equipment, procedures, and treatments their infant is receiving. Direct telephone access allows an update from their nurse or physician at all times. In support of oral communication, written information helps parents remember important facts. In addition, written communication also provides a place to refer to later when the information is more relevant to the care of the infant or when there are more questions (Herd et al., 2014; Menghini, 2005). Information can also be reinforced with digital and online materials (Breitenstein, Gross, & Christophersen, 2014). Providing multiple avenues for information sharing provides better support to families who may not always be ready to take in information when shared but have other ways to obtain the information at a later point in time.

Family Presence During Rounds

In many NICUs the practice of inviting family members to participate in medical rounds is becoming common (Aronson et al., 2009). Families are part of the decision-making process and as such are provided information so that they can, in collaboration

with the medical/nursing team, decide when they would like to be present and make decisions for their child and when they feel they would rather not be involved (Gasparini et al., 2015; McGrath, 2011; Pichler-Stachl et al., 2011). Through their presence in rounds, families are involved in the assessment of and planning for their child (Raines & Brustad, 2012; Reid, 2007; Reis et al., 2010). Caregiving issues related to scheduling of rounds, teaching of medical staff, and confidentiality for families during rounds are still unresolved and remain a concern for care providers (IPFCC, 2013a, 2013b; Morey & Gregory, 2012). However, provision of HIPAA is not a viable excuse for not including families in patient rounds (IPFCC, 2010a, 2010b, 2013a, 2013b). For the most part, units where these practices are now common have found that the partnership between the family and the medical team is worth the effort required to implement such decision-making relationships (Butt, McGrath, & Samra, 2013; Grzyb, Coo, Ruland, & Dow, 2014). Providing for and facilitating the family's role as the constant in the infant's life is the best approach for the infant's long-term development. Critical pathways (see Supporting Families With Caregiving Protocols below) can also be used as an excellent means of providing education and anticipatory guidance to parents and families, especially when provision of information with skill-building must be completed over a long hospitalization or by several staff members (Butt et al., 2013).

Family Presence and Participation in Procedures

One of the fundamentals of FCC is the belief that the family is an active member of the caregiving team right from admission. Members of the caregiving team are *not visitors*. Parents are not asked to leave for rounds or procedures but are integral members of the caregiving team; they are invited to be as involved during procedures as they feel comfortable with; the degree of involvement would vary from parent to parent and family to family (Axelin et al., 2010; McGrath, 2011). Parents need to have enough information to feel welcome and supportive of their infant during procedures to be present (Palomaa, Korhonen, & Pölkki, 2016). Presence during resuscitation is one of the areas where more and more NICUs are providing families the support to be present and supportive to their child. However, this means someone from the healthcare team needs to be supportive of parents during the event (Gasparini et al., 2015). Staff members may resist including families in these interventions because of the degree of risk to the infant. Nurses must also take into consideration that even though parent participation might lead to short-term physiological losses for the infant, these losses might outweigh the long-term gains for the family and make a decision with the family that is in the best interest of the infant. Established protocols and education of both staff members and parents help with the transition to increased parental participation in the NICU (Mundy, 2010; Raiskila et al., 2017).

Supporting Families With Caregiving Protocols

Critical pathways and caregiving protocols have been developed to aid in the organization and evaluation of nursing assessments and interventions with children and families. These pathways help promote continuity of care and aid the nurse in prioritizing the needs of the child and family. They are outcome-oriented and provide an excellent means of documenting nurses' actions. They can be used to enhance interaction between parents and their preterm infant. The pathway serves as a means to educate parents about the changing needs of their developing preterm infant. Implementation of the pathway increases parents' knowledge and responsiveness to their infant's behavior and helps parents develop independent, cue-based caregiving skills with their infant (Tooten et al., 2012; Zelkowitz et al., 2011). Other pathways have been developed with five areas of emphasis: 1) environmental organization; 2) structure of caring; 3) feeding (all of which relate more to the infant); 4) family involvement; and 5) family education (which relate more to the needs of the family). Involving families in the development and testing of these protocols is important (Celenza, Zayack, Buus-Frank, & Horbar, 2017). Outcomes for infants include physiological stability, behavioral organization, and establishing predictable behavioral patterns; outcomes for the family include enhancing social support, increasing knowledge, and increasing involvement in the infant's care while preparing for discharge (Boykova & Kenner, 2012; McGrath, 2012). Critical pathways also are an excellent means of providing education and anticipatory guidance to parents and families, especially when teaching must be done over a long hospitalization or by several staff members.

Family Integrated Care

Recently the concept of delivering supportive care to the infant and family in the NICU has been reconceptualized as the Family Integrated Care (FICare) model in which parents provide all care for their infant, except the most advanced medical care, with support from the healthcare team (O'Brien et al., 2015). First introduced in Canada, the premise of this model is based in the fact that it is essential that parents are an integral part of the healthcare team. Parents who participate in this program are required to be in the NICU at least 6 hours a day, 5 days each week to provide care to their infant. Parent participation is facilitated by parent education programs that provide the content and facilitation for parents to be successful in providing complete care to their infants. Educational tools and self-directed learning approaches are utilized to increase parental confidence and decrease parental stress (Bracht et al., 2013; O'Brien et al., 2015). The educational programs encompass materials that empower parents to recognize infant cues and behaviors through engagement in their unique role in their infant's life. Ongoing dialogues among the team are encouraged to accommodate a variety of learning styles and remain flexible to adapt materials to meet the diverse needs of families (O'Brien et al., 2013). The use of veteran parents as support partners also facilitates parent participation in FICare (Galarza-Winton, Dicky, O'Leary, Lee, & O'Brien, 2013). Staff nurses who participated in FICare also report high levels of satisfaction although there was a learning curve in becoming a "coach" to parents delivering the care to their infants (Macdonnell et al., 2013). The outcomes of this research have been very positive with more studies now in progress in both Canada and the United States. One limitation of the research to date is the high refusal rate (>50%) related to the degree of parent presence required if parents choose to participate. In addition, there are no true measures of degree of parent engagement in the studies and there is yet little support for whether this dose (6 hours a day for 5 days each week) is the right dose to achieve the desired outcomes. While more research is needed to better understand how to best implement FICare, this model of care is definitely propelling caregiving that increases the family's true partnership in the care of their infant in the NICU.

Family Conferences

Family conferences can be used to evaluate the intervention strategies and how well they were able to meet the family's goals. Collaboration during conferences allows all present the opportunity to examine individual perspectives and goals while negotiating and reevaluating strategies to increase satisfaction with the

treatment plan (Brett et al., 2011; McCormick et al., 2008). The type of information communicated is also an important consideration. Healthcare professionals have often provided families with a lot of information about their infant in the here and now; what is sometimes missing is the "so what" of that information (Fox et al., 2005; McGrath, 2007a; Morey & Gregory, 2012; Reis et al., 2010). The result of this type of communication is that parents are not always provided with all the information they need to understand the whole situation for their child now and in the future so that appropriate participation in decision making can occur (McGrath & Hardy, 2008).

Facilitating Transfer to Another Facility

If the infant is transported from another facility or being transferred to another hospital, parents need time to be with their infant prior to the move and should go on the transport with the infant whenever possible (Fidler & McGrath, 2009; van Manen, 2012). These brief interactions before transport reduce anxieties about the status of the neonate and promote bonding and attachment behaviors (Aagaard et al., 2018; van Manen, 2012). Occasionally, the mother's condition is unstable and she or a family member cannot be present in the NICU. Instant pictures can be taken and given to the mother as soon as possible. Some NICUs are also using video conferencing to keep families better connected to their infant.

The number of nursing or medical personnel in nondescript surgical scrub outfits who interact with the parents can be overwhelming. Therefore, introductions by name and position are important to families, and personnel should wear name tags to help further identify each staff member. Many institutions have adopted a primary nursing style of care where the number of caregivers is limited to a small group of professionals to increase consistency of caregiving and information-sharing. Families often feel more secure knowing that one nurse or team of nurses direct their baby's nursing care throughout the hospitalization and this allows a trusting, collaborative relationship to be established (Box 35.7). A friendly approach facilitates open communication and demonstrates openness and approachability.

Using language that invites participation is also important (Box 35.8). The primary nurse can act as liaison between the family and the healthcare team. The liaison ensures that information about the infant's current condition, any changes in condition, and long-term outcomes for the infant are communicated to the family. The liaison role becomes essential if the infant is transported back to a community hospital or to another unit in the same facility (Aagaard et al., 2018; Fidler & McGrath, 2009; van Manen, 2012). Parents need to know what to expect in the new unit and to understand how this environment is now actually better suited to meet the changing needs of their infant. Otherwise, parental mistrust may develop (Aagaard et al., 2018).

Preparing for Discharge. As nurses prepare the infant for discharge from the NICU, it is important that the parents feel prepared to care for their infant (Bos et al., 2018; Boykova & Kenner, 2012). Building on the already established relationship, parents can be provided one last boost in confidence by allowing them to room-in with sick newborns before discharge (Peyrovi et al., 2015; Toral-López et al., 2016). Structured education has also been found to increase parent confidence and caring knowledge prior to discharge, which could make the transition from hospital to home easier for families (Bos et al., 2018; Lopez, Anderson, & Feutchinger, 2012; Moradi et al., 2018; Shieh et al., 2010). Parents feel secure knowing that nurses are close by if they are needed. This process also allows parents the assurance that they can care for their babies adequately.

Box 35.7

PRINCIPLES OF FAMILY–PROFESSIONAL COLLABORATION

Family–professional collaboration accomplishes the following:

- Promotes a relationship in which family members and professionals work together to ensure the best services for the child and family
- Recognizes and respects the knowledge, skills, and experience that families and professionals bring to the relationship
- Acknowledges that the development of trust is an integral part of a collaborative relationship
- Facilitates open communication so that families and professionals feel free to express themselves
- Creates an atmosphere in which the cultural traditions, values, and diversity of families are acknowledged and honored
- Recognizes that negotiation is essential in a collaborative relationship
- Brings to the relationship the mutual commitment of families, professionals, and communities to meet the requirements of children with special health needs and their families

Box 35.8

LANGUAGE THAT FACILITATES COLLABORATION

"Do you prefer us to call you by your first name or your last name?"

"Here's what I'm thinking, but I'm wondering how this will work for you."

"Tell me how I can help you."

"Our institution usually does it this way. Would that work for you?"

"These are the things I plan to provide for your child today. Would you like to provide some of these activities?"

"What goals do you have for your child's care?"

"How does your child look to you today?"

"Do you have any questions or suggestions about your child's care?"

"This sounds important; help me understand your concern."

"Who would you like to have included in discussions about your child's care?"

"Let's talk about how much you want to be consulted."

Source: Adapted from Fox et al. (2005).

Many times the neonatal intensive care hospitalization is the beginning of chronicity for the infant and the family (Bally et al., 2018). Parenting a chronically ill child is qualitatively different from parenting a normal child. Nurses must promote the parents' and family's role as caregivers for the child by determining the

family's mode of coping and supporting those strategies while promoting family adaptation to the chronic illness and parent learning of self-management skills (Hägi-Pedersen et al., 2017). A major goal of care for these families is to integrate the child back into the family unit rather than to make the child with a chronic illness a "special nucleus" that becomes the only priority or focus of family needs (Nightingale, Wirz, Cook, & Swallow, 2017).

FCC of an infant or child with any chronic illness is based on the premise that the family is the main source of support and caregiving for the child. Thus, FCC can be achieved through specific nursing strategies aimed at creating opportunities for families to use their own strengths and abilities to meet the infant's and family's needs (Ahlqvist-Björkroth, Boukydis, & Lehtonen, 2013; Bally et al., 2018). Ultimately, family-centered interventions empower families to develop and maintain healthy lifestyles, leading to overall improvement of the family's quality of life.

Providing Support for Parents and Families

Parent networking can be a vital tool for promoting parenting. Knowing that other families have survived this crisis can be reassuring. Support groups are generally helpful; however, they are not appropriate for every situation (Al Maghaireh et al., 2016). Some couples need counseling so they can feel more comfortable with decision making and participation in care. The primary nurse plays a key role in assessing signs that the family is not coping and needs therapeutic counseling. Support groups or counseling help families examine problems objectively and learn alternative behavior for adaptive coping (Ardal et al., 2011; Hall, Ryan, Beatty, & Grubb, 2015). The nurse also can assist parents in identifying additional means of support. Ideally, parents should be permitted to define their "family" as needed to provide support during this crisis, allowing family members to be present as unit policy dictates. Grandparents, extended family, neighbors, and friends may constitute this group (Stefana & Lavelli, 2017).

Grandparents are a source of support for many parents. However, grandparents may be forced into an uncomfortable role by seeing their own child in pain without a way to relieve that pain. Understanding intergenerational dynamics is important in providing the best support to families. Grandparents are also trying to cope with this new crisis and may relive their own birthing experiences, which could result in associated anxieties and prevent them from being available to provide support for the parents (Frisman, Eriksson, Pernehed, & Morelius, 2012). Extended family members may be more helpful if discord exists between grandparents and the nuclear family (Greisen et al., 2009). Friends of the family can be an asset if they are effective listeners. They can offer to provide transportation for the mother and child care for siblings or they can take over housekeeping chores to help alleviate family responsibilities. Just having someone to make telephone calls to other friends and family to update them on the infant's condition can be a great relief for the family.

Social workers involved early in the hospital stay provide parents with an objective person to discuss caregiving options and provide contact with community resources. Families are often reluctant to express dissatisfaction with their child's care to nurses. Social workers can help parents express concerns without fear of retaliation against their child. Clergy provide spiritual support for a family. Families often turn to religion for comfort and support at a time of crisis. It is important to offer these resources to parents and to provide the appropriate privacy to exercise their religious freedom. Recently it has been recommended that we reconceptualize the neonatal intensive care environment to be the neonatal intensive parenting unit (NIPU; Hynan et al., 2015; Hall et al., 2017). This reconceptualization places the parent with the infant at the center of caregiving. The evolution of caregiving such that care providers are for the support of parents and infants is one that needs increasing support as the family is the constant and the long-term care provider for the infant.

PARENT AND STAFF EXPECTATIONS

When parents have a sick infant in the NICU, they have expectations. They expect excellent medical and nursing care for their child (Latour et al., 2010). They expect accurate and timely information throughout their child's illness, and they expect to be involved in decision making about the infant's care (Hardy & McGrath, 2008). They expect that this relationship that is developing with the healthcare team will be a partnership and that the partnership will be honored in every interaction. The medical and nursing staff members, working as a team supportive of each other and the family, have the ability to instill confidence in parents through this partnership (Raines & Brustad, 2012). Parents develop advocacy skills through collaborative communications with the nursing and medical team (Hardy & McGrath, 2008; McGrath, 2011; McGrath & Hardy, 2008; Morey & Gregory, 2012). Conversely, members of the medical and nursing staffs have expectations of the infants and families within this partnership related to the care of the infant. Expectations for the family may include regular presence and participation in caregiving, respecting the routines of the NICU setting, and sharing information that may be helpful in the care of the infant (Meiers et al., 2007). Sometimes these expectations are unrealistic. For example, the staff may expect parents to be present and more active in caregiving more often, even though the parents live far from the hospital, have other children, must return to work, and have other responsibilities that may prevent more frequent presence and participation in caregiving (Craig et al., 2015). Parents may also feel there is no role for them in the NICU if a collaborative partnership has not been established and the environment is not welcoming (Klegerg, Hellstrom-Westas, & Widstrom, 2007; Reis et al., 2010). Staff expectations for the infant may include wanting the infant to nipple-feed more often or be weaned from oxygen faster. It can be distressing to parents to think that the medical staff is not pleased with their infant's progress, even though this attitude may not be verbalized. For this reason, incongruities should be avoided both in actions and in communications (Hardy & McGrath, 2008; Reid, 2007). It seems reasonable to assume that parents who are partners, well informed, and participating in the care are less likely to experience these concerns (Brett et al., 2011; Hopwood, Clerke, & Nguyen, 2017).

Staff members' attitudes are an important part of the development of positive parenting (Box 35.9). Staff behaviors and attitudes can inhibit or encourage parenting skills. Conflict about parenting roles can exist between parents and staff members and this conflict may escalate into a struggle for control. Parents may view staff members as acting as the infant's parents, or the infant as belonging to the staff because staff members provide most of the care (Epstein et al., 2013). The staff members' pet names for the neonate further reinforce parents' fears. Nursing staff can help the family by encouraging them to personalize the infant's care and then following their lead with naming and dressing. Bringing in clothes, toys, and pictures of other family members and making recordings of family voices are ways parents contribute to caretaking.

Nurses who care for families need to provide support and promote the family as a unit; however, overinvolvement of nurses can be detrimental to the family unit. Establishing appropriate relationships with families in our care can sometimes be difficult. It

KEY CONTENT OF FAMILY-CENTERED TRAINING PROGRAMS FOR HEALTH PROFESSIONALS

- Principles of family-centered care
- Cultural competence
- Child development
- Family systems
- Fostering communication with children and families
- Building of collaborative relationships with families
- Support for and strengthening of families in their caregiving roles
- Impact of hospitalization, illness, and injury on children and families, including the impact of healthcare costs on family resources
- Support for the developmental and psychosocial needs of children and families through hospital policies and programs
- Function and expertise of each discipline in the medical setting
- Multidisciplinary collaboration and team-building
- Ethical issues and decision making
- Community resources for children and families

Box 35.10

BEDSIDE CAREGIVER BEHAVIORS THAT MAY BECOME BARRIERS TO POSITIVE PARENTING

- Infant "belongs" to the nurse and the NICU rather than to the family; nurse refers to assignments or primaries as "my babies."
- Family is not considered a member of the caregiving team; for example, they are asked to leave for rounds and shift reports.
- Family is not asked about the characteristics of their infant or included in discussions related to the infant. Families are not seen as the experts on their infant. They are talked about rather than talked with.
- Care is task-oriented and staffing is acuity-based rather than based on meeting the needs of families. Families are not invited to participate in the child's care.
- Infant's schedule belongs to the nurse and the NICU rather than to the family, so that feeding and caregiving might occur when the family is unavailable to participate. Scheduling is inflexible.
- Family is seen as an adjunct to infant care. They are not the client or patient. Spending time with families is not considered a priority but rather a luxury. Spending time with families is not seen as essential to providing care for the infant.

is necessary to identify inappropriate nursing behaviors and correct them. Educating the nursing staff about the parenting process facilitates identification of inappropriate nursing behaviors (Box 35.10). The education can be initiated during orientation of new staff members and reinforced at intervals with continuing education workshops on the subject. Nurses must provide support while always acknowledging the boundaries of the family. Some families build walls and are so private about family matters that it is difficult to obtain enough information to meet family needs, whereas other families become overly dependent on the nursing staff, needing their support at every moment. Interventions that promote independent family decision making include the following (IPFCC, 2017):

- Respecting the family as a unique unit
- Providing unbiased care to all families
- Providing as much continuity in the care provider as possible to promote family strengths
- Allowing the family to determine the implementation of the plan of care

With adequate staffing, nurses can better promote parenting in the NICU. Overworked nurses can become frustrated and stressed, overwhelmed by their own anxieties. These feelings may impede their ability to interact calmly and therapeutically with a fragile family unit. Nursing management considerations should include provision for adequate staffing to allow nurses the time and emotional energy to meet the needs of parents in crisis. Patient assignments should be evaluated not only for the technical care an infant requires but also for the psychosocial demands of the family. Institutional policies should be carefully evaluated as to how they meet the needs of families. Rationing or missed care must be regularly evaluated and considered such that optimal care is delivered to all infants and families (Tubbs-Cooley et al., 2017). FCC activities are more likely to be among those caregiving tasks that are missed, such as family teaching, breastfeeding education, discharge planning, holding, and SSC.

SIBLINGS

Siblings have needs because they are an important part of the new infant's life. Sibling visits may help relieve anxieties and make the birth a reality. Siblings have a variety of responses to a newborn's arrival in the home, especially after a lengthy hospitalization. Family routines are disrupted by a "normal" birth and are further disturbed by an admission to the NICU and then again at the time of discharge (Peyrovi et al., 2015). Siblings may feel displaced while parents are at the NICU participating in the caregiving of the ill infant. Siblings are often left with babysitters when they have rarely had experience with caretakers outside the immediate family. Fathers who may be uncertain about their family role may embrace their familiar work role and spend more time on the job. In these ways, routines are disrupted and parents are less available for their other children. These feelings may result in a variety of acting-out experiences.

The birth of a new baby precipitates a family upheaval and the need for a realignment of relationships and positions within the family constellation. Becoming a sibling is known to be a stressful or "crisis" experience for young children and can have an effect on their mental, emotional, and social development. The birth of a preterm or critically ill neonate who requires intensive care constitutes a further crisis for parents and consequently disrupts the equilibrium of the family system (Morrison & Gullon-Rivera, 2017; Stefana & Lavelli, 2017). Parents are reported to experience

feelings of anxiety, grief, fear, anger, and guilt in response to the unanticipated events. Siblings are also affected and may experience helplessness, powerlessness, guilt, and anger in addition to the disruption of their daily routines and separation from their parents. The siblings may feel very alone because their worried parents are preoccupied with the newborn baby. Siblings feel like the forgotten family member at the very time they need attention most (Morrison & Gullon-Rivera, 2017).

Addressing the needs of the families of hospitalized patients has gained acceptance and support among nurses since the advent of the concept of FCC (IPFCC, 2013b, 2017). All members of the family, parents and siblings, may exhaust their coping strategies and feel unsupported by those who are usually available emotionally and physically. The philosophy of FCC in the NICU is reported to encourage not only parent participation but also involvement of the well sibling or siblings in the family process. This involvement allows children to see their new sibling and to feel as if they are a part of the family process. Feelings of isolation may engender fantasies about what is taking place in the NICU. At any age, it is easier to cope with reality than with what can be imagined. Increasing numbers of hospitals are encouraging the participation of children at a sibling's birth, sibling contact with the infant at birth, sibling contact with the infant on the postpartum unit, and sibling visits in intensive care nurseries.

For nurses facing these challenges, the philosophy of FCC can provide a firm foundation in striving toward excellence in the practice of caring for children and families (Agency for Healthcare Research and Quality, 2013; IPFCC, 2018; Provenzi et al., 2015; Stefana & Lavelli, 2017). The development of a sibling–infant bond is vital to establishing and enhancing the relationship within the family unit. Holistic care surrounding childbirth may set up patterns or pathways that dramatically affect subsequent family interactions.

Some families feel they cannot be part of the care team. They either do not desire to provide care or cannot do so. Sometimes there is a tendency to label them as noncompliant with what the healthcare professional believes the family should do or how they should act. Before a label is used, it is important to find out from the parents why they do not want to participate. Is it because they fear they will hurt the infant? Is it because they want to just be parents and not be responsible for the care? Is it a lack of understanding of what is being asked of them? Based on their response, an individualized plan of care can be developed. For example, for the parent that is fearful about providing care, the healthcare team can provide education, psychological support, and be present to support caregiving activities. The key to success is to talk to the family, listen to their concerns/perspectives, and then tailor a plan to increase their participation as a care team member.

Sibling Visitation to the NICU

Sibling visitation in the hospital after the delivery of a newborn has become common practice. However, limited recent research exists that examines the consequences of permitting and prohibiting sibling visits in the NICU, despite the argument that sibling involvement is consistent with the concept of family-centered perinatal care. Early studies of NICU sibling visitation programs provided valuable descriptive data on siblings' responses to the sick neonate (Griffin, 2013). NICU visits provided an opportunity for the older brother or sister to see, touch, and talk to the newborn. This exposure was reported to help the children integrate the reality of the experience, to prepare for the possible loss of the newborn, and in some cases to reverse regressive behavior that had begun during the newborn's hospitalization. However, the findings of these studies reflected the perceptions of providers and not necessarily those of the parents or siblings (Gooding et al., 2011). More research is needed in this area. Some NICUs restrict sibling visitation during respiratory syncytial virus (RSV) season, whereas some do not have a strict policy for how visiting might still occur during this time of the year. The same is true for varicella exposures and how to safeguard infants (Kellie, Makvandi, & Muller, 2011). Again, more research is needed in this area.

Implications for Practice

Nurses have a unique opportunity to support the development of positive sibling relationships in the NICU environment. Evolving models of comprehensive care no longer overlook or delegate the care and needs of the whole family. Research on the families of NICU neonates has demonstrated parents' desire for a family-centered approach to care (Miyagishima et al., 2017). Siblings are an integral part of any family and their adjustment or lack of adjustment to the birth of a newborn greatly affects the well-being of the whole family. Siblings' adjustment to the once-sick infant needs further exploration.

When the birth of a sibling is further complicated by the baby's being ill or at risk, professionals caring for the baby are in a position to reassure parents that siblings will respond to the neonate in various ways based on each child's personality, age, and interests. Professional reassurance can help parents realize that siblings cannot help feeling angry and displaced by the baby. The parents' ability to accept their older children's competitive feelings and yet continue to love them helps those children to integrate ambivalence. Support through this ambivalence facilitates acceptance of the infant and the infant's incorporation into the family. Increasing parents' knowledge about promoting positive sibling relationships through parent education programs may influence parental attitudes, thereby enhancing future sibling relationships. In response to consumer demand, many hospitals have implemented sibling visitation and educational programs. This preparation can help siblings deal with the realities of the experience. Special attention from the NICU staff can also help siblings feel recognized, supported, and appreciated during this time of stress. Encouraging the sibling to gently touch and talk to the infant and allowing gifts of toys or even a drawing of themselves to be kept with the baby are activities that may foster attachment and growing connection with the newborn.

The death of a sibling usually has profound and lasting effects on surviving children. Surviving siblings, however young, may need some evidence that the baby existed—a visit to see the ill newborn in the incubator, a photograph, or a chance to participate in the funeral. Regardless of the child's age, it seems that the level of care offered to these siblings is crucial to determining the psychological and life adjustment of the bereaved child. Nurses need to be alert to the range and depth of childhood reactions. Many research findings discussed here can serve as invaluable guides to help NICU nurses promote and facilitate effective sibling interactions and positive involvement between the sick neonate and the siblings. An appropriate environment in which nurses can assist children in coping with the profound changes that affect the sibling bond should also be provided, because such efforts help siblings fully integrate this major event into their young lives.

Environmental Effects

A quiet, comforting atmosphere with low lighting helps calm both infants and their families. External stimuli in the NICU must be controlled; unnecessary stimuli aggravate these infants' already overwhelmed immature nervous systems and loud monitor alarms and excessive staff noise can be upsetting and unnerving to parents (D'Agata & McGrath, 2016). In general, the equipment is

overwhelming to families and makes them feel like outsiders. Their discomfort inhibits interactions with the infant and delays their participation in caregiving. Researchers suggest changes in the technology of the NICU, such as use of different kinds of alarm signals with diminished volume; wireless, handheld information terminals; and remote monitoring. Some of this technology is already appearing in the NICU. The technology used in the NICU must be continually reevaluated and designed with a parent- and consumer-based perspective (D'Agata & McGrath, 2016). Achieving a balance between the high-technology environment and the need that parents have to touch their infant frequently helps foster parental self-confidence. This balance must be a priority for the neonatal nurse.

Recommendations for single rooms in the NICU and other acute care areas throughout the hospital setting are now included in the 2006 Guidelines for the Design and Construction of Hospital and Healthcare Facilities (Ninomura, Rousseau, & Bartley, 2006). These guidelines are based on several significant research studies where single rooms throughout the healthcare setting were found to offer higher occupancy rates, reduced transfer costs, and lower labor costs, even when the cost of new construction was calculated into the equation (McGrath, Samra, & Kenner, 2011; White, Smith, & Sheply, 2013).

In addition, hospital-acquired infection and medication errors were reduced in these settings. Most patients and families also report better communication with healthcare professionals in single rooms because the provider often spends more time, answers questions more thoroughly, and is more compassionate and caring. Patient length of stay has been documented as shorter in private single rooms, which also adds to the decrease in costs (Please see the 2006, Updated Guidelines for the Design and Construction of Hospital and Healthcare Facilities). This movement to single rooms in the hospital setting is also important for compliance with the patient and family privacy requirements under the Health Insurance Portability and Accountability Act of 2003, which includes speech privacy rulings.

So how do these guidelines affect the NICU? There is little research directly related to the effects of neonatal single-room design. Most units across the United States have always been equipped with a few isolation rooms that have been used for infants with highly infectious diseases and, more recently, to isolate extremely low birth weight preterm infants who appear to be most overstimulated by the big open room environment of the NICU. With new construction, and a greater emphasis on individualized family-centered developmentally supportive care, more units have added more of these single rooms and some units have chosen to move to an entirely single-room design (Baker & McGrath, 2010).

Research to support a less stressful NICU environment with lower lights and less noise and activity has demonstrated shorter lengths of stay, decreased iatrogenic effects, and increased deep sleep and alerting behaviors in the infant, which may provide greater opportunities for more normal cognitive development. Moreover, in changing the environment to meet the needs of infants and families, the less stressful environment is oftentimes more positive for caregivers and should have a positive impact on patient outcomes and a decrease in medication errors (Domanico et al., 2010; Pineda et al., 2012). The challenge in providing care in these designs is finding a balance between the needs of infants, families, and caregivers in the NICU. This may be best achieved in a single-room design, where areas in the unit can be designed to meet the needs of those who use them most, yet allow others to adjust their individualized areas or rooms to meet their needs (Baker & McGrath, 2010). Evidence-based design standards for the NICU do exist and should be considered with any remodeling or new construction project (Jones, Peters, Rowe, & Sheeran, 2016; White et al., 2013). These guidelines should be used as a standard, especially when data are needed to support the need to invest upfront in more space, better traffic patterns, multiple kinds of lighting, and noise reduction materials. Paying attention to design is especially important for vulnerable infants who are at risk of developing disabilities. Research data also exist and should be used to support the need to choose colors and textures that increase health and well-being for all who interface in healthcare settings. For staff to transition to and work with ease in single-room designs, they must have access to and become comfortable with central monitoring and communication systems that provide them knowledge about patient status even from remote locations. Work areas for nurses must also be near the private rooms and allow for interaction and teamwork among staff. More research is needed in this area and should be a focus for the future.

SUMMARY

The birth of any infant produces tremendous change in the lives of each member of the family. Normal adaptation can be complicated by the birth of a premature, critically ill infant, or one with congenital anomalies requiring admission to the NICU. If the family does not have adequate coping strategies or resources, this crisis has the potential to produce much role stress and strain which ultimately can weaken or destroy the family unit. The nurse plays an integral role in supporting and guiding the family to appropriate resources and services. By promoting adaptive roles, the nurse can ensure an intact family unit after the crisis of intensive care.

EVIDENCE-BASED PRACTICE BOX

John Jones was born at 33 weeks' gestation. The nurses described him as a typical preemie with respiratory distress syndrome and intermittent apnea and bradycardia. He required continuous positive airway pressure (CPAP) for several days and then hood oxygen for a week. After being weaned to room air, he was moved to the transitional nursery, where he stayed for another week until he mastered sucking, swallowing, and breathing. John's mother was present often and participated in caregiving. Mrs. Jones kept John supplied with breast milk and the latest drawings from his two sisters, Suzie, age 6, and Becky, age 4. John's father was present in the NICU irregularly. He tried to make the time to be present on his way home from work but did not take an active role in caretaking. He said that he was afraid to hold John but that he would as soon as John got bigger and stronger. John was a cuddly little guy who had an uneventful recovery and was discharged after 3 weeks in the NICU.

Several days before discharge, John's mother confided in his primary nurse that she was at the end of her rope because her husband was working longer hours and her daughters were acting up in ways they never had before. Becky had demonstrated regression behaviors of bed-wetting and thumb-sucking. She had also started carrying around her "blankie" again, something she had stopped doing long ago. Becky was particularly

(*continued*)

EVIDENCE-BASED PRACTICE BOX (*continued*)

close to her mother, and after her mother's daily trips to the NICU, Becky would hit her mother, crying, "I hate you! I wish the baby would go away!" Mrs. Jones said that when she tried to console Becky, the child ran and hid under her bed, crying, "Leave me alone! You only love that baby!" If that weren't bad enough, Suzie had begun waking up with stomach aches and refusing to go to school. Suzie had always loved her teacher and classmates and now was frequently in trouble for misbehaving in class. When Mrs. Jones would make Suzie go to school, the little girl would cry and say, "I hate that baby! I'd like to run over him with Daddy's car!" Mr. Jones had withdrawn from family life and was spending long hours at work. Mrs. Jones was beside herself.

The nurse was able to reassure Mrs. Jones that the behaviors of her husband and daughters were typical. Although this reassurance didn't immediately alter the situation, at least Mrs. Jones knew that many families respond to NICU hospitalization in this way and that, given time, the family would reestablish equilibrium. Mrs. Jones was encouraged to take the weekend off from her NICU caregiving routine. She was able to spend a couple of special days with her daughters and engage her husband in life outside the worries of the NICU.

However, this did not provide Mrs. Jones with emotional support or help with her feelings of being overwhelmed and depressed. The nurse was able to listen to her concerns and then put her in touch with a parent organization that had been formed to help support families through the transition home. The parent organization offered peer support from parents who had been through the experience. They were also able to help Mrs. Jones place the experience in its proper perspective.

The girls had enjoyed their weekend with their mother and were in a better frame of mind for the homecoming. Peer support helped Mrs. Jones so that she could in turn be available to her family. John was about ready for discharge and had progressed normally. Once John was home, Mrs. Jones included the girls in the baby's routine as much as possible by asking them to get his diapers and having them feed their dollies while she fed John. Suzie brought pictures of John to school for show and tell, and after Mrs. Jones called to speak to the teacher to explain the disruptions at home, Suzie gradually quit misbehaving. Becky continued to have problems with thumb-sucking and bed-wetting for several months while incorporating John into the family and establishing a new family routine.

PARENT VOICES

Ali Dunn

Allowing someone you have just met to care for your tiny, sick baby is one of the hardest things a parent can do. Having to rely on the nurses to tell me how my babies were doing, to show me how to care for them, and to give me permission to hold them was heartbreaking, as I had waited so long to be a mother. But over the days and months that my babies stayed in the NICU, the good nurses helped me realize that the nights spent apart or the feeds you missed did not diminish your mothering heart. The good nurses empowered me to change tiny diapers without assistance, so for brief moments I could feel like a normal parent. The good nurses waited for me to do the next feed, even if it meant putting themselves behind schedule, so I could momentarily forget about the wires and tubes, the monitors and machines, and just enjoy a nurturing moment with my child. The good nurses know that even though parents don't always say it, we are forever grateful to them for loving our children when we were not there, and for caring for our babies when we could not.

Jennifer M. Driscoll

Both of my children were both prematurely, Lilian Hope in 2007 and Aidan Patrick in 2013. Lily spent just under a month in the NICU, and Aidan only a few days. Being discharged from the hospital with Lily was probably one of the most nerve-racking days of my life. Fortunately, when Aidan came home, I had that "mom" confidence, and having been in the NICU before, I knew what to expect.

I personally need a lot of information and dialog when it comes to caring for my children. I learned that I need to visualize what this new "normal" would look like and have a clear understanding before taking on this big change. I remember asking tons of questions, taking advantage of infant CPR classes, apnea monitor classes, reading all the literature from the hospital, and even staying over in the hospital NICU with Lily the night before she was discharged for practice. I'm a rule-follower by nature, so when coming home with Lily, I tried to instill the rules and guidelines that the NICU staff suggested. These were things like limiting the number of visitors, having hand sanitizer at every sink, no touching the baby until they washed their hands and used hand sanitizer, not taking the baby out in public if you

(*continued*)

(*continued*)

can avoid it, and more. And I listened, which was great and tough. I felt lonely and nervous because I was a new mom caring for this 3 lb, 11 oz baby that had just entered our lives so abruptly.

Home became a learning experience. Where do I buy preemie clothing, diapers, and this special formula? I don't think I was ever even in a Babies R Us but to register for my shower, Amazon Prime wasn't even a thing in 2007. We went day by day, spending time doting on her, learning about her, and trying to comfort and nurture her as best we could. Home brought new challenges like severe reflux, visiting nurses waking her up from nap times, severe lack of sleep, a husband that worked a swing shift and caring for this little infant alone, a dog that barked every time she cried, and much more. We learned to roll with the punches, stay flexible, but yet always be in tune with what the baby was "telling" us.

Katie Reginato Cascamo, MA

Neonatal staff who truly transform families begin with their own wellness first. The metaphor of putting on one's own breathing mask before caring for others is more critical than ever before in healthcare. As healthcare providers become more whole and fill their own emotional bucket, they effortlessly pour that out to families in crisis. As clinicians grow as healthcare leaders, they build the container skills for families who will need to take a leadership role in their family. Even the most difficult families respond well to healthcare providers who have invested in their wellness and leadership development. As you engage in your work holistically, you are equipping parents to take the initiative to transform their lives. So, take that hike. Do yoga. Develop a spiritual practice. Participate in wellness programs. Create meaningful connections with your coworkers. Care first for yourself so we can depend on you to care for us.

Our NICU was organizationally healthy and committed to transforming our lives. Our NICU served a large geographic area of nine counties and we lived 100 miles away over a snowy pass in the middle of winter. We did not trust our local, rural hospital primarily due to the lack of interpersonal development of the staff. The day after our NICU discharge and our return home, our son desaturated to 82% O_2 that I believed had to do with a 3,000-foot elevation change. I took him to our local dysfunctional emergency room simply because I had no other choice and we spent three more days in the hospital that redefined my mission to transform dysfunctional healthcare. The local healthcare staff refused to believe that the elevation change played any role in his desaturation and drastically changed how we perceived the community we called home. One year later we moved to a healthy, thriving community with world-class healthcare solely based on our experience in a healthy, engaged healthcare system and its counterpart, a toxic, dysfunctional healthcare system. Through our relocation to a community with high-quality healthcare came a world-class education system, commitment to the integration of children with special needs into society, and my ability to retrain for a job in healthcare practice administration.

All parents that come into the NICU have a story. Be willing to listen to our story and discover our strengths. Most of us have professional experience and are equipped to care for our babies. We are often fearful of touching our babies and experiencing trauma and it is the very act of learning how to care for our babies that heals us. The best amenities for families are parent-led resources. The world's best, most empathetic resources are those resources written for parents, by parents who have experienced a NICU stay. Our resources are very high quality, have the oversight of neonatal professionals, and are trusted by healthcare systems.

Integrating families into the care processes of the NICU is a win-win for everyone involved. For nursing staff, investing in our skill development is one more item to check off the healthcare checklist. As we learn to do nonessential tasks such as diapering, feeding, and dressing, we help you manage your workload better. We want to care for our baby and need guided instruction so we can take over nonessential tasks. Most importantly, when we leave the NICU, the skills you are teaching us are skills we will need when we return home. As we learn these skills, we become leaders in our families and we make sure that we engage in ongoing developmental therapies for our children through early intervention. As we broadly became the primary caretakers from birth throughout childhood, we are ensuring successful developmental outcomes of our preemies.

CHAPTER 36

Palliative and End-of-Life Care

Carole Kenner and Donna J. Ryan

INTRODUCTION

In the neonatal intensive care unit (NICU), the assurance that "everything possible is being done" often is interpreted as meaning that the patient is receiving state-of-the-art technologic care. Yet the healthcare system fails both infants and their families when death occurs. The failure lies not in the infant's death itself, but rather in the neglect to emphasize state-of-the-art palliative care. Until it is evident that all dying infants receive highly skilled palliative care, as well as advanced technologic care, modern medicine cannot say that the best possible care has been provided to these infants and their families. This chapter focuses on the care of infants and their families who are facing life-threatening illnesses or are dying and the urgent need for exemplary neonatal and pediatric hospice and palliative care programs.

ETHICAL OBLIGATION TO PROVIDE OPTIMUM END-OF-LIFE CARE

It can be argued that all members of the healthcare team have an ethical obligation to plan and implement end-of-life (EOL) care; to provide highly skilled care at all times except at the EOL is to ignore the essence of comprehensive healthcare. The ethical dimensions of neonatal EOL care include an obligation to provide compassionate care; autonomy; beneficent and nonmaleficent care, especially in regard to infant pain; respecting family values, and in the provision of treatment options; justice in ensuring equitable access to care and resources; dignity in being treated with respect and honor; and truthfulness and honesty in providing information in a gentle, sensitive, and compassionate manner (Thaxton, Carter, & Dang Hornic, 2016).

Compassionate Care at the EOL

More than two decades ago, Pellegrino and Thomasma (1993) argued that healthcare professionals have a special responsibility to provide compassionate care at the EOL. They identified compassion and temperance as among the essential virtues of medical practice and cautioned against overuse of high-technology equipment in place of human engagement with patients. They noted that particularly at the EOL, healthcare professionals can become so focused on technologic processes that they use them as "substitutes for human and compassionate care."

Palliative Care Globally and Nationally

Palliative care is a global issue especially in the pediatric population. The World Health Organization (WHO) estimates that there are 1.2 million children in the world who are in need of palliative care (WHO, 2014). Variations in how children with life-threatening illnesses are treated are sometimes linked to cultural values and beliefs around the concept of death. Other barriers to access to such care are related to health policies (Fowler-Kerry, 2012). Fowler-Kerry outlines a paradigm for pediatric palliative care emerging on a global stage. A study of childhood deaths in Canadian hospitals found that the acuity of care was high before death and that most of the decisions about EOL issues were made very close to the actual time of death (McCallum, Byrne, & Bruera, 2000). In that study, most of the children were intubated at death (73%), and most died in the intensive care unit (ICU; 83%). Even today, infants in the NICU frequently die while still intubated and connected to various pieces of equipment.

In the United States, most pediatric deaths also occur in hospital ICUs (Kerr, 2001), and there is evidence that children often suffer needlessly before death (Stephenson, 2000; Wolfe et al., 2000). Most of these deaths take place in hospitals. According to the Centers for Disease Control and Prevention (CDC), the infant mortality rate in the United States in 2015 was 5.9 deaths per 1,000 births (CDC, 2018). These figures have implications for neonatal care.

Since the late 1990s when this study was done, some progress has been made in the creation of policies and procedures (Carter et al., 2004). Books are available on the subject to guide the practitioner in working with children and their families during this very difficult period of their life (Carter, Levetown, & Friebert, 2011). Catlin and Carter (2002) developed a palliative care protocol that has assisted many perinatal and neonatal centers in the development of policies to assist with EOL and palliative care issues. Rogers, Babgi, and Gomez (2008) developed an education program to address issues of moral distress in NICU nurses and in 2010, the National Association of Neonatal Nurses (NANN, 2010) published a position statement "NICU Nurse Involvement in Ethical Decisions (Treatment of Critically Ill Newborns)." Additionally, NANN (2015) in their 2015 position statement "Palliative and End-of-Life Care for Newborns and Infants," Kenner, Press, and Ryan (2015), and the American Academy of Pediatrics (AAP, 2013) have recommended practices for neonatal palliative care. Despite all of these resources to health professionals, many

providers remain uncomfortable discussing palliative care with families because their focus has always been on saving lives (Kenner et al., 2015).

New approaches must be taken to establish compassionate EOL care for all infants in the NICU. This challenge is intensified in a system in which healthcare professionals are oriented toward active intervention with technologic devices rather than toward an acceptance of death (Jecker & Pagon, 1995; Kenner & Boykova, 2010). "Palliative care is still an option often offered too late and rarely delivered in an integrated approach" (Kenner et al., 2015, p. S10). Often, many disciplines offer advice, unaware of what has already been conveyed to parents (Kenner et al., 2015). Cortezzo, Saunders, Brownell, and Moss (2013) found that palliative care education was deemed important and needed among healthcare providers and discovered that barriers included emotional difficulties, staff disagreements, and difficulty forming palliative care teams. Cortezzo et al. (2013) further reported that palliative care teams or staff bereavement groups were willing to initiate palliative care and had more positive views or experiences. However, they recommended that further exploration of differing views of palliative care among interdisciplinary team members is needed. Tan, Docherty, Barfield, and Brandon (2012) found that "anticipatory support initiated prior to the death of an infant can help parents experience a smoother transition from caring for their ill baby to coping with the actual death and aftermath" (p. 579). A study that implemented a quality of life program to evaluate moral distress in healthcare providers found that after implementation of the Pediatric Quality of Life Program, nurses and other providers encountered morally distressing situations less often (Brandon, Ryan, Sloan, & Docherty, 2014). The researchers further discovered that providers felt they had greater comfort with, and competence in, providing care focused on patients' quality of life after completing the program. Brandon et al. (2014) recommended that as "palliative care programs include many activities that reduce moral distress, nurses should actively participate in debriefing sessions and staff education to maximize their work quality of life" (p. 189). Healthcare providers should also take into consideration the bereaved families that may lack support during a sudden and unexpected perinatal loss (Gold, Tredwell, Mieras, & Laventhal, 2017), and any lack of agreement that might exist among health professionals and parents regarding palliative care.

Regardless of the setting, the goal should be to provide family-centered perinatal and neonatal palliative care and support to bereaved families experiencing anticipated or unanticipated life-limiting conditions or death of their infant (Kenner et al., 2015). Wolfe (2000) identified the "principle of family" in pediatric EOL care: that is, an obligation to treat the whole family. Wolfe (2000) saw the healthcare staff as having an ethical obligation to "pursue comfort aggressively" and to fully engage the parents in the decision-making process for their child.

The interprofessional team needs to be informed of the parents' choices, so care can be coordinated and the family's wishes are carried out (Kenner et al., 2015). Perinatal loss needs to be acknowledged as a unique type of bereavement that will require bereavement care. "Advances in genetics and technology enable many families to know well in advance that their fetus has a potentially life-limiting condition" (Kenner et al., 2015, p. S20). In either anticipated or unanticipated losses, efforts should be made to include families as part of the decision-making process.

Cultural Influences

For culturally competent care to reflect the complexity of care to support the infant and family, the nurse must be sensitive to cultural, ethnic, and religious values and must adapt and individualize care (Thaxton et al., 2016). Families need to be provided options of memory making, and asked if there is a ritual that is important to their cultural or belief system (Kenner et al., 2015). Footprints, handprints, a lock of hair, a receiving blanket, photos, and special keepsake boxes are examples of mementos related to the baby's hospital stay and provide parents with options for remembering their baby, although these may not be acceptable in some cultures (Kenner et al., 2015). Photographs provide visual proof of the reality of their baby's life and can be valuable in the mourning process (Kenner et al., 2015). "Dressing the baby is important, so the family has a photo or mental picture of their baby and not one that is naked connected to tubes and wires" (Kenner et al., 2015, p. S21). Parents should also be offered peer-to-peer support or referred to a regional or national parent support organization if there are no functioning peer support programs (Kenner et al., 2015).

Palliative care can be delivered within the NICU or special care unit, an ambulatory care center in the community or the home. Despite the reality that very few pediatric hospice groups exist and fewer for the neonate and family, Catlin found that many infants stay 6 months or longer in the hospital with 20% of the NICU infants transferred to the pediatric intensive care unit (PICU) to die even when care is futile (as cited in Thaxton et al., 2016).

Some settings are developing a connection with perinatal hospices when a problem is detected prior to delivery that may result in a stillborn or "born dying" infant. One example of this is "Alexander's House" in Kansas City, Missouri (Pearce, 2006). Children's Hospital Medical Center, Cincinnati, Ohio, developed a perinatal hospice program called "Star Shine Hospice," another example of a hospice specifically focused on children (for more information, see www.cincinnatichildrens.org/service/s/starshine/default). Many families decide to take their baby home to die. Assessment of the family's ability to cope, what support systems will be in place, and whether palliative care or hospice care for families and neonates is available in their community is recommended before being discharged from the hospital (Kenner et al., 2015). Additional stress will occur if technology is used at home to care for a medically fragile and technology-dependent infant (Carnevale, Alexander, Davis, Rennick, & Troini, 2006).

Obligation to Provide Beneficent Care

The widely accepted ethical principle of beneficence requires that healthcare professionals actively provide care that directly benefits their patients. As defined by Beauchamp and Childress (2001), the principle of beneficence encompasses both positive beneficence and actively providing benefit and utility, which requires a balancing of benefits and adverse effects. Professional codes of ethics require that nurses and physicians act in a manner that benefits those entrusted to their care. Healthcare professionals therefore are obligated to examine their actions with regard to intended beneficial outcomes while simultaneously considering the drawbacks or adverse consequences of their actions.

Obligation of Nonmaleficence

Healthcare professionals also have a legal and moral obligation to avoid inflicting harm on their patients (Beauchamp & Childress, 2001). Adherence to this ethical principle, known as nonmaleficence, may encompass the provision of life-sustaining treatment, as well as the cessation of such treatment. For example, when a treatment ceases to provide the intended benefit for a patient, it may be considered futile, and the healthcare professional therefore

is no longer obligated to continue that treatment (Beauchamp & Childress, 2001). It also refers to the adequate management of pain and not inflicting undue harm from inadequate management.

Healthcare professionals who continue to provide futile and burdensome treatments may be viewed as doing more harm than good. The distinction is made by meticulously balancing the benefits and burdens to the patient. For critically ill infants in the NICU, procedures or treatments can be considered inhumane if they inflict pain or discomfort on the infant without actual benefit (Jecker & Pagon, 1995).

Despite these arguments for humane care, burdensome, futile treatments sometimes still are given in the NICU. Weir (1984, 1995) has argued that death should not be considered the worst outcome for some infants, particularly when the chances for survival are remote or when physiologic survival is accompanied by unrelieved pain and suffering. In such cases, healthcare providers may be merely prolonging dying.

Recognition of Parents' Moral Authority

Parents have both the legal and moral authority to serve as surrogate decision makers for their infants. A growing body of literature supports parental decision-making authority, particularly for extremely premature or near-viable infants (Ho, 2003; Jecker & Pagon, 1995; Manning, 2005; Pinkerton et al., 1997; Raines, 1996); however, few studies have examined ways to empower parents to exercise this authority fully. Furthermore, a body of literature written by both parents and healthcare professionals suggests that parents may not be involved adequately in decisions about prolonged, aggressive treatments for their infants (Harrison, 1993; Pinch & Spielman, 1993, 1996; Raines, 1996; Stinson & Stinson, 1979). It can be argued that parents may not be as fully involved in decisions about their infant's care as they would like and have the authority to be, especially in cases in which aggressive therapies are of uncertain benefit to the infant. As Catlin and Carter (2002) point out, the real need in these instances is clear communication with parents and an understanding of how they wish to be involved in these decisions.

A consensus is growing among ethicists, clinicians, and families that when the benefits of life-sustaining therapies are questionable, parental involvement in treatment decision making is an ethical imperative (Harrison, 1993; Jakobi, Weissman, & Paldi 1993; Penticuff, 1987, 1988, 1995, 1998; President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, 1983). When life-sustaining therapies have proved futile, parents and professionals often are uncertain as to how to provide EOL care. The following quote is from Robert Stinson, father of Andrew, who was born in 1976 at 24 weeks' gestation. At that time, Andrew's survival was unprecedented. He underwent intensive care for 6 months, was critically ill throughout this time, and was resuscitated numerous times before his death.

> What they never understood was that one can care deeply enough about a child like Andrew to want his misery ended. Allowing Andrew to die naturally was what we wanted for him, not just to him. I thought often, when I did go in to see him, about his massive pain. He was sometimes crying then; a nearly soundless, aimless cry of pain, undirected and unlistened to except, I sometimes thought, by me. As often as I wanted to gather him into my arms, I wanted him to be allowed to die. What is the name for that? (Stinson & Stinson, 1979)

Although the Stinsons' experience occurred many years ago, evidence suggests professionals do not always incorporate the parental perspective into care decisions (Harrison, 1993; King, 1992; Mehren, 1991; Pinch & Spielman, 1996; Raines, 1996), particularly with regard to burdensome, futile treatments (Yellin et al., 1998).

There can also be differences between mothers and fathers in their reaction to the loss of their infant. Mothers often feel like they failed as a woman to produce a healthy child or they feel guilty because they blame themselves even if they did not do anything to cause the premature delivery or congenital anomaly. Fathers often feel like they failed to protect their family (Kenner et al., 2015). Either mother or father may be reluctant to share their feelings with each other and mothers may be more accepting of support groups and counseling than fathers (Kenner et al., 2015).

Burden of Treatment

The burden of treatment experienced by extremely premature infants in the NICU, especially those with minimal chance for survival, requires further ethical examination. In a national survey of physicians certified in neonatal-perinatal medicine, Yellin et al. (1998) found that many neonatologists believe that "there is an ethical or legal obligation to perform treatments that are not in the infant's best interests, regardless of parental preference." Yellin and coworkers concluded that because some neonatologists are unwilling to withdraw treatments, they may be overtreating some infants in the NICU. Unfortunately, this situation has not changed that much today (Kenner & Boykova, 2010).

Penticuff (1998) identified harm that ensues for infants, families, the healthcare team, and society when there is no accepted definition of futility. Such harm includes "needless infant suffering through prolongation of the process of dying" and "psychologic entrapment of the medical team and the family," in which initial aggressive therapies lead inexorably to more aggressive therapies, with death as the only stopping point. An example is the controversy around treatment options for children with trisomy 13 and 18 where mixed opinions exist about how far treatment should go and how parents must be included in the decision making including decisions about palliative care (Carey, 2012).

Brody, Campbell, Faber-Langendoen, and Ogle (1997) call for compassionate clinical management during the withdrawal of intensive life-sustaining treatment for adult patients using a strategic approach with well-defined goals that dictate the plan of care. Once the goals have been identified, the team examines both the benefits and the burdens of the proposed treatment plan with the family. With this approach, any treatment that is more burdensome than beneficial is limited or eliminated. Brody and coworkers identified pain and discomfort as components of treatment burden and said that there is "no sound rationale for withholding adequate analgesia or sedation" during EOL care. This is an area that requires further examination as it relates to critically ill neonates at the EOL.

The Institute of Medicine identified five core competencies that guide patient care. These are patient-centered care, interdisciplinary teams, evidence-based medicine, quality improvement, and information technology (Greiner & Knebel, 2003). All these competencies have relevance to palliative care, as it is patient and family focused and requires an integrated interprofessional team approach to provide quality care. Mullins et al. (2012) conducted a study funded by the National Institute for Nursing Research (NINR; 1 R21 NR010103-01A1) that examined the needs of parents of children newly diagnosed with cancer. Findings supported the needs parents had for clear messages from the healthcare team, and for information to support positive coping and decrease stress (Mullins et al., 2012).

COMFORT CARE AT THE EOL

Palliative care includes optimum symptom relief for the neonate, regardless of the length of life or the place the life is lived (Thaxton et al., 2016). There are always interventions that can be used to promote comfort during EOL care for infants with complex chronic conditions (Thaxton et al., 2016).

Only limited research is available on the provision of analgesia and sedation for infants at the EOL. One study focused on medications administered during life-support (e.g., ventilator) withdrawal. Partridge and Wall (1997) conducted a retrospective chart review to examine the practice of opioid analgesia administration in one NICU at the time of life-support withdrawal. **Emergency Alert: Despite growing concern over opioid use, pain management including opioids is essential for babies who are potentially dying**. They found that of infants who had a known painful condition (e.g., acute abdominal or surgical pain) and were receiving analgesia before the decision was made to withhold further life-sustaining treatment, 84% received opioid analgesia during life-support withdrawal. An interesting finding of this study was that the infants who did not receive any analgesia at the time of life-support withdrawal had also not received any pain medication before the decision was made to discontinue life support. These findings suggest that analgesia is not being given to ease the possible suffering associated with withdrawal of life support, but rather to manage specific disease processes. (Additional aspects of neonatal pain management are discussed in Chapter 23.) It is recognized that even the smallest of patients have rights, and these include palliative care.

PEDIATRIC HOSPICE CARE

The use of hospice and palliative care has made a significant difference in EOL care for adults. Its primary focus while still supporting life is care, not cure (Friebert & Williams, 2015). According to the National Hospice and Palliative Care Organization (NHPCO; 2001, 2018a), hospice care can be provided in select hospitals, in individual hospice facilities, or in a person's home. In 2013, the AAP Section on Hospice and Palliative Medicine and Committee on Hospital Care published a paper outlining the care commitments and recommendations for pediatric palliative and hospice care programs. These recommendations included that interdisciplinary trained teams are available to provide this care, if the child is in a large institution (AAP, 2013). This type of care is considered a critical component of quality care and facilitates safe care. **Quality and Safety Issue: Family support, as well as compassionate care with consideration of family wishes and cultural values, is important.**

> Reliable statistics for children who receive PP/HC services remain difficult to parse from existing sources. It is also difficult to characterize children who might be appropriate or eligible for services because this characterization is a moving target. Variations in chronological, definitional, and prognostic criteria, as well as accessibility to establish programs, hinder accurate descriptions of this population. (Friebert & Williams, 2015, p. 4)

"As with adults, most children are still dying in the hospital, and most in an intensive care unit (ICU) setting. In a prospective, observational cohort study of all patients served by six hospital-based pediatric palliative care programs, 44.6% of patients were cared for in a home or hospice facility. Most patients (62%) who died did so in a hospital setting while 36.6% died at home or in a hospice facility" (Feudtner et al., 2011, as cited by Friebert & Williams, 2015, p. 6). A study conducted by Children's International Project on Palliative/Hospice Service (ChiPPS, now referred to as Children's Project on Palliative/Hospice Services) found that only a small percentage of children who could have benefited from palliative or hospice care were actually provided this care (5,000 out of 53,000) and most very late in their disease (NHCPO, 2001). Awareness of the need for hospice and palliative care in the neonatal/pediatric population is growing. About 69% of the U.S.-based children's hospitals have palliative care teams and 30% offer home visits (Freudtner et al., 2013).

Barriers to Pediatric Hospice Service

Unfortunately, there are many barriers to the availability and provision of hospice care to ill children and families who could benefit from it. The NHPCO (2000) described psychologic, financial, educational, and regulatory barriers to pediatric palliative care. One of the psychologic barriers is the association of palliative care with the concept of giving up or going against hope (Kenner & Boykova, 2010). Families often avoid palliative care, rather than identifying with the life-enhancing benefits it offers. Financial barriers arise because the home-based, multidisciplinary care is often not reimbursed. The educational barriers for care providers are evident in the lack of palliative care training for most physicians and the avoidance of discussing hospice care with parents (Moody, Siegel, Scharbach, Cunningham, & Cantor, 2011). Some of these training issues can be addressed through simulated difficult conversations (Brown, Lloyd, Swearingen, & Boateng, 2012). Regulatory barriers also exist because the reimbursement system is based on the needs of adults. Ignoring the differences in care needs between children and adults creates barriers to hospice as an option for many families.

PEDIATRIC PALLIATIVE CARE

The AAP issued guidelines in 2000 for the care of children with life-threatening and terminal conditions. The AAP recommended palliative care for infants when "no treatment has been shown to alter substantially the expected progression toward death." According to the AAP guidelines, palliative care incorporates control of pain, symptom management, and care of the psychologic, social, and spiritual needs of children and their families. The AAP also has established five principles of palliative care: (a) respect for the dignity of patients and families, (b) access to competent and compassionate palliative care, (c) support for the caregivers, (d) improved professional and social support for pediatric palliative care, and (e) continued improvement of pediatric palliative care through research and education. There is a section on Hospice and Palliative Medicine within the AAP that is updated on a regular basis. This section upholds the AAP (2000) guidelines and reinforces the need to enhance the quality of life for the child and family. It also stresses care coordination and a team approach while carrying out the five previously listed principles of care (AAP, 2013).

Respect for the Dignity of Patients and Families

Respect for patients' and families' dignity means that information about palliative care should be provided, and the parents' ability to make their own choice of a program should be respected. Also, the plan of care must incorporate and respect the parents' expressed wishes for their child's care, specifically with regard to testing, monitoring, and treatment (AAP, 2000). This respect should consider religious beliefs and cultural values.

Access to Competent and Compassionate Palliative Care

Compassionate palliative care includes alleviation of pain and other symptoms and access to supportive therapies, such as grief counseling and spiritual support. This principle includes provision of adequate respite care for parents (AAP, 2000; Goldman, Hain, & Liben, 2012).

Support for the Caregivers

The AAP recognizes the importance of support for healthcare professionals involved in the child's care. This support may include paid funeral leave, peer counseling, or remembrance ceremonies (AAP, 2000).

Improved Professional and Social Support for Pediatric Palliative Care

The barriers discussed in this chapter can prevent families from obtaining pediatric palliative care. Healthcare professionals must help families overcome these obstacles (AAP, 2000).

Continued Improvement of Pediatric Palliative Care Through Research and Education

Healthcare professionals need continuing education on ways to provide comprehensive palliative care. Also, research that focuses on the effectiveness of palliative care interventions and on models of pediatric palliative care delivery is needed (AAP, 2000). The creation of End-of-Life Nursing Education Consortium (ELNEC) training through the City of Hope and the American Association of Colleges of Nursing (AACN, 2018) has helped facilitate hospital-based nurses, nurse faculty, and, in turn, students to learn palliative care principles. The ELNEC modules can be used in undergraduate and graduate curricula as a part of any clinically based management course or in a standalone elective. The NHPCO (2018b) has a similar program called EPEC-end-of-life care that focuses on interdisciplinary palliative care training. Both of these programs are train-the-trainer models.

Incorporating Pediatric Palliative Care Into the NICU

The AAP recommends that palliative care begin at the time of diagnosis of a life-threatening or terminal condition (AAP, 2000). In the NICU, particularly for extremely premature neonates and for neonates with life-threatening anomalies, palliative care should begin at the time of admission. For many healthcare professionals, this requires a rather dramatic shift from providing intensive high-technology care to providing intensive palliative care. This is in direct contrast to another common tenet of neonatal care: that is, that discharge planning should begin upon admission. At times, particularly during the early diagnostic phase, palliative care can be provided along with technologic care; this arrangement allows the staff to focus on symptom management and pain control while weighing the benefits and harm of treatment. It also provides for interdisciplinary team members who can provide the support the family needs.

Often, when a neonate is born at the edge of viability, the clinical course shows a downward trend. The neonate's physiologic parameters cause concern as evidence mounts that the organ systems are failing. This scenario represents the inevitable point at which intensive efforts to prolong life merely serve to prolong the infant's dying. In such cases, both infants and their families would benefit from a smooth transition to intensive palliative care. This requires a level of skilled care that is not always present in the NICU. The care providers must quickly recognize the futility of sustained therapies and must be expert at providing palliative care to both infant and family. Unfortunately, as research has indicated, all too often infants and children die while still intubated (McCallum et al., 2000); suffer from pain that is inadequately controlled or untreated (Kenner & Boykova, 2010; Partridge & Wall, 1997); and have not received the benefits of palliative care measures (Byock, 1997; Goldman, 1998; Rushton, 2000; Stephenson, 2000). The NANN, the Association of Pediatric Oncology Nurses (APON), and the Society of Pediatric Nurses (SPN) have stated that this area of neonatal care is very important. Under the auspices of the National Leadership Academy on EOL Issues, which is sponsored by Johns Hopkins University, these three organizations are adapting the Last Acts Precepts (https://www.caringcommunity.org/helpful-resources/models-research/last-acts/) for neonatal and pediatric patients. The Last Acts organization provides support for healthcare professionals and families through publications and taking action on EOL issues. It believes that appropriate language must be included to reflect cases such as an infant who is literally born dying, as well as the family's unique needs in such cases. This collaboration is a milestone in efforts to recognize that neonatal and pediatric patients and their families deserve the same level of care that adults have received.

Worldwide recognition of the need for neonatal and pediatric palliative care is growing, thanks to funding from the Soros Foundation, the Robert Wood Johnson Foundation, City of Hope, Johns Hopkins University, the Association of American Colleges of Nursing, and other organizations that support educational efforts about EOL and palliative care. Nursing curricula are being revised to include content and competencies on EOL care. Training programs such as the ELNEC (www.aacn.nche.edu/elnec) are broadening nurses' knowledge in this specialty. One ELNEC training focuses specifically on the neonatal/pediatric population (AACN, 2018). Modules that focus specifically on developmental issues regarding the concept of death and dying as well as how to assess for pain in the nonverbal child help health professionals to adapt materials to their settings. Organizations such as the International Association of Hospice and Palliative Care, the NHPCO, and the Hospice and Palliative Care Nurses Association, which traditionally have focused primarily on adult issues, have begun incorporating pediatric palliative care concerns into their initiatives. The inclusion of a chapter (Kenner & Boykova, 2010) on palliative care in the NICU in Dr. Betty Ferrell's palliative care textbook—the gold standard in palliative care—will increase the awareness of the need for EOL care in this population. All these actions bode well for the integration of EOL care into customary pediatric and neonatal care as a standard that is expected and demanded.

In 2015, the National Perinatal Association under the leadership of Drs. Sue Hall and Michael Hynan invited neonatal/perinatal specialists and parents to develop program standards for psychosocial support of parents and infants admitted to an NICU (Hall et al., 2015). Part of these recommendations focused on palliative and bereavement care (Hall et al., 2015; Hynan & Hall, 2015; Kenner et al., 2015). Recommendations for NICU bereavement and palliative care (Kenner et al., 2015) can be found in Boxes 36.1 to 36.3.

Box 36.1

NICU RECOMMENDATIONS FOR PALLIATIVE AND BEREAVEMENT CARE

1. Parents who lose a baby before, during, or shortly after birth, or later in the NICU, should be offered:
   a. Anticipatory guidance regarding the grieving process, including how mothers and fathers, and other family members, may grieve differently (Wallerstedt & Higgins, 1996). This anticipatory guidance should begin antenatally if a life-limiting diagnosis has been determined (Bennett, Dutcher, & Snyders, 2011; Calhoun, Napolitanto, & Terry, 2003).
   b. Participation in bereavement rituals, including those that meet their spiritual, religious, and cultural preferences. These rituals may include a variety of practices and items that will help them remember their baby, such as provision of hand prints, foot prints, and photographs (Carter, 2004; De Lisle-Porter & Podruchny, 2009). Smooth communication should be facilitated between parents and the staff of the NICU and obstetric units throughout the dying process; a perinatal social worker or other designated person can assist with this (National Association of Perinatal Social Workers, 2007).
   c. Psychosocial support for all members of the family, including but not limited to grandparents and the baby's siblings (American Academy of Pediatrics Section on Hospice and Palliative Medicine and Committee on Hospital Care, 2013; Pearson, 1997).
   d. Peer-to-peer support and/or referral to community or Internet support organizations.
   e. Counseling regarding both the physical and psychological considerations of attempting another pregnancy (American Academy of Pediatrics Section on Hospice and Palliative Medicine and Committee on Hospital Care, 2013).
   f. Post-hospital follow-up in a variety of forms, including individual contact by a staff member at various time periods as well as a conference 4–6 weeks after the baby's death to review autopsy and other results that will help parents understand what happened to their baby (Levetown, 2008).
2. When intensive care will not be provided, a collaborative, interdisciplinary approach should be used to provide palliative care including bereavement care to any family whose fetus or neonate is facing a life-limiting condition or imminent death (Aladangady, & de Rooy, 2012).
3. Physicians and nurse practitioners should follow the guidelines outlined by the American Academy of Pediatrics when engaging in discussions with parents about whether to initiate or continue intensive care for a baby who may not survive (American Academy of Pediatrics Committee on Fetus and Newborn, 2007; Cummings, & American Academy of Pediatrics, Committee on Fetus and Newborn, 2015); neonatal nurses and perinatal social workers should be included in the decision-making process as well (National Association of Neonatal Nurses, 2010; National Association of Perinatal Social Workers, 2007). Intensive care should be provided only if it is believed that the baby will benefit from it. The best interests of the baby should be the guiding standard (American Academy of Pediatrics Committee on Fetus and Newborn, 2007; Cummings, & American Academy of Pediatrics, Committee on Fetus and Newborn, 2015).
4. In cases where there are disagreements between parents and the healthcare team when making end-of-life decisions, particularly around the futility of further care for a baby, a bioethics consult should be obtained and/or the case presented to the hospital Bioethics Committee (American Academy of Pediatrics Committee on Fetus and Newborn, 2007).
5. Parents whose babies with life-limiting conditions survive to hospital discharge should be offered both practical and psychosocial support to help them prepare for discharge, learn how to both care for and cope with their baby at home, (Craig & Goldman, 2003; Criag & Mancini, 2013) and/or they should be referred to a hospice with experience caring for infants. Their baby's primary care provider, neonatal specialist, medical home, or any subspecialists should be fully involved in making and carrying out home care plans and providing follow-up support.

Box 36.2

ANTENATAL RECOMMENDATIONS

Parents anticipating a perinatal loss should be offered:

1. An antenatal interdisciplinary conference to develop the following plans, which should be individualized according to parents' desires and cultural, spiritual, and religious beliefs:
   a. A birth plan, which should include parents' preferences regarding the conduct of labor, the circumstances surrounding delivery, and the care for baby and parents after the baby's birth;
   b. A plan for the extent of resuscitation to be performed and whether to allow a natural death; and
   c. A palliative care plan as indicated and desired when babies are not expected to survive. This plan should include parents' preferences on where the baby's care will be delivered, how nutrition will be provided, and how baby's pain and discomfort will be managed (Craig & Goldman, 2003; Criag & Mancini, 2013).
2. Encouragement to bond with their baby and to create memories throughout the pregnancy whenever feasible, recognizing the barriers parents may face in bonding.
3. Psychosocial support for all members of a family, including grandparents and the infant's siblings.
4. Both practical and psychosocial support to help parents cope with their baby at home when infants with life-limiting conditions survive to hospital discharge (American Academy of Pediatrics Section on Hospice and Palliative Medicine and Committee on Hospital Care, 2013).

Box 36.3

HEALTH SYSTEM RECOMMENDATIONS

1. All health professionals who work with pregnant women, neonates, and their families should receive education and demonstrate competence in palliative and bereavement care that is appropriate within their scope of practice. This education should include training in how to communicate effectively and empathetically with families (American Academy of Pediatrics Section on Hospice and Palliative Medicine and Committee on Hospital Care, 2013; Boss, Hutton, Donohue, & Arnold, 2009; National Association of Neonatal Nurses, 2015).
2. Policies for palliative care and bereavement practices in any part of a healthcare system should be in place and easily accessible to all staff, to ensure a standard of care for all families.
3. Palliative and bereavement care resources in the community should be available to anyone who is providing care to a neonate and family facing a life-threatening condition or imminent death or has experienced a loss, whether or not there is a palliative care team or program at a specific institution.
4. Hospitals should work in partnership with their local organ donation organizations to determine whether specific babies are eligible to become organ donors and to assess, in collaboration with the family, whether organ donation is the right choice for them.
5. Healthcare staff who provide palliative and/or bereavement care should receive psychosocial support and engage in self-care (Sanchez-Reilly, Morrison, Carey, Bernacki, O'Neil, & Kapo, 2013), to enable them to provide optimal care to the families they serve, as well as to prevent burnout, compassion fatigue, or secondary traumatic stress (American Academy of Pediatris Section on Hospice and Palliative Medicine and Committee on Hospital Care, 2013). The perinatal social worker (De Lisle-Porter, & Podruchny, 2009), NICU psychologist (Gold, Dalton, & Schwent, 2007), or pastoral care staff (Sharp, 1991) can be instrumental in providing this support.

BEREAVEMENT

Grief is unique to each individual and varies in expression, duration, and meaning. Parents often move through the grief process differently. The infant's mother may express her grief by crying, whereas the father may express his grief by isolating himself.

For many parents, grief is a lifelong process. Significant life events can trigger grieving, as can such routine childhood milestones as seeing a neighbor's child get on the school bus for her first day of kindergarten or, many years later, receiving a high school graduation announcement for what would have been their child's class.

As parents progress through the first year after their loss, it is important to prepare them for the grief they are likely to experience in the future and to help them develop a plan for themselves. Every family is unique and determines their own milestone days, those days that bring special remembrance of their child. Milestone days may include the child's birthday, the anniversary of the child's death, or holidays. It sometimes is helpful for parents to schedule time off on these milestone days so that they can plan a special activity. Some parents may want to be alone and take a quiet walk together. Others may prefer to be surrounded by relatives or a few close friends. Still others may want to spend the day with another parent who has experienced similar grief.

The nurse should stress three important points to bereaved families: (a) grief is individualized; (b) grief is a process; and (c) family members should not hesitate to seek assistance with their grief, even years after the child's death.

SUMMARY

Even when death approaches quickly in the NICU, measures can be taken to ease the infant's transition and adequately assist the family. It is no longer enough to provide quality bereavement and postmortem care to infants and their families. Research into and evaluation of care guidelines are needed so that infants can receive the same quality of EOL care afforded to other members of society. Neonatal nurses have been at the forefront of this movement and now have the opportunity to serve as leaders in the design and implementation of exemplary neonatal palliative care programs.

CASE STUDY

An infant was born at 24 weeks' gestation to a family that had just moved to a new city and had no relatives in the area. This was a first baby for the family. Shortly after birth, it was recognized that the infant would probably not survive because, in addition to being premature, overwhelming sepsis was present. The care team (without the family) met. Some felt that the family needed to be given options immediately to call the palliative care team in for a discussion of treatment options, while other team members believed that a few more days should be given to the baby to see how the infant would respond to ventilation and antibiotic therapy. A consultation was done with the palliative care team that convinced the neonatal team to talk with the family, describe the infant's status, discuss the possible course, and ask them to be part of the team to make decisions about palliative care and in what form—in other words, how aggressive they wanted the treatment to be, how in either case palliative care would be provided, how care would be coordinated, and how they as a family would be supported irrespective of the outcome. Over the course of the next week, the infant continued to get progressively sicker, the family was supported by the palliative care team, and relatives were contacted via Internet to ensure they could support the family and see the baby. The family planned the care and eventually made the decision to take the infant, whom they named Sarah Elizabeth, off the ventilator. They held and rocked the baby surrounded by staff they selected until the moment of death. The death was peaceful, and the palliative care team continued to follow up with the family for the next month. The team also debriefed the neonatal caregivers who worked closely with the family to ensure they were supported. The principles of dignity, respect, and need for caregiver support for both the family and professional staff were upheld.

EVIDENCE-BASED PRACTICE BOX

Much progress has been made since the early 2000s when protocols for perinatal and neonatal palliative care appeared. An instrument called the Perinatal Palliative Care Perceptions and Barriers Scale Instrument was developed by Drs. Charlotte Wool and Sally Northam. This instrument was developed and validated over time for use with nurses and physicians. The focus is to determine perceptions of the health professionals in order to develop staff/faculty training programs with the ultimate goal to provide better support of patients and families. This instrument can be used in a variety of ways and needs further testing to broaden its use.

PARENT VOICES

Amy Blanchard

After we realized our daughter was not going to get better, my husband and I met with the palliative care team. This team included the chaplain, pain management team, and the social worker. The most important thing for nurses to do is not to act like the baby has already passed away. Know that she is still alive and the parents are in the process of making life decisions for their child. We had some phenomenal nurses who treated our daughter like their own. That absolutely meant the world to us. We were comfortable leaving our daughter in their capable hands. Having a care team of nurses was one of the most important aspects of Molly's nursing care. These nurses not only cared for and loved our daughter, but also us (her parents) as well.

During palliative care, we would ask for the nurses' opinions. They knew our daughter almost as well as we did. They knew how certain medications affected her and if she was in pain. We valued their opinion in regard to some of the care that she received during the end. They wanted Molly to be pain free and as comfortable as we wanted her to be.

I will always remember the last day of my daughter Molly's life like it was yesterday. Discontinuing care was the hardest decision my husband and I have ever had to make. On that day, we were able to call two of our favorite nurses from Molly's care team. They were not scheduled to work but came to Molly's room to say their goodbyes. They sat with us and cried with us while we held our daughter for the last time. These two nurses gave my sweet baby girl her last bath when I was not able to. They were angels who flew in and took over when I myself was an emotional wreck. I'll be forever grateful for Molly's loving nurses.

To some families, like mine, NICU nurses should know that they are not just a nurse. They are also caretakers to the baby's parents. They will cry along with mothers and fathers and when a baby passes away, they are the first ones the parents may want to see. A strong bond forms when your baby spends 4 to 5 months with a nurse. I hope these nurses know that they will forever be a part of some family's lives, even if the baby passes away and the family no longer visits. These nurses will be remembered always.

CHAPTER 37

Postdischarge Care of the Newborn, Infant, and Families

Marina V. Boykova, Carole Kenner, Karen Walker, and Deborah A. Discenza

INTRODUCTION

The multiple problems that bring an infant to a neonatal intensive care unit (NICU) have been described, in depth, throughout the preceding chapters. Upon hospital discharge, high-risk infants require no less care than in the hospital as the healthcare needs of the initially sick infant often remain numerous and complex. Postdischarge and follow-up care focuses on the convalescing infant's growth, development, health promotion, disease prevention, chronic disease management, and care coordination. Importantly, parents also need care after the infant's hospital discharge. The transition from hospital to home for infants and their families is a very important and crucial period. This transition starts when the family begins to accept the role of the full-time caregiver outside the safety net of the hospital. The focus of this chapter is on the infant and parental care after hospital discharge.

POSTDISCHARGE CARE FOR HIGH-RISK INFANTS

The American Academy of Pediatrics (AAP) and the American College of Obstetricians and Gynecologists (ACOG) recommend healthcare professionals to give special considerations to the four following groups of high-risk newborn infants before discharge: (a) preterm infant, (b) infant with special healthcare needs or dependence on technology, (c) infant at risk because of family issues, and (d) infant with anticipated early death (AAP & ACOG, 2017). Discharge criteria as well as the postdischarge care depend on the different needs of these patient categories. In general, for high-risk infants to be discharged, they have to be physiologically stable; the decision is based on the clinical judgment of health professionals and determination of the infant's medical status.

The first category, preterm infants, can be discharged when oral feedings are sufficient to support appropriate growth. Also, preterm infants can be discharged when they are able to maintain normal body temperature in a homelike environment without supplemental heat and when sufficient mature respiratory control is present (AAP Committee on Fetus and Newborn, 2008). Most preterm infants achieve major physiological milestones by 36 to 37 weeks' postmenstrual age (AAP & ACOG, 2017), but feeding and oxygen milestones are often achieved last (Bakewell-Sachs, Medoff-Cooper, Escobar, Silber, & Lorch, 2009). Apneic episodes are common in preterm infants before discharge; feedings and weight gain are also challenging issues (Briere, McGrath, Cong, & Cusson, 2014; Eichenwald et al., 2016; Ross & Browne, 2013). Thus, observation (up to 7 days without apnea) and stable pattern in feeding/gaining weight before discharge from an NICU is recommended (Eichenwald et al., 2016); readiness in these physiological skills will depend on the gestational age (Lorch, Srinivasan, & Escobar, 2011).

For NICU infants before discharge, weight gain of 15 to 30 g/day must continue over a reasonable time (several days to 1 week); milk fortification, iron, vitamins, foliate, and vitamin D supplementation are often necessary (LaHood & Bryant, 2007; Teller, Embleton, Griffin, & van Elburg, 2016); and weight gain should occur in an open environment (crib). This gain should continue during the first 3 to 4 months of life and then decline to 5 to 15 g/day by the age of 12 to 18 months (Sherman, Lauriello, & Aylward, 2016). For larger and healthier infants, 108 kcal/kg/day can be sufficient for adequate growth. For preterm infants, 110 to 130 kcal/kg/day can be required with increased protein (Shakeel, 2016; Sherman et al., 2016). There is a need to avoid excessive weight gain, which may result in health problems such as obesity, hypertension, and cardiovascular disease (Casey, 2008; Sherman et al., 2016). Nutritional requirements vary depending on the infant's past medical problems, status, and tolerance of feedings; thus, individualized postdischarge instructions are necessary. Available and widely used growth charts are not always valid for preterm infants or infants with continuing health problems, but some recent information is available for infants of different gestational ages (Villar et al., 2014). Length, head circumference, and weight should always be considered together, and nutritional assessment of the infant is more than just body measurements and may even require indirect calorimetry (Sherman et al., 2016). In general, frontal-to-occipital head circumference in preterm infants should be 0.7 to 1 cm/week (in term infants 0.5 cm) in the immediate postnatal period; by 12 to 18 months of age, it should decline to 0.1 to 0.4 cm/month (Sherman et al., 2016). Increase in crown-to-heel length should be approximately 0.8 to 1.1 cm/week in preterm infants (0.7–0.75 in term babies), and by 12 to 18 months of age, it should decline to 0.75 to 1.5 cm/month (Sherman et al., 2016). Consultation with a pediatric dietitian or an infant nutrition specialist should be obtained if there are concerns about growth failure and catch-up (Peters & Pompeii-Wolfe, 2018) as the adherence to the nutrition guidelines can be low

(Francis et al., 2018). Additional information on specific formulas, nutrition aspects, and standardized growth charts are presented in Chapter 20, Nutrition Management of Premature Infants, of this book.

In the second category, the infant with special healthcare needs or dependence on technology will have differing needs than the average NICU graduate. Depending on the exact health condition (chronic lung disease [CLD], genetic condition, congenital heart disease [CHD], and postsurgical and late preterm infants), the infant may require more calories due to the "work of breathing" such as in a case with CLD or CHD. With CLD, the infant may require 120 to 150 kcal/kg/day plus increased protein intake, fluid restriction, electrolyte management, and control of vital functions (Sherman et al., 2016). An infant with CLD will often require home oxygen therapy, so appropriate parental teaching should be done before discharge. A pediatric pulmonologist should also be involved in postdischarge management of such patients; periodic evaluation of electrolyte status should also be performed due to the use of diuretics in such infants. An infant with cardiac disease will also often require fluid restriction and may need increased caloric intake as well. A pediatric cardiologist should be involved in postdischarge management of such infants; periodic evaluation of electrolyte status also should be performed due to the use of diuretics in such infants.

The third category of infants who should receive attention before and after discharge are infants who are at health risk because of family issues. The infant may or may not be premature, or having specific health needs, but the family may have problems in adjusting to having a once sick infant at home who now is ready for discharge (discussed later in this chapter). For infants in the fourth category—infants with anticipated early death—the aspects of the care are described in Chapter 36, Palliative and End-of-Life Care.

Follow-Up of High-Risk Infants

Careful attention should be given to any NICU graduate. Since 1936, the attention was given to taking preterm infants home (Lundeen, 1937). The follow-up appointments with primary care providers for high-risk infants should occur in accordance with the needs of the patient (AAP & ACOG, 2017). For preterm infants (including late preterm) and infants with early discharge from the maternity unit (<48 hours after delivery), AAP and ACOG (2017) recommend that the first appointment with the primary caregiver should occur in the first 24 to 48 hours after discharge. In the immediate period after discharge, some of the high-risk infants should be examined weekly or semimonthly (AAP & ACOG, 2017). Neurodevelopmental, behavioral, and sensory status should be assessed more than once during the first year "to ensure early identification of problems and referral for the appropriate interventions" (AAP & ACOG, 2017, p. 471). Infants born with birth weight less than 1,500 g, as well as infants with hypoxic–ischemic encephalopathy (HIE), seizures, hypoxic cardiorespiratory failure, and multiple congenital anomalies, should have standard neurodevelopmental tests at 1 and 2 years of corrected age (AAP & ACOG, 2017). Infants who underwent major and minor surgeries (e.g., diaphragmatic hernia, major heart defects, pyloric stenosis, inguinal hernia) have been shown to have some degree of developmental delays (Walker, Holland, Halliday, & Badawi, 2012). Several risk factors can be identified for developmental delays in surgical patients: genetic predisposition, prematurity, premorbid status, age at the time of surgery, duration of the procedure, and type of anesthetic/analgesic agents used (Walker et al., 2012). Purdy and Melwak (2012) have also suggested the following "red flags" when thorough high-risk infant follow-up care is required:

- Low Apgar score at 5 minutes (<4)
- Intraventricular hemorrhage more than Grade II, hydrocephalus
- HIE, abnormal neurological examination (tremors, hypotonia/hypertonia), seizures
- Hyperbilirubinemia close to exchange transfusion levels
- Severe infections (sepsis, meningitis)
- Hypoglycemia requiring treatment
- Persistent pulmonary hypertension, extracorporeal membrane oxygenation, and use of inhaled nitric oxide
- Discharge on apnea monitor and caffeine
- Infant of substance-abusing mother
- Congenital birth defects (such as Trisomy 21 or Down's syndrome; Purdy & Melwak, 2012)

Frequency of follow-up visits for the *well infant* varies with local and community practices as well as with the patient (AAP & ACOG, 2017); however, it should be consistent with AAP's guidelines on preventive pediatric healthcare. *The Bright Futures* online resource provides guidance, tools, and schedules for promoting health in the neonatal and pediatric populations (for resource, see https://brightfutures.aap.org/Pages/default.aspx). The follow-up visit can take place at home or clinic; physical examination and measurements, developmental surveillance, psychosocial, and behavioral assessments are recommended at the infancy period at 1, 2, 4, 6, and 9 months of age. In early childhood, these visits should take place at 12, 15, 18, 24, and 30 months of age and then at 3 and 4 years of age. Developmental screening is recommended at 9, 18, and 30 months of age (AAP, 2019; Figure 37.1). However, high-risk infants might require additional health checkups; thus, every infant should be managed on the individual basis.

Due to risks of visual impairments in NICU patients (i.e., retinopathy of prematurity, ROP), ophthalmic examinations should be performed. Infants less than or equal to 1,500 g or less than or equal to 32 weeks, infants with unstable clinical course, should have retinal screening (starting at the hospital usually). The first fundal examination in infants above 22 weeks of gestation should occur at 31 weeks' postmenstrual age or between 4 and 9 weeks of chronological age, depending on the gestational age at birth; follow-up appointments should occur in 1- to 3-week intervals depending on the initial fundal examination (Fierson, AAP Section on Ophthalmology, American Academy of Ophthalmology, American Association for Pediatric Ophthalmology and Strabismus, & American Association of Certified Orthoptists, 2018). It had also been recommended that preterm infants with or without ROP should be evaluated at 4 to 6 months of age and then yearly (Fierson, AAP Section on Ophthalmology, American Academy of Ophthalmology, American Association for Pediatric Ophthalmology and Strabismus, & American Association of Certified Orthoptists, 2018). Special attention should be given to parents of preterm infants with low health literacy and limited English language proficiency: These parents often lack knowledge about ROP (Eneriz-Wiemer et al., 2018).

Hearing screening is also vitally important as hearing-impaired children suffer irreversible delays in speech and language development; all infants should be screened regardless of the risk (Delaney, 2018). Permanent hearing loss remains a serious complication of prematurity, certain neonatal diseases, or prolonged oxygen and antibiotics' use (Delaney, 2018). Hearing screening should be performed before discharge in any infant who was hospitalized for more than 5 days; auditory brainstem response (ABR), otoacoustic emissions (OAEs), and automated ABR (AABR) are the widely used methods for newborn hearing screening; ABR and auditory steady-state response testing (ASSR) can be especially helpful to obtain specific information about specifics of infant

hearing loss (Delaney, 2018). After discharge, an infant should be evaluated at 1 and 3 months of age; infants with identified hearing loss should be enrolled in early intervention (EI) programs by 6 months of age (AAP Early Hearing Detection and Intervention, 2018). Very early screening (by 1 month of age), diagnosis in the first 3 months, and enrollment into EI services are beneficial for infants with hearing loss in terms of language development (AAP Early Hearing Detection and Intervention, 2018). Many states also recommend that at-risk children should be evaluated by an audiologist every 6 months for the first 3 years of life (Delaney, 2018). Healthcare professionals at follow-up clinics, EI programs, and primary care settings should pay careful attention to NICU patients in terms of hearing—only 61% of NICU graduates with permanent hearing loss were enrolled in EI programs in 2012 (Williams, Alam, & Gaffney, 2015). Special attention should be given to low educational level of the families: One study showed that only one third of infants were screened and followed up within the recommended time frame (Holte et al., 2012) and found that there are certain misunderstandings, misconceptions, and myths in parents regarding hearing loss in infants (Delaney, 2018). The AAP (2018a) Program to Enhance the Development of Infants and Children (PEHDIC) developed 1-3-6 guidelines for pediatric medical home providers: screening by 1 month of age, diagnosis of hearing loss by 3 months of age, and entry into EI services by 6 months of age. This guideline can be found at www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/PEHDIC/Documents/Algorithm1_2010.pdf (see Figure 37.2). According to AAP (2018a), only 86.9% of infants receive hearing re-screening before 1 month of age; only 69.1% of infants who do not pass a hearing screening test are diagnosed with hearing loss before 3 months of age; of those who are diagnosed, only 67% receive intervention before 6 months of age; and almost 36% of infants who do not pass a newborn hearing test are lost to follow-up (AAP, 2018a). Although early screening and EI are vital (Vohr, 2016), wide variations in tests used for infants as well as differences in waiting times (up to 5 months), loss to follow-up, and limited referral to EI were reported (C. L. Liu, Farrell, MacNeil, Stone, & Barfield, 2008; Munoz, Nelson, Goldgewicht, & Odell, 2011; Wang, Elliott, McGlynn, Brook, & Schuster, 2008).

Immunizations

Appropriate immunizations should be given at discharge from a hospital (AAP, 2019). The full schedule can be found at https://redbook.solutions.aap.org/selfserve/ssPage.aspx?SelfServeContentId=Immunization_Schedules. Vaccinations for preterm infants should be given according to the chronological age; routine immunization schedules are not changed. Some specifics related to the hepatitis B (HepB) immunizations in infants weighing less than 2,000 g are as follows: The first HepB vaccine is given at 1 month of age or at discharge and then four vaccines are given at 1, 2, and 6 (up to 18) months of age (AAP, 2019). AAP (2019) recommends adding HepB immunoglobulin to HepB vaccine in infants of mothers with unknown HBsAg status. In infants who are heavier than 2,000 g and those mothers who are HBsAg positive, immunoglobulin should be added to HepB vaccine, but no later than 1 week after birth (AAP, 2019).

Vaccinations can be delayed if needed (i.e., due to the present medical conditions, transient illnesses, and rehospitalizations). Careful attention should be given to the immunization schedule of NICU graduates: One study reported that only 51% of NICU infants were given routine immunizations and 27% of infants had no vaccines at all (Navar-Boggan, Halsey, Escobar, Golden, & Klein, 2011). The schedule for the recommended vaccinations and catch-up schedule for patients who start late, or more than 1 month behind, can be found at the Red Book online resource mentioned previously (AAP, 2018a, 2019). Please see some recommended schedules for immunization in Figure 37.3.

To prevent respiratory infection, specifically respiratory syncytial virus (RSV) infection, a monoclonal antibody (palivizumab or Synagis by AstraZeneca Pharmaceuticals, Wilmington, DE) can be administered to preterm infants born before 29 weeks' gestation. A proper use and adequate number of doses are of vital importance. RSV immunizations range from one dose to five monthly doses (intramuscularly, 15 mg/kg/dose). Palivizumab can be given at 48 to 72 hours before discharge or as soon as possible after discharge, preferably 1 month before RSV season. During RSV season in North America (November to March, sometimes April), fewer doses may be required (AAP & ACOG, 2017). Infants with CLD or CHD who are younger than 12 months of age and on the medical therapy, as well as preterm infants born before 29 completed weeks of gestation, are eligible for maximum five monthly doses (AAP, 2014). For preterm infants with CLD or CHD, immunizations usually start on November 1 for most geographic locations of the United States. For Florida and Alaska timing for vaccination may vary due to different in the length of RSV season. Adequate coverage of the infants eligible for the RSV vaccination can be a problem: One French study reported that only 77% of infants received complete prophylaxis (Torchin et al., 2018). For preterm infants without CLD, the detailed dosage and timing can be found at the Red Book online resource (AAP, 2019). Importantly, RSV seasons may vary from country to country and region to region; the reference to appropriate professional guidelines should be made.

Early Intervention Services

EI services and programs aim to prevent or improve cognitive, behavioral, developmental, and physical outcomes in infants and preschoolers; these services also provide family support and decrease parental stress, improving mother–infant interactions and feeding practices, and having positive effects on both maternal and infant outcomes (Borghini et al., 2014; Fontana et al., 2018; Litt, Glymour, Hauser-Cram, Hehir, & McCormick, 2018; Rose, Herzig, & Hussey-Gardner, 2014; Spittle, Anderson, Boyd, & Doyle, 2015; Spittle & Treyvaud, 2016; Zhang, Kurtz, Lee, & Liu, 2014). In the United States, EI service is covered under the Individuals with Disabilities Education Act (IDEA), Part C, and infants are eligible to participate (U.S. Department of Education, 2011). However, these programs are expensive, and referral to them can be problematic. Nationally, EI services cost an estimated $611 million (Behrman & Butler, 2007); special education services associated with a higher prevalence of four disabling conditions (such as cerebral palsy [CP], mental retardation, vision impairment, and hearing loss) add $1.1 billion or $2,200 per preterm infant (Behrman & Butler, 2007). In Massachusetts, the program costs were estimated to be about $66 million in 2003 with a mean cost of $857 per infant involved in EI; however, for infants whose gestational age was 24 to 31 weeks, the costs were over $5,000, and for 32 to 36 weeks' gestation, they were $1,578 (Clements, Barfield, Ayadi, & Wilber, 2007). Additionally, criteria for these programs vary by state, and not all high-risk infants and their families are ever referred (Little, Kamholz, Corwin, Barrero-Castillero, & Wang, 2015; Tang, Feldman, Huffman, Kagawa, & Gould, 2012). Tang et al. (2012) found that 34% of infants who had high-risk conditions were not referred, even though they were eligible for EI programs. Other disparities in EI referral practices have also been documented: Referral was more likely in multiple-birth infants and less likely in infants more than 28 weeks of gestation, infants of non-Hispanic black mothers and mothers without private

American Academy of Pediatrics

Recommendations for Preventive Pediatric Health Care

Bright Futures/American Academy of Pediatrics

Bright Futures
prevention and health promotion for infants, children, adolescents, and their families™

Each child and family is unique; therefore, these Recommendations for Preventive Pediatric Health Care are designed for the care of children who are receiving competent parenting, have no manifestations of any important health problems, and are growing and developing in a satisfactory fashion. Developmental, psychosocial, and chronic disease issues for children and adolescents may require frequent counseling and treatment visits separate from preventive care visits. Additional visits also may become necessary if circumstances suggest variations from normal.

These recommendations represent a consensus by the American Academy of Pediatrics (AAP) and Bright Futures. The AAP continues to emphasize the great importance of continuity of care in comprehensive health supervision and the need to avoid fragmentation of care.

Refer to the specific guidance by age as listed in the Bright Futures Guidelines (Hagan JF, Shaw JS, Duncan PM, eds.Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents. 4th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2017).

The recommendations in this statement do not indicate an exclusive course of treatment or standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

ANTICIPATORY GUIDANCE	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●	●

1. If a child comes under care for the first time at any point on the schedule, or if any items are not accomplished at the suggested age, the schedule should be brought up-to-date at the earliest possible time.
2. A prenatal visit is recommended for parents who are at high risk, for first-time parents, and for those who request a conference. The prenatal visit should include anticipatory guidance, pertinent medical history, and a discussion of benefits of breastfeeding and planned method of feeding, per "The Prenatal Visit" (http://pediatrics.aappublications.org/content/124/4/1227.full).
3. Newborns should have an evaluation after birth, and breastfeeding should be encouraged (and instruction and support should be offered).
4. Newborns should have an evaluation within 3 – 5 days of birth and within 48 – 72 hours after discharge from the hospital to include evaluation for feeding and jaundice. Breastfeeding newborns should receive formal breastfeeding evaluation, and their mothers should receive encouragement and instruction, as recommended in "Breastfeeding and the Use of Human Milk" (http://pediatrics.aappublications.org/content/129/3/e827.full). Newborns discharged less than 48 hours after delivery must be examined within 48 hours of discharge, per "Hospital Stay for Healthy Term Newborns" (http://pediatrics.aappublications.org/content/125/2/405.full).
5. Screen, per "Expert Committee Recommendations Regarding the Prevention, Assessment, and Treatment of Child and Adolescent Overweight and Obesity: Summary Report" (http://pediatrics.aappublications.org/content/120/Supplement_4/S164.full).
6. Blood pressure measurement in infants and children with specific risk conditions should be performed at visits before age 3 years.
7. A visual acuity screen is recommended at ages 4 and 5 years, as well as in cooperative 3-year-olds. Instrument-based screening may be used to assess risk at ages 12 and 24 months, in addition to the well visits at 3 through 5 years of age. See "Visual System Assessment in Infants, Children, and Young Adults by Pediatricians" (http://pediatrics.aappublications.org/content/137/1/e20153596) and "Procedures for the Evaluation of the Visual System by Pediatricians" (http://pediatrics.aappublications.org/content/137/1/e20153597).
8. Confirm initial screen was completed, verify results, and follow up, as appropriate. Newborns should be screened per "Year 2007 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs" (http://pediatrics.aappublications.org/content/120/4/898.full).
9. Verify results as soon as possible, and follow up, as appropriate.
10. Screen with audiometry including 6,000 and 8,000 Hz high frequencies once between the ages of 11 and 14 years, once between the ages of 15 and 17 years, and once between the ages of 18 and 21 years. See "The Sensitivity of Adolescent Hearing Screens Significantly Improves by Adding High Frequencies" (http://www.jahonline.org/article/S1054-139X(16)00048-3/fulltext).
11. See "Identifying Infants and Young Children With Developmental Disorders in the Medical Home: An Algorithm for Developmental Surveillance and Screening" (http://pediatrics.aappublications.org/content/118/1/405.full).
12. Screening should occur per "Identification and Evaluation of Children With Autism Spectrum Disorders" (http://pediatrics.aappublications.org/content/120/5/1183.full).
13. This assessment should be family centered and may include an assessment of child social–emotional health, caregiver depression, and social determinants of health. See "Promoting Optimal Development: Screening for Behavioral and Emotional Problems" (http://pediatrics.aappublications.org/content/135/2/384) and "Poverty and Child Health in the United States" (http://pediatrics.aappublications.org/content/137/4/e20160339).
14. A recommended assessment tool is available at http://www.ceasar-boston.org/CRAFFT/index.php.
15. Recommended screening using the Patient Health Questionnaire (PHQ)-2 or other tools available in the GLAD-PC toolkit and at http://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/Mental-Health/Documents/MH_ScreeningChart.pdf.
16. Screening should occur per "Incorporating Recognition and Management of Perinatal and Postpartum Depression Into Pediatric Practice" (http://pediatrics.aappublications.org/content/126/5/1032).
17. At each visit, age-appropriate physical examination is essential, with infant totally unclothed and older children undressed and suitably draped. See "Use of Chaperones During the Physical Examination of the Pediatric Patient" (http://pediatrics.aappublications.org/content/127/5/991.full).
18. These may be modified, depending on entry point into schedule and individual need.

(continued)

19. Confirm initial screen was accomplished, verify results, and follow up, as appropriate. The Recommended Uniform Newborn Screening Panel (https://hrsa.gov/advisory-committees/heritable-disorders/rusp/index.html), as determined by The Secretary's Advisory Committee on Heritable Disorders in Newborns and Children, and state newborn screening laws/regulations (http://genes-r-us.uthscsa.edu/home) establish the criteria for and coverage of newborn screening procedures and programs.
20. Verify results as soon as possible, and follow up, as appropriate.
21. Confirm initial screening was accomplished, verify results, and follow up, as appropriate. See "Hyperbilirubinemia in the Newborn Infant ≥35 Weeks' Gestation: An Update With Clarifications" (http://pediatrics.aappublications.org/content/124/4/1193).
22. Screening for critical congenital heart disease using pulse oximetry should be performed in newborns, after 24 hours of age, before discharge from the hospital, per "Endorsement of Health and Human Services Recommendation for Pulse Oximetry Screening for Critical Congenital Heart Disease"(http://pediatrics.aappublications.org/content/129/1/190.full).
23. Schedules, per the AAP Committee on Infectious Diseases, are available at http://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx.Every visit should be an opportunity to update and complete a child's immunizations.
24. See "Diagnosis and Prevention of Iron Deficiency and Iron-Deficiency Anemia in Infants and Young Children (0–3 Years of Age)" (http://pediatrics.aappublications.org/content/126/5/1040.full).
25. For children at risk of lead exposure, see "Low Level Lead Exposure Harms Children: A Renewed Call for Primary Prevention" (http://www.cdc.gov/nceh/lead/ACCLPP/Final_Document_030712.pdf).
26. Perform risk assessments or screenings as appropriate, based on universal screening requirements for patients with Medicaid or in high prevalence areas.
27. Tuberculosis testing per recommendations of the AAP Committee on Infectious Diseases, published in the current edition of the AAP *Red Book: Report of the Committee on Infectious Diseases.*Testing should be performed on recognition of high-risk factors.
28. See "Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents"(https://www.nhlbi.nih.gov/health-topics/integrated-guidelines-for-cardiovascular-health-and-risk-reduction-in-children-and-adolescents).
29. Adolescents should be screened for sexually transmitted infections (STIs) per recommendations in the current edition of the AAP Red Book: Report of the Committee on Infectious Diseases.
30. Adolescents should be screened for HIV according to the USPSTF recommendations (http://www.uspreventiveservicestaskforce.org/uspstf/uspshivi.htm) once between the ages of 15 and 18, making every effort to preserve confidentiality of the adolescent. Those at increased risk of HIV infection, including those who are sexually active, participate in injection drug use, or are being tested for other STIs, should be tested for HIV and reassessed annually.
31. See USPSTF recommendations (http://www.uspreventiveservicestaskforce.org/uspstf/uspscerv.htm). Indications for pelvic examinations prior to age 21 are noted in "Gynecologic Examination for Adolescents in the Pediatric Office Setting" (http://pediatrics.aappublications.org/content/126/3/583.full).
32. Assess whether the child has a dental home. If no dental home is identified, perform a risk assessment (https://www.aap.org/RiskAssessmentTool) and refer to a dental home. Recommend brushing with fluoride toothpaste in the proper dosage for age. See "Maintaining and Improving the Oral Health of Young Children" (http://pediatrics.aappublications.org/content/134/6/1224).
33. Perform a risk assessment (https://www.aap.org/RiskAssessmentTool). See "Maintaining and Improving the Oral Health of Young Children" (http://pediatrics.aappublications.org/content/134/6/1224).
34. See USPSTF recommendations (http://www.uspreventiveservicestaskforce.org/uspstf/uspsdnch.htm). Once teeth are present, fluoride varnish may be applied to all children every 3–6 months in the primary care or dental office. Indications for fluoride use are noted in "Fluoride Use in Caries Prevention in the Primary Care Setting"(http://pediatrics.aappublications.org/content/134/3/626).
35. If primary water source is deficient in fluoride, consider oral fluoride supplementation. See"Fluoride Use in Caries Prevention in the Primary Care Setting" (http://pediatrics.aappublications.org/content/134/3/626).

Summary of Changes Made to the Bright Futures/AAP Recommendations for Preventive Pediatric Health Care
(Periodicity Schedule)

This schedule reflects changes approved in February 2017 and published in April 2017.
For updates, visit www.aap.org/periodicityschedule.
For further information, see the *Bright Futures Guidelines* , 4th Edition, *Evidence and Rationale chapter* (https://brightfutures.aap.org/Bright%20Futures%20Documents/BF4_Evidence_Rationale.pdf).

CHANGES MADE IN FEBRUARY 2017

HEARING
- Timing and follow-up of the screening recommendations for hearing during the infancy visits have been delineated. Adolescent risk assessment has changed to screening once during each time period.
- Footnote 8 has been updated to read as follows: "Confirm initial screen was completed, verify results, and follow up, as appropriate Newborns should be screened, per 'Year 2007 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs' (http://pediatrics.aappublications.org/content/120/4/898.full)."
- Footnote 9 has been added to read as follows: "Verify results as soon as possible, and follow up, as appropriate."
- Footnote 10 has been added to read as follows: "Screen with audiometry including 6,000 and 8,000 Hz high frequencies once between 11 and 14 years, once between 15 and 17 years, and once between 18 and 21 years. See 'The Sensitivity of Adolescent Hearing Screens Significantly Improves by Adding High Frequencies' (http://www.jahonline.org/article/S1054-139X(16)00048-3/fulltext)."

PSYCHOSOCIAL/BEHAVIORAL ASSESSMENT
- Footnote 13 has been added to read as follows: "This assessment should be family centered and may include an assessment of child social–emotional health, caregiver depression, and social determinants of health. See 'Promoting Optimal Development: Screening for Behavioral and Emotional Problems' (http://pediatrics.aappublications.org/content/135/2/384) and 'Poverty and Child Health in the United States' (http://pediatrics.aappublications.org/content/137/4/e20160339)."

TOBACCO, ALCOHOL, OR DRUG USE ASSESSMENT
- The header was updated to be consistent with recommendations.

DEPRESSION SCREENING
- Adolescent depression screening begins routinely at 12 years of age (to be consistent with recommendations of the U.S. Preventive Services Task Force [USPSTF]).

MATERNAL DEPRESSION SCREENING
- Screening for maternal depression at 1-, 2-, 4-, and 6-month visits has been added.
- Footnote 16 was added to read as follows: "Screening should occur per 'Incorporating Recognition and Management of Perinatal and Postpartum Depression Into Pediatric Practice' (http://pediatrics.aappublications.org/content/126/5/1032)."

NEWBORN BLOOD
- Timing and follow-up of the newborn blood screening recommendations have been delineated.
- Footnote 19 has been updated to read as follows: "Confirm initial screen was accomplished, verify results, and follow up, as appropriate. The Recommended Uniform Newborn Screening Panel (http://www.hrsa.gov/advisorycommittees/mchbadvisory/heritabledisorders/recommendedpanel/uniformscreeningpanel.pdf), as determined by The Secretary's Advisory Committee on Heritable Disorders in Newborns and Children, and state newborn screening laws/regulations (http://genes-r-us.uthscsa.edu/sites/genes-r-us/files/nbsdisorders.pdf) establish the criteria for and coverage of newborn screening procedures and programs."
- Footnote 20 has been added to read as follows: "Verify results as soon as possible, and follow up, as appropriate."

NEWBORN BILIRUBIN
- Screening for bilirubin concentration at the newborn visit has been added.
- Footnote 21 has been added to read as follows: "Confirm initial screening was accomplished, verify results, and follow up, as appropriate. See 'Hyperbilirubinemia in the Newborn Infant ≥35 Weeks' Gestation: An Update With Clarifications' (http://pediatrics.aappublications.org/content/124/4/1193)."

DYSLIPIDEMIA
- Screening for dyslipidemia has been updated to occur once between the ages of 9 and 11 years, and once between the ages of 17 and 21 years (to be consistent with guidelines of the National Heart, Lung, and Blood Institute).

SEXUALLY TRANSMITTED INFECTIONS
- Footnote 29 has been updated to read as follows: "Adolescents should be screened for sexually transmitted infections (STIs) per recommendations in the current edition of the AAP*Red Book: Report of the Committee on Infectious Diseases*".

HIV
- A subheading has been added for the HIV universal recommendation to avoid confusion with STIs selective screening recommendation.
- Screening for HIV has been updated to occur once between the ages of 15 and 18 years (to be consistent with recommendations of the USPSTF).
- Footnote 30 has been added to read as follows: "Adolescents should be screened for HIV according to the USPSTF recommendations (http://www.uspreventiveservicestaskforce.org/uspstf/uspshivi.htm) once between the ages of 15 and 18, making every effort to preserve confidentiality of the adolescent. Those at increased risk of HIV infection, including those who are sexually active, participate in injection drug use, or are being tested for other STIs, should be tested for HIV and reassessed annually."

ORAL HEALTH
- Assessing for a dental home has been updated to occur at the 12-month and 18-month through 6-year visits. A subheading has been added for fluoride supplementation, with a recommendation from the 6-month through 12-month and 18-month through 16-year visits.
- Footnote 32 has been updated to read as follows: "Assess whether the child has a dental home. If no dental home is identified, perform a risk assessment (https://www.aap.org/RiskAssessmentTool) and refer to a dental home. Recommend brushing with fluoride toothpaste in the proper dosage for age. See 'Maintaining and Improving the Oral Health of Young Children' (https://pediatrics.aappublications.org/content/134/6/1224)."
- Footnote 33 has been updated to read as follows: "Perform a risk assessment (https://www.aap.org/RiskAssessmentTool). See 'Maintaining and Improving the Oral Health of Young Children' (http://pediatrics.aappublications.org/content/134/6/1224)."
- Footnote 35 has been added to read as follows: "If primary water source is deficient in fluoride, consider oral fluoride supplementation. See 'Fluoride Use in Caries Prevention in the Primary Care Setting' (http://pediatrics.aappublications.org/content/134/3/626)."

insurance were also referred less than white mothers or those with insurance (Barfield et al., 2008). Regional variation in EI participation/utilization has been also shown to be significant: Services are less likely to be delivered in the South of the United States (Grant & Isakson, 2012). McManus, McCormick, Acevedo-Garcia, Ganz, and Hauser-Cram (2009) found that both child characteristics (poverty) and state program (strict or liberal eligibility criteria) influenced EI participation: Nonpoor children, those who lived in states with strict eligibility criteria, were nearly as likely as poor children who lived in states with liberal eligibility criteria to receive EI services (McManus et al., 2009). In this study, the overall rate of EI participation was 45.7%, ranging from 23.1% to 83.3% across the states.

Another important issue is that some health professionals do not feel prepared to assess the high-risk infant and their families; thus, referral may be inadequate because of insufficient knowledge and training of health professionals (Ballantyne et al., 2017; Brown & Smith, 2018; Browne & Talmi, 2012; G. Currie et al., 2018; Tregay et al., 2016). In Colorado, a statewide survey revealed that 77% of providers would like to have more education on infant evaluation, and 86% were interested in further education (Browne & Talmi, 2012). After implementing the collaborative educational programs where additional training and education were provided for health professionals involved in EI services (BABIES and Pre-STEPS), the referral rate and service provision increased from 33% to 52% over a 1-year initiative (Browne & Talmi, 2012). The Zero to Three National Center for Infants, Toddlers, and Families is another nonprofit organization that provides training and education to professionals and families (www.zerotothree.org).

Long-term measurable outcomes of EI programs are sometimes not precisely detectable through the years after NICU discharge, yet beneficial effects have been found in the most vulnerable children with complications (Spittle et al., 2015). Many high-risk infants are discharged with home oxygen, specific medications, and feeding tubes and may suffer long-term consequences of initial disease. In the United States, the estimated number of children with special healthcare needs (CSHCN) nationwide is 11,203,616 or 15.1% of the population; 14.8% of those have at least one unmet specific health need, and 23.4% have problems with getting referrals (National Survey of Children With Special Health Care Needs, 2009–2010, retrieved from www.childhealthdata.org). Thus, health professionals should carefully consider all the problems with provision of adequate postdischarge care and undertake appropriate actions to help NICU graduates, such as appropriate referral to specific treatments or EI services. Resources for information in EI services include the national Early Childhood Technical Assistance Center (ECTA; http://ectacenter.org/Default.asp).

One of the complications of newborn health issues is CP. The prevalence of CP at present is decreasing; even extremely low birth weight infants have only minor functional impairments (Johnson & Marlow, 2017). However, this is an important topic in postdischarge care that deserves attention from healthcare professionals. Over 1 billion people live with a disability, of which 200 million are children; more than 17 million people are living with a diagnosis of CP in the world (World Health Organization, 2011). CP is the most common physical disability of childhood, with one baby born with CP every 500 live births. The prevalence across the world varies with difficulty in obtaining accurate data from countries without data registries. Recently published Australian data report one of the few national decreases in the prevalence (and severity) of CP from 2–2.5 to 1.6–2 per 1,000 live births (Smithers-Sheedy et al., 2016).

In 2007, Rosenbaum and colleagues defined CP as a group of permanent disorders of the development of movement and posture, causing activity limitations that are attributed to nonprogressive disturbances that occurred in the developing fetal or infant brain (Rosenbaum et al., 2007). The motor disorders of CP are often accompanied by disturbances of sensation, perception, cognition, communication, and behavior; by epilepsy; and by secondary musculoskeletal problems (Rosenbaum et al., 2007). The injury to the brain in CP is static; however, accompanying impairments and comorbidities can be as disabling as the motor impairment and worsen over time (Novak, Hines, Goldsmith, & Barclay, 2012). Associated impairments include epilepsy (29%), speech (>60%), vision (>30%), and hearing impairments (>10%), with greater than 50% of children at 5 years having some level of intellectual impairment. CP is classified into four predominant types: spastic (85%), dyskinetic (6%), ataxic (5%), and hypotonic (3%). The majority of injury occurs in the perinatal period (94%); however, CP does occur in early childhood. Prematurity and low birth weight are known risk factors for CP; however, for many infants, the complete causal pathway remains unclear. It is often associated with factors such as birth asphyxia, congenital infections, birth defects, sentinel events such as acute and sustained fetal bradycardia, head trauma, or cerebral infarctions (Smithers-Sheedy et al., 2016).

The average age at which a child receives a diagnosis of CP is approximately 18 months. However, earlier identification is important as the optimal time for neuroplasticity, and therefore, the opportunity for targeted EI is in the young infant. Within the past few years in some neonatal units and follow-up clinics, there has been a significant shift in focus from a referral for EI with a confirmed diagnosis of CP to the referral of babies deemed to be "at risk" of CP (McIntyre, Morgan, Walker, & Novak, 2011) related to the implementation of the general movements (GMs) assessment into clinical practice within many neonatal units. The GMs assessment evaluates the quality of movement in infants to approximately 5 months post-term age. Research has shown that the GMs is a strong predictor of CP in the preterm infant and has also been shown to be useful when used with infants requiring major surgery (Crowle, Galea, Walker, Novak, & Badawi, 2018). It is important, therefore, that neonatal nurses should have knowledge of the risk factors and tools available for early identification of babies with CP or those in the neonatal units deemed to be "at high risk" of CP. Neonatal nurses have an integral role, not only in saving the lives of small and sick neonates, but preventing disability and in the early identification of these "at-risk" infants.

In 2017, the landmark international guidelines were published, providing contemporary evidence-based data on optimal early diagnosis and intervention for children with CP. These guidelines state that CP can be predicted with a high degree of accuracy in infants less than 5 months of age using the GMs assessments, the Hammersmith Infant Neurological Assessment (HINE), and neuroimaging with magnetic resonance imaging (MRI; Novak et al., 2017). They also provide data to guide early detection of infants in low- and middle-income countries (LMICs) where imaging may not be available. Neonatal nurses should be aware of these guidelines as increasing evidence supports the value of EI in improving outcomes: The earlier the CP is identified, the more optimal the outcomes are. As CP is a lifelong condition, parents require accurate information regarding the outcomes, interventions, and supports available (Ballantyne et al., 2018). Neonatal nurses must consider that the priority is not only saving lives but consistently implementing neuroprotective strategies to prevent or minimize disability. These include, but are not limited to, skilled biochemical knowledge, gentle handling and positioning, minimizing stressors and reducing pain, optimizing nutrition and growth, and supporting families in the care of their baby. Babies identified as "at risk"

can be referred for intervention to therapists while in the NICU, and families may be referred to CP-specific services when they leave the neonatal unit. Neonatal intensive care transcends from the immediate focus on survival to the long-term infant.

Rehospitalizations and Readmissions

The health issues of NICU graduates can be complex and numerous. The associated costs of the hospital and posthospital care, readmissions, and rehospitalizations are enormous as well (Arth et al., 2017; Barradas et al., 2016; Frawley, 2017; Grosse, Waitzman, Yang, Abe, & Barfield, 2017; McLaurin, Wade, Farr, & Franklin, 2017; McLaurin, Hall, Jackson, Owens, & Mahadevia, 2009; Underwood, Danielsen, & Gilbert, 2007). In 2013, in the United States, the cost of birth defects' hospitalizations only was estimated at $23 billion (Arth et al., 2017). Readmissions in the NICU patients, especially in preterm infants, can be twice as high as those in the term group, even when there is good follow-up care (McLaurin et al., 2009). In today's healthcare market and with the move toward the creation of accountable care organizations (ACOs), the concerns are growing around increased costs related to readmissions. Population-level study in the United Kingdom showed that 5% of healthy infants were readmitted within the first 30 days after birth (Harron, Gilbert, Cromwell, Oddie, & van der Meulen, 2017). The rates of readmission in preterm infants can be much higher (up to 50%) depending on the initial neonatal health problems, comorbidities, and adequacy of postdischarge and follow-up care, especially in the first 3 months after discharge (Bird et al., 2010; Girgin & Güler, 2017; Kuzniewicz, Parker, Schnake-Mahl, & Escobar, 2013; Ralser et al., 2012; Spicer et al., 2008). Readmission rates are also related to postdischarge mortality rates. In infants weighing less than 1,000 g and less than 27 weeks of gestation, De Jesus and coworkers found that post-NICU discharge mortality rate was 22.3 per 1,000 extremely low birth weight infants, with African American race, unknown medical insurance, and prolonged hospital stay as risk factors (De Jesus et al., 2012). To understand the magnitude of this fact, it is important to note that the overall infant mortality rate in the United States in 2010 was 5.87 infant deaths per 1,000 live births (Ely, 2018). Preterm infants are likely to require readmission more often than their term counterparts: Late preterm infants had almost four times the risk of readmission compared with term infants, early preterm twice the risk, and moderate preterm 2.5 times the risk (Kuzniewicz et al., 2013; McLaurin et al., 2009). Surgical patients also have a high incidence of readmissions. South and colleagues reported that 40% of NICU graduates with gastroschisis were readmitted, and 65% of readmissions occurred during the first year of life (South, Wessel, Sberna, Patel, & Morrow, 2011). Readmissions were not associated with gestational age, birth weight, or the length of hospital initial stay; one of the main reasons was abdominal distention/pain. In children with CHD, readmissions occurred in one in five infants within 1 month after discharge (Mackie, Ionescu-Ittu, Pilote, Rahme, & Marelli, 2008); data from the U.K. national cardiac audit (2005–2010) showed that up to 7% of infants with CHD were readmitted within 1 year after discharge (Crowe et al., 2015). The first weeks and months following discharge are the times of highest risk for readmissions, especially if the mother is a teenager (Ray, Escobar, & Lorch, 2010). Emergency department visits are much more costly than primary care visits, yet families often feel they need the expertise of an acute care facility. The use of the hospital versus primary care services needs further research, as does the impact of parents' readiness for the transition to home on readmissions. Providing care for parents after discharge is just as important as providing family-centered care in the NICU.

Postdischarge Family Care

The concept of the family as a unit is another important issue for providing adequate care for infants after discharge. Postdischarge care should focus not only on the mother but other family members as well. The father and siblings are often forgotten during discharge preparation and afterward despite the stress they suffer (Noergaard, Ammentorp, Garne, Fenger-Gron, & Kofoed, 2018; Prouhet, Gregory, Russell, & Yaeger, 2018). Most fathers want to participate in the care and decision making for a healthy or sick/premature newborn; they require the same support (e.g., social) as mothers (Kim, 2018). The responses of fathers are sometimes different from those of mothers, but fathers also get stressed to a large extent while the baby is in the NICU and afterward (Hynan, 2016; Noergaard et al., 2018; Prouhet et al., 2018). Siblings must also adjust to the infant, who may not seem real to them, until they are able to visit the infant in the NICU (Gaal et al., 2010; Morrison & Gullón-Rivera, 2017). Many units now encourage sibling visits to help ease the infant into the family well before the actual discharge. The change in NICU design to more single rooms and the inclusion of family areas or transition areas afford the family more opportunities to stay together as a family unit. This design provides the family with more of a homelike atmosphere while offering more privacy to them (White, 2011). This concept of care needs to continue following the discharge.

CARE FOR PARENTS AFTER HOSPITAL DISCHARGE

Parenting and caring of the vulnerable infant upon coming home can be very challenging for parents. AAP Committee on Fetus and Newborn (2008) guidelines for discharge of the high-risk infants state that the "infant may be discharged before one of the infant's physiological competencies has been met, provided the health care team and the parents agree that it is appropriate, and suitable plans have been made to provide the additional support needed to ensure safe care at home" (p. 1121). These guidelines also state that parents should be actively involved and prepared for caring for a baby at home. Preparedness of parents for discharge and postdischarge as well as professional support are vital to ensure a successful transition home (AAP & ACOG, 2017). However, it has repeatedly been shown that mothers rarely recall all the information given to them by health professionals within the hospital: Stress related to their infant's hospitalization and at the time of discharge makes advice and teaching overwhelming (Burnham, Feeley, & Sherrard, 2013; Kenner & Lott, 1990; Loo, Espinosa, Tyler, & Howard, 2003; McKim et al., 1995; Weiss et al., 2017). Smith and colleagues found that 12% of families (N = 285) feel unprepared for discharge; those families were more likely to report feeding problems, difficulties in obtaining supplies, and the inability of the pediatrician to access the discharge summary (Smith, Dukhovny, Zupancic, Gates, & Pursley, 2012; Smith, Young, Pursley, McCormick, & Zupancic, 2009). Also, nurses need to address parental views on their infant before discharge: In pediatric populations, parents' perception of their child's health at discharge was associated with the risk of a subsequent, unplanned readmission (Berry et al., 2013). The hospitalization and discharge of high-risk and preterm newborn infants always hold certain risks for the health of the infant. These times should be considered as serious challenges for parents.

NICU Experience

Giving birth to a sick or small infant interferes with the development of the role of the parent. Try to remember the first time you walked into the NICU. What were your thoughts and feelings? We

know what ours were—an overwhelming urge to flee. Time seemed to be running. People were rushing and talking loudly; alarms were buzzing, intercoms were blaring, and doors were slamming. We suddenly felt tense, on edge, and fearful of our ability to survive in such an environment. Then we walked over to an incubator and peered in at a premature infant—born at 28 weeks' gestation and weighing less than 1,000 g—who looked as though she had been through a war. Scratches and cuts were visible. Tape cut into the infant's face to hold an endotracheal tube in place. The right arm was pinned to the bed to hold an intravenous line in place, and her legs were restrained to prevent dislodgment of an umbilical arterial line that was being used for blood gas sampling. Our hearts sank. We could never be responsible for providing care to this type of infant. We tried to summon the courage to walk—if not run—out of there. We were almost immobilized—yet we recognized some of the ventilators, intravenous pumps, and monitors. Surely, with this passing acquaintance, we could learn to work in this environment and actually care for the critically ill infant. Now more than 30 years later, the units are quieter, and they look more like a home environment. Attention is paid to lighting and noise, and parents are an integral part of the environment. Yet the sense of overwhelming responsibility still resides in new health professionals.

If we feel that way, what do parents feel? Their feelings are much more intense. They have the additional fear of death of a family member, a vulnerable infant whose birth should be celebrated and yet a sense of doom clouds the birth experience. For the most part, parents lack knowledge about the medical diagnosis, equipment, treatments, and routines necessary to support neonates—their baby. In the past few decades, research has repeatedly shown that the NICU environment is extremely stressful for parents and can lead to alterations in their parental role, both inside and outside the hospital, that can last a lifetime if there is no attention/intervention (Diffin, Spence, Naranian, Badawi, & Johnston, 2016; Gerstein, Njoroge, Paul, Smyser, & Rogers, 2019; Holditch-Davis et al., 2009; Holditch-Davis, Miles, Burchinal, & Goldman, 2011; Miles, Funk, & Kasper, 1992; Raines, 2013; Seideman et al., 1997). The mothers must, in addition, make a physiological and psychological postpartum adjustment. They are also in need of care, yet most mothers when asked express the need to put aside their own time for healing to focus on their infants. For the fathers, the NICU experience is also stressful (Mackley, Locke, Spear, & Joseph, 2010; Prouhet et al., 2018; Sloan, Rowe, & Jones, 2008); the need to run between two units (the postpartum and the NICU) is an added stress even if these units are in the same institution. Constraints of work are also impressive (Hollywood & Hollywood, 2011; Ireland, Minesh, Cescutti-Butler, van Teijlingen, & Hewitt-Taylor, 2016; Noergaard et al., 2018). The parents' concern for their partners and their children often forces them between the two. For the family with other children at home, the stress becomes even greater. Who can take charge of the children? How long will it be necessary for another person to help with family responsibilities? Is someone who can or will step in to help even be available? These are very real family concerns that continue to exist after hospital discharge of the former NICU infant. New challenges also occur—questions about care to give to the infant, infant development, and the future. Along with these concerns comes the assumption of the new parental role. This role adjustment occurs for both first-time and experienced parents. It requires a change from a previous functional pattern to a new one. This change marks a developmental passage or transition.

Transition

Throughout life, events necessitate change. These life changes are often viewed as turning points. In the case of an NICU family, these turning points are the birth of a sick or preterm infant, hospitalization, and discharge from hospital and the transition to home. All these events require a new role acceptance (to accept the reality, facts about their infant's health), an adjustment or change in role, a setting of new priorities, and an examination of expectations. Taking on a new role requires energy, commitment, and, most of all, a change in the pattern of functioning—thus a transition. Transition involves change—leaving behind the familiar and trying something new. There are at least three transition processes for parents of NICU infants: transition to parenthood, transition to home, and transition to primary healthcare settings.

Transition to Parenthood. The role of parent is a good example of the transition process. For parents of an NICU infant, the transition to parenthood may have two time points—one associated with becoming parents at the time of birth and the other occurring at the time of discharge. Two important processes can be impeded in NICU parents, specifically mothers, while in the hospital: maternal role attainment (MRA) and attachment. These disturbances have consequences that may extend beyond the immediate posthospital discharge period, and both mothers and fathers can be struggling with certain problems, such as psychological distress and lower confidence in parenting (Brandon et al., 2011; Harris, Gibbs, Mangin-Heimos, & Pineda, 2018; Holditch-Davis et al., 2015; Hollywood & Hollywood, 2011; Noergaard et al., 2018; Prouhet et al., 2018; Wolke, Eryigit-Madzwamuse, & Gutbrod, 2014).

Once a pregnancy is confirmed, both mother and father begin the task of examining their individual roles. For first-time parents, this means considering what it will be like to be a mother or father to a dependent infant. For parents with other children, the new infant will bring a unique personality and another dimension to the already formed family unit. This infant, too, will require role adjustment on the part of the parents. Acquisition of the maternal role and maternal identity, as described by Rubin (1984) and Mercer (1995), focused on mothers of healthy, term infants (Mercer, 1995; Rubin, 1984). When the infant is premature or sick and does not fit the image of the desired child, women lose their normal frame of reference for the development of their own role expectations and the expectations of their infants as well. Later, MRA had been replaced with the new term, "Becoming a Mother" (BAM), as a more inclusive and comprehensive concept where maternal confidence and identity continues to grow or can be disrupted with a child's developmental challenges and life's realities (Mercer, 2004). Decreased MRA was observed with medically fragile infants due to high levels of worry in mothers and less responsiveness of infants (Miles, Holditch-Davis, Burchinal, & Brunssen, 2011); parenting quality has been shown to be influenced more by MRA than by child illness severity (Holditch-Davis et al., 2011).

The immediate process of attachment, a formation of a relationship between a parent and her or his newborn infant, occurs with wanting the pregnancy, positive maternal feelings, seeing the infant soon after birth, and immediate contact with the infant after birth (Bialoskurski, Cox, & Hayes, 1999; Vazquez & Cong, 2014). Delayed and problematic attachment occurs with a premature infant; uncertain outcomes; a handicapped child; poor maternal health; prolonged care that limits the family's ability to touch, hold, and protect their infant; a poor attitude in the partner; a lack of social support; drug dependency; and a taking-one-day-at-a-time attitude (Spinelli et al., 2015; Zabielski, 1994). Attachment, which is considered a dyadic process, becomes a triadic relationship in the NICU, in which NICU personnel—especially nurses—can alter the process. The mother of a premature infant is also a premature mother. Not only are the binding-in and claiming processes affected, but the mother herself is a "preemie" as well. Her pregnancy has ended before her own expectations were met and

needs were fulfilled. The interactive and therapeutic relationships between a nurse and a mother foster the process of BAM; moreover, instructions without nurse input are not effective (Mercer & Walker, 2006). Nurses can hinder or facilitate a mother's attachment to her infant by encouraging mother–infant touch or by forbidding it. Provision of accurate information about the infant's care, health status, and ongoing communication can facilitate the formation of attachment and bonding (Cox & Bialoskurski, 2001; Mäkelä, Axelin, Feeley, & Niela-Vilén, 2018) as well as improve interactions between parents and healthcare professionals (Epstein et al., 2017). Nurses at the NICU were named as the best source of information that helped parents to understand infants' medical conditions (Kowalski, Leef, Mackley, Spear, & Paul, 2006). Research has also shown that a decrease in maternal stress as well as a decrease in early separation during hospitalization can prevent the development of distorted attachments in mothers of preterm infants (Korja, Latva, & Lehtonen, 2012). Also, those mothers can form balanced attachments with their infants, and maternal–infant interaction may be more positive and of higher quality than in mothers of full-term infants if maternal stress is managed and their interaction is fostered prior to and following discharge (Korja et al., 2012; Treherne, Feeley, Charbonneau, & Axelin, 2017).

In addition to possible affected attachment and development of parental role, the actual assumption of the new parental role can be quite overwhelming. Even when a healthy newborn is brought into a family, stress and even crisis can occur (Emmanuel & St John, 2010; Miller & Sollie, 1980). Some researchers and clinicians view transition to parenthood as a *crisis* rather than just a developmental passage to a new functional level. Since the 1970s, research has shown that families see birth hospitalization and bringing home a premature or ill infant who has been in the NICU as a crisis (Affleck & Tennen, 1991; Caplan, Mason, & Kaplan, 1965). Even parents of low-risk premature infants suffer from distress (Jones, Rowe, & Becker, 2009). During hospitalization, parents often suffer from acute stress disorder (Helle, Barkmann, Ehrhardt, & Bindt, 2018; Jubinville, Newburn-Cook, Hegadoren, & Lacaze-Masmonteil, 2012) that can exist for a longer time after discharge as posttraumatic stress disorder (PTSD; Helle et al., 2018; Kersting et al., 2004; Shaw et al., 2009). Symptoms of PTSD include (a) reexperiencing the phenomenon (NICU traumatic experience); (b) avoiding thoughts, feelings, places, and people associated with the event; and (c) hyperarousal symptoms (such as irritability, startling easily, anger, and difficulties with sleeping; Mowery, 2011). One national survey showed that 9% of new mothers experience PTSD (Beck, Gable, Sakala, & Declercq, 2011). Even if the infant requires no special equipment postdischarge or does not suffer from the initial neonatal disorder, the family may still experience PTSD related to the initial hospitalization and long-term consequences of initial psychological trauma for family. Recent research showed that parents of high-risk newborns often had higher levels of PTSD symptoms and depression; for an entire family, parenting of high-risk neonates led to fewer years of education of family members, higher unemployment, lower incomes, distortion of marital relationships, and family strain (Cook, Ayers, & Horsch, 2018; Placencia & McCullough, 2012). Fortunately, the negative effects of neonatal hospitalization on family functioning, quality of life, and child behavior have been shown to decrease with time, and the family may adjust well, even with a neurosensory-impaired child (Hall et al., 2017; Saigal, Pinelli, Streiner, Boyle, & Stoskopf, 2010). A recent study reported an unclear role of PTSD on infant development (Cook et al., 2018). Rautava, Lehtonen, Helenius, and Sillanpaa (2003) followed 170 Finnish preterm infants and their families for 12 years. At 3 years of age, children in a high-risk group were reported as having more sleep and behavioral problems compared with those in a low-risk group; all of these differences disappeared by the time the children were 12 years old (Rautava et al., 2003). In Saigal et al.'s (2010) study that examined the impact of illness in young adults born with extremely low birth weight at age 20, mothers reported that caring for their child with neurosensory impairment had even brought their family closer together (Saigal et al., 2010). What is important is helping families to cope with initial transitions after hospital discharge. At 2 years after discharge, social isolation, financial burden, unpaid time off from work, issues related to home safety, and enrollment to the EI programs were the important issues revealed by parents of preterm infants and infants with CHD (Brown & Smith, 2018; Lakshmanan et al., 2017).

Two other major problems can occur when parenting high-risk and preterm infants after discharge. These are vulnerable child syndrome (VCS) and compensatory parenting. Parental responses to their infant are mediated by the infant's illness, the hospitalization, and "near-miss" events. The VCS is one such response that has an impact on both the infant and parents. Green and Solnit (1964) hypothesized that, when children are expected to die prematurely or were seriously injured, the result is a disturbed psychosocial development of the family, based on the parent–child relationship (Green & Solnit, 1964). Because the child is seen as "vulnerable," parents overprotect the child, make more visits to healthcare providers for relatively minor illnesses, and may discipline the child in a gentler manner, which may result in behavior problems (Kokotos & Adam, 2009; Levy, 1980; Tallandini, Morsan, Gronchi, & Macagno, 2015). It has been shown that even neonatal jaundice and inpatient phototherapy can contribute to the VCS development because the infant is labeled as sick and vulnerable by the parents (Usatin, Liljestrand, Kuzniewicz, Escobar, & Newman, 2010). What is important is the fact that VCS is a family disorder cyclically affecting both parents and children (Chambers, Mahabee-Gittens, & Leonard, 2011; Greene, Rossman, Meier, & Patra, 2017). Allen et al. (2004) found that higher maternal perception of child vulnerability was associated with worse developmental outcomes and lower adaptive functioning in preterm infants less than 32 weeks of gestation with CLD at 1-year adjusted age. The mothers who perceived their children as more vulnerable were more anxious, more depressed, and perceived a greater impact of illness on the family; longer hospitalization and maternal anxiety at discharge predicted higher perception of child vulnerability (Allen et al., 2004). Research has shown that maternal adaptation during the neonatal period and maternal self-inefficacy beliefs about feeding the infant predicted the mother's later perceptions of the infant's vulnerability at the first 4 months of corrected age (Teti, Hess, & O'Connell, 2005). Thus, maternal attachment, development of parental role, and perception of the infant health influence the entire postdischarge well-being of the family and infant.

Compensatory parenting is another disturbance when parenting an initially hospitalized child. This parenting style is compensation for feeling sorry for or guilty about having an infant in the NICU (Miles & Holditch-Davis, 1995). Parents try to provide special experiences for their infants born preterm and avoid other experiences; sometimes more stimulation to foster development with these children is provided. At the same time, they have shielded their children from other life situations to protect them from further hurt, viewing them as "special" and "normal" at the same time (Miles & Holditch-Davis, 1997).

Disturbances in parenting occurring in parents are tightly related to parental psychological well-being. Anxiety and depression have been documented in parents of high-risk and preterm infants, both in the hospital and postdischarge, and especially

in low-income families (Enlow et al., 2017). At discharge, 43% of mothers of preterm infants had moderate-to-severe anxiety, and 20% had clinically significant levels of depression (Rogers, Kidokoro, Wallendorf, & Inder, 2013). Importantly, maternal anxiety and depression at the NICU was shown to be predictive of adverse interactive behaviors, lower child cognitive development, and behavioral problems in infants weighing less than 1,500 g at later ages (McManus & Poehlmann, 2012; Zelkowitz, Na, Wang, Bardin, & Papageorgiou, 2011). Fortunately, it has also been reported that parental distress, depression, and anxiety decrease over time and sometimes have no negative impact in terms of parenting; however, correlation of depression can be different at discharge and a few months later (Hall et al., 2017; Mew, Holditch-Davis, Belyea, Miles, & Fishel, 2003; Padovani, Carvalho, Duarte, Martinez, & Linhares, 2009). In addition, on a positive note, a recent study showed that participation in EI programs was not limited by depressive symptoms in mothers (Feinberg, Donahue, Bliss, & Silverstein, 2012).

"Searching for normalcy" and grief are other aspects of parental challenges (Benfield, Leib, & Reuter, 1976; Golish & Powell, 2003; May, 1997; Tomlin, Deloian, & Wollesen, 2016; Valizadeh, Zamanzadeh, & Rahiminia, 2012; Whittingham, Boyd, Sanders, & Colditz, 2014). Mothers are searching for normalcy in their lives through caring of the low birth weight infants when they are at home; learning caregiving, maintaining vigilance for infant's progress, normalizing with caregiver burden, and help seeking are main themes (May, 1997). Contradictory feelings of joy and grief are also present in parents of preterm infants who lost the "ideal child" and are often unable to communicate that feeling of loss (Golish & Powell, 2003). Unresolved grief may lead to insecure attachment and inadequate interactions between mother and baby (Shah, Clements, & Poehlmann, 2011). What is important here is that the normal grief response can become a chronic sorrow in parents who have a child with permanent, progressive, or cyclic health problems; this chronic sorrow can even become a pathological grief (Gordon, 2009).

Transition to Home. Although the NICU discharge is the overriding goal for the healthcare professional and the family, the actual transition to home can be a time of crisis for the family. Transition to home can be even more difficult for parents than the period of the infant's hospitalization because parents are moving from a safe hospital environment to home and taking all the responsibilities for the care of their vulnerable infant (Ballantyne et al., 2017; Murch & Smith, 2016). For many parents, the NICU reinforces learned helplessness. Parents express the need to understand their role and what is expected of them in relationship to their infants' care needs; yet they feel "in the way" and unable or incapable of caring for their infants. Thus, they learn to be helpless. The picture changes, however, at the time of discharge when parents move from the safety net of the hospital to independent caregiving at home and accepting total responsibility for their infants. The parents are told, "Now it is your turn." It is no wonder that this discharge can be cognitively appraised as being a stress and that early parenting problems, possible risks in relationship development, can affect both family and the infant (Anderson, Riesch, Pridham, Lutz, & Becker, 2010; Lutz, Anderson, Riesch, Pridham, & Becker, 2009). Parents should be a part of the NICU healthcare team in order to fully understand what is wrong with their infant and to feel able to make decisions. When given the opportunity to discuss their concerns, parents are vocal about their feelings regarding their NICU care and preparation for discharge. One family stated, "The only time that the physicians really asked us our opinion or told us about the baby's condition was when they were obligated to get informed consent for an experimental treatment." Another family said, "We would ask the nurses about the baby's apnea, but they said they had to check with the physicians and they would have to talk to us." Other comments included, "I never understood why nurses just came over and turned off our baby's sounding alarms without seemingly looking at the baby."

Preparedness for discharge is vital. Information is critical to the successful transition home. Recent studies show that families are not always well prepared for discharge, and especially those with limited English proficiency (Berman et al., 2018; Obregon, Martin, Frantz Iii, Patel, & Smith, 2019; Smith et al., 2012). Even when parents report that they are prepared at discharge, parents can be naively confident in caregiving and, in fact, be unable to provide proper care at home (Hess, Teti, & Hussey-Gardner, 2004). It can be assumed that inadequacy of caregiving and skills when caring for vulnerable infants may affect the health status of an infant and lead to readmissions or overuse of healthcare services. This assumption needs further research.

Transition to home can be especially challenging for parents if the infant requires technology at home or has specific healthcare needs. All the healthcare needs of the infant often require advanced knowledge and skills from parents and primary healthcare providers. One study showed that 19% of moderately preterm infants were discharged home with ongoing medical needs and the use of durable medical equipment such as apnea monitors, oxygen, or feeding tubes (Kirkby, Greenspan, Kornhauser, & Schneiderman, 2007). All these ongoing healthcare needs require additional support and education of parents postdischarge. Feeding issues (such as tube feedings, food intolerance, breastfeeding problems, and formula selection) as well as developmental concerns bring enormous stress on parents (Lutz, 2012; Sanchez, Spittle, Slattery, & Morgan, 2016; Spiegler et al., 2013). More than two decades of research showed that the needs in informational support in parents of infants is very high, both when healthy and sick, both in the hospital and afterward (Boykova, 2016a, 2016b; Brazy, Anderson, Becker, & Becker, 2001; De Rouck & Leys, 2009, 2011; Kenner, 1990; Kenner & Lott, 1990; McKim, 1993; Radecki, Olson, Frintner, Tanner, & Stein, 2009). Parents often feel unprepared (Sneath, 2009), and especially adolescent mothers (Enke, Oliva y Hausmann, Miedaner, Roth, & Woopen, 2017; Hymas & Girard, 2018; White-Traut et al., 2017). Importantly, knowledge and skills needed by parents sometimes differ from those provided by health professionals (Drake, 1995; Toral-López et al., 2016), and fulfilling individual information needs of parents is vital. Even assuming that some infants have to be rehospitalized due to medical conditions and parent education might have little effect in such cases (Klein, 2011); transition from hospital to home remains to be dependent on the levels of parental knowledge and skills, competency and confidence in caring for an infant, and availability of professional and social supports. Yet there is limited research on transitional problems in parents of NICU patients, as well as solid theoretical frameworks and validated measurement tools. Some concepts of transition for parents of NICU infants are presented in Figure 37.4. One of the available models and instruments is described as follows.

Example of Theoretical Framework on Parental Transition From NICU to Home. One theoretical model has been developed in the 1990s for parents of NICU patients who transitioned from hospital to home—the Transition Model developed by Kenner and colleagues (Flandermeyer, Kenner, Spaite, & Hostiuck, 1992a, 1992b; Kenner, 1988, 1990; Kenner & Lott, 1990). A series of studies were conducted on parents of both term and preterm infants after hospital discharge. Five main parental transitional challenges were identified in the immediate postdischarge period: Informational Needs, Parent–Child Role Development, Stress

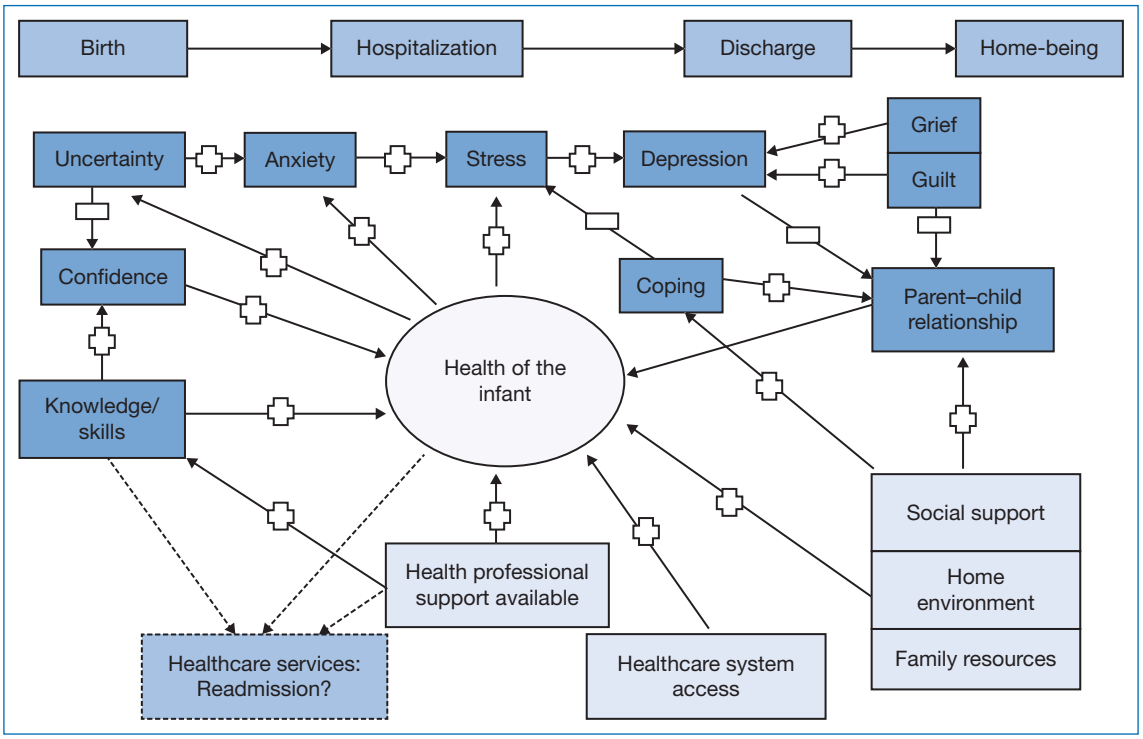

FIGURE 37.4 Concepts involved in transition derived from the literature and possible relationships among parental challenges, knowledge, infant health, professional support, and readmissions.

and Coping, Social Interaction, and Grief. Despite the changes in neonatal intensive care and health provision, these concepts are still standing for transitional concerns of parents of high-risk infants who were hospitalized after birth.

Informational Needs. The informational needs of parents include the following:

1. How to provide routine newborn care (e.g., feeding, bathing)
2. How to recognize normal newborn characteristics, both physical and behavioral (amount of "normal" crying) as well as any warning signs
3. How to keep the infant healthy after discharge (i.e., immunizations)
4. How to recognize if their infant is not well; sleeping and awake periods
5. Infant development and prognosis for future
6. Equipment used on their infant at home if any. During home follow-up, parents, particularly mothers, want more information about feeding, formula, breastfeeding, elimination patterns, weight gain, and the infant's breathing pattern.

Parent–Child Role Development. This category refers to parents and children's role expectations that are influenced by the development of relationships and interactions with an infant, which can be impaired by the infant's initial illness or special healthcare needs and interfere with the development of parental role. For anyone making a transition or entering a new level of functioning or a new stage of life, certain expectations about what is to come exist. New parents of healthy infants adjust in how they carry out the tasks of daily living once their newborn is at home. When a problem with the infant who requires more attention or special care arises, parents may have to set aside their expectations of their roles and feel inadequate in parenting and making healthcare decisions for the infant. The parents may feel that they are not "real" parents and not capable of parenting and caring for their infant and that the physician's permission is necessary to make even the smallest change in the infants' routines that had been established in the hospital.

Stress and Coping. Stress and coping are related to alterations in parental role, uncertainty and anxiety caused by health problems of the infant, and parental perceptions of their abilities to care and cope with challenges at home. The expected feelings of joy and the months of anticipation of discharge to home are replaced by sharply contrasting feelings of fear, anxiety, caregiver's tiredness, and overwhelming stress. Coping abilities that have to be present to overcome the stress of discharge depend on resources available (informational, material, and social).

Social Support and Interaction. The Social Interaction category includes parents' ability to socialize after their infant is born sick or preterm. Often, parents isolate themselves due to healthcare risks for their infant (such as RSV infection) or limit their social activities because of misunderstanding about their infant's health issues or if their infant is technology dependent; the feeling of isolation related to protection of a baby is prominent in contemporary research as well (Enlow et al., 2017; Gullino et al., 2017). On the other hand, family and friends may be frightened to approach the parents for fear of doing or saying the wrong thing, thus isolating parents of a vulnerable infant. Social interaction depends on social support from the parental informal network, and the recipient (Kim, 2018; McKim et al., 1995) determines support from healthcare professionals, which can be viewed positively or negatively as perception of the support. Recent studies on transition from hospital to home showed that support improves confidence in care as parenting a high-risk or preterm infant can be socially disruptive (Adama, Bayes, & Sundin, 2016; Ballantyne et al., 2017; Boykova, 2016a).

Grief. Grief found in parents of NICU infants is related to loss of the image of an "ideal" infant and fear of the infant's ultimate death that influences relationships between the parent and infant within the family as a whole and social interaction. Parents express the loss of their expected child once the reality of the neonatal problem shatters their hopes and fantasies. As time goes on, parents continue to grieve but in the form of anticipating that the infant

would eventually die if he or she would be sick enough to require special care or have developmental problems. The process of grief and the period of mourning begin once the infant does not meet the parents' expectations of the fantasy or ideal child. If the parents have other children, they may speak of how different this child is from their other children or how different the infant is from their expectations. Another component of grief is the loss of the expected parenting role—that is, their normal role. Some or all of the social rituals that socialize mothers into their impending role and prepare them for their new responsibilities—such as baby showers, parenting classes, and birth announcements—may often have been absent with the birth of a premature or ill infant. Friends and family who would normally be happy to help celebrate the joyous occasion of birth with the exuberant parents may feel uncomfortable and helpless around them, thus withdrawing needed psychological support.

These categories form the basis for transition to home and have not changed in almost three decades (Boykova, 2016b; Boykova & Kenner, 2012). These five categories of parental concerns represent the taxonomy for transitional care follow-up. All concepts are interrelated, and relationships between them are reciprocal, with Informational Needs being the core category. The main feature of the model is that transition is viewed as a process, not the product or outcome of changes that were brought to parents with the birth of a vulnerable child. Hospitalization of an infant is the key factor that might influence postdischarge transition to home. This assumption was confirmed in other studies through the years: Kenner (1988) and Bagwell (1990) found that parents from Level II and III units had similar concerns after hospital discharge; Boykova (2008) did not find any correlation between parental transitional concerns and birth weight or gestational age of former NICU infants (see the depiction of the model in Figure 37.5; Bagwell, 1990; Boykova, 2008; Kenner, 1988); a recent UK study also revealed information needs in parents of high-risk infants (Tregay et al., 2016).

The Transition Model has a specific multidimensional tool for the measurement of transition challenges in parents of NICU infants—the Transition Questionnaire.

Transition Questionnaire. The original Kenner Transition Questionnaire (Boykova & Kenner, 2012) consisted of four parts:

1. Thirty-seven statements in Likert-scale format that measure parental concerns and perceptions postdischarge
2. Three multiple-choice-format items considering certain informational needs in parents
3. Three open-ended questions related to parental concerns after discharge that they might have had
4. Demographic information part of the tool, consisting of 21 items about the parent and infant

Several items are negatively worded in order to decrease response bias; 17 items have to be reversed when scoring. Scores on each item of the Likert-scale format are summed for the total score, as well as for subscales. The possible range of scores is 37 to 185, with the larger score reflecting fewer problems after discharge. The dimensions of the instrument are Informational Needs (6 items), Stress and Coping (15 items), Parent–Child Role Development (9 items), Grief (4 items), and Social Interaction (3 items). The item readability level is the fifth grade; time to complete the tool is approximately 15 to 25 minutes. Examples of the items are (a) "I feel competent in caring for my child," (b) "I have trouble sleeping at night because I worry about my child," (c) "I believe no one really understands how I feel," (d) "The people I live with have been supportive of me," (e) "I cannot control my child's health." The development of the instrument has been described elsewhere;

both the Transition Model and instrument warrant further development and validation (Boykova & Kenner, 2012).

Recently, the questionnaire was revised, updated, and tested (Boykova, 2018). Based on three studies conducted in 2012 to 2015, the items were revised, and exploratory factor analysis (principal axis factoring with oblimin rotation) on the construct of transition in parents was performed. The original version of the questionnaire was reduced to 17 items in four major dimensions, as reported by parents (N = 704): *Isolation*, *Worry*, *Confidence*, and *Professional Support*. It seems that in the era of a vast amount of online resources, parental informational needs transformed into more prominent and more important, for parents, professional support after discharge. The revised instrument demonstrated adequate psychometric characteristics; however, the tool requires further testing and validation as well as five major factors revealed in the study.

Transition to Primary Health Care. The third type of transition in parents and infants in the postdischarge period is the transition to the primary healthcare settings. Continuity of care, comprehensiveness, timeliness, and appropriateness of posthospital care can influence the health of an infant and family tremendously. Often, parents have difficulties in finding primary care providers who would be experienced and knowledgeable about NICU populations' needs and risks. Research in the population of adult patients has shown that:

1. Less than half of the patients are able to list their diagnoses, medications, and their purpose or adverse effects after discharge.
2. Up to 20% of the discharge summaries lack information about hospital treatment.
3. Up to 40% of summaries do not mention discharge medications.
4. Ninety-two percent of discharge summaries lack information of patient or family counseling (Kripalani et al., 2007; Makaryus & Friedman, 2005).

The linkage between patient readmissions, avoidable complications, and appropriateness of postdischarge care has been well documented in the population of adult patients. The Transitional Care Model of Dr. Mary Naylor and colleagues from the University of Pennsylvania is an example of a practice model that has been proven to be effective and efficient in the population of elder/older patients with various medical conditions (Naylor et al., 2004; Naylor, Aiken, Kurtzman, Olds, & Hirschman, 2011; Naylor, Bowles, et al., 2011). This model provides in-hospital planning and home follow-up for chronically ill high-risk patients, with a transitional care nurse as an assigned leader and coordinator for a multidisciplinary transitional care team of medical doctors, social workers, discharge planners, pharmacists, and other members of healthcare teams (Naylor et al., 2009). More recent study on transition to home in high-risk NICU infants also showed that home visits by social workers and family resource specialists reduce readmissions and thus healthcare use and medical spending (Y. Liu et al., 2018); moreover, parent–infant interaction seems to be improved after home visits as well (Goyal, Teeters, & Ammerman, 2013).

Less is known about parents of NICU infants after discharge. A recent online survey on parents of preterm infants (N = 52; 99.9 were mothers) conducted with the help of the moderator of the blog from PreemieWorld, Deb Discenza, revealed that only 44.2% of parents participated in transitional care/follow-up programs (Boykova, 2016a). Parents often had difficulties with getting appointments and finding specialists who would manage their infant's medical problems after discharge (such as pulmonologist, pediatrician, dietitian, developmental specialist, and lactation specialist). Despite the expansion of developmental and family care principles all over the world during recent decades, in this pilot study, 77.1% of parents had been separated from their infants during the hospital stay, and 41.7% could do only a small amount of caregiving while in the hospital. At least one rehospitalization after discharge occurred in 52.4% of cases. However, parents who were participating in transitional care programs were very satisfied with healthcare. And yet, attendance can be a problem. In Canada, where healthcare coverage is universal, Ballantyne, Stevens, Guttmann, Willan, and Rosenbaum (2012) found that attendance in follow-up programs decreased during the first 12 months from 84% to 74%, and the higher withdrawal from the programs occurred after NICU discharge, followed by withdrawal after the first appointment (Ballantyne et al., 2012). The reasons provided by mothers for nonattendance were not completely clear, as they were not fully reported. From the limited data this study could collect from mothers (two thirds did not voluntarily provide reasons), the main nonattendance reasons were preference to be followed closer to home or by different healthcare provider (pediatrician). Hypothesized reasons were reluctance of having the child assessed (especially when a disability is suspected), elevated depression, socioeconomic differences, and PTSD (Ballantyne et al., 2012). In Australia, parents of prematurely born infants preferred to use services that were instrumental in accessing needed services, provided there was consistent information, and supported parental self-efficacy in caring for their child (Pritchard, Colditz, & Beller, 2008). In this study, parents also highly evaluated NICU follow-up programs and were less reluctant to follow recommendations; the use of helplines was not helpful and led to confusion and an increase in anxiety in the early postdischarge period. At the discharge point, helping with pediatrician selection was found to be assistive for parents in preparation for taking the baby home (Smith et al., 2009); NICU follow-up clinics also facilitate participation in EI services (Greene & Patra, 2016). Families who felt unprepared to go home at the discharge point were more likely to report that their pediatrician could not access the infant's discharge summary and that they were not able to obtain needed feeding supplies for their infant (Smith et al., 2012). Unpreparedness for discharge, in addition to inadequate continuity of care and limited knowledge of primary healthcare providers, can be related to the overuse of services or avoidable readmissions. Three months postdischarge was reported as a period when parents use healthcare services most (Spicer et al., 2008). Wade et al. (2008) found that preterm infants during the first year after NICU discharge had frequent pediatric visits and prescription medications (mean 20 visits and 5.5 medications); surprisingly and unfortunately, half of the highest using infants were relatively healthy (who did not have CLD, necrotizing enterocolitis, or severe intraventricular hemorrhages; Wade et al., 2008). These findings dictate better continuity of care in the postdischarge period. Better care coordination of postdischarge services is needed in order to provide support to the family unit, ease the transition to the home, and promote positive growth and development of the infant.

Strategies to Help Families Postdischarge

Many interventions can alleviate a crisis for a family of an NICU or premature infant in a postdischarge period. Some approaches and strategies are described in the following.

Discharge Teaching and Information Giving. The NICU nurse—in the role of primary nurse, clinical nurse specialist, or neonatal nurse practitioner—can advocate for positive parental discharge. Recognizing parents' need for information about their infants and the required at-home care facilitates development of a collaborative, interdisciplinary plan of care, including discharge and follow-up. This type of collaborative plan should include the

parents' demonstrating competence and comfort with routine newborn care. The nurse should ensure that the parents are completely comfortable with bathing, feeding, and diapering their infant and with administering any special care procedures, such as medication or oxygen therapy. Information given to parents about feeding patterns of preterm infants should include differences and similarities between term and preterm infants. Preterm infants often have shorter periods of sustained sucking, whether receiving feedings from the breast or bottle. Signs of adequate intake are similar for both groups: exhibiting feeding cues on a regular basis, seven to 10 feeds per 24 hours, and five to six wet diapers and two to three stools per 24 hours. Pre- and postdischarge interventions have been shown to be effective for the duration of breastfeeding, promoting exclusive breastfeeding and improving maternal satisfaction as well as decreasing readmissions (Ahmed & Sands, 2010; Braet, Weltens, & Sermeus, 2016); if available, a board-certified lactation consultant (BCLC) should assist the mother, as continued support of the breastfeeding mother is essential to decreasing the risk of early weaning. The parents also need to be taught how the NICU infant's temperament may differ from that of a healthy newborn. Parents need to be informed and reminded that even though their infant is 6 months old by chronological age, she or he may be only 3 months old by conceptional age. Thus, the infant may act more like a 3-month-old than like a 6-month-old.

Comprehensive discharge teaching has also been advocated in NICUs for a long time. Quality of discharge teaching provided by nurses is vital. Good discharge teaching includes all this as well as developmental information and has positive outcomes on parental levels of anxiety and depression, as well as hospital costs. Melnyk and coworkers have developed a specific educational-behavioral program for parents of NICU infants, the Creating Opportunities for Parent Empowerment (COPE), which works in the hospital and postdischarge. The program consists of audio-taped information and workbooks for parents; parents are taught about behavior and development and caring for their infant. Teaching parents occurs in four phases, the first of which starts at an NICU. This program has been proven to be effective and efficient; the cost savings for healthcare systems are estimated at more than $2 billion per year if the program would be routinely implemented in NICUs across the country (Melnyk et al., 2010; Melnyk, Crean, Feinstein, & Fairbanks, 2008; Melnyk & Feinstein, 2009). Parenting Preemies is another program that helps parents to ease the transition to home, with educational materials, follow-up telephone calls, and home visits lasting 10 weeks (Willis, 2008). Such programs bring needed support and reassurance to parents, as well as contributing to continuity of care. Importantly, advice on financial issues, insurance coverage, and available programs is often needed, too (Discenza, 2009). Use of technology, for example, a smartphone application, NICU-2-HOME, may also provide support to parents of vulnerable premature infants as they leave the NICU (Garfield et al., 2016).

Communication and Continuity of Care. Parents often report that they feel supported and reassured if a professional in addition to family or friends advise them (Lindberg, Axelsson, & Öhrling, 2009). However, many parents also express the frustration of trying to build rapport with medical and nursing staff in primary healthcare settings. Follow-up nurses, nurse practitioners, should recognize that it could be difficult to build trust and rapport with parents who have suffered and been traumatized by their infant's hospitalization and health problems. Communication is the key element to successful relationships. Nurses are expert communicators, as the art of nursing has revolved around the ability to convey care and personal attention to the patient. Unfortunately, because of today's healthcare crisis, nursing shortages have resulted in staff mixes and use of unskilled personnel, coupled with economic constraints resulting in shortened hospital stays; nurses are also falling into the trap of assembly-line healthcare delivery. However, nurses have the advantage of being able to identify and assess a family's needs and to convey these needs to other healthcare team members. Being an advocate for the family is an essential part of preparing a family for discharge. Follow-up, in essence, is allowing an open line of communication among healthcare professionals, the healthcare delivery system, and the family. It allows a partnership to develop between the healthcare team and the family. It gives the family back some control. Follow-up moves the family away from the learned helplessness acquired in the hospital to a more participative role. Families who want to vent feelings and concerns often seek out nurses—as long as the family feels that the nurses care enough to be concerned. Parents need to be able to openly express their concerns without fear of being judged as "bad" parents. Nonverbal cues can get in the way of communication. The nurse's expertise, knowledge, and use of medical terminology without explanations all convey the nurse's need to be in control. Someone has to be in control, but relinquishing some control to the family does not lessen one's credibility as a professional. It conveys to the family that they have a role in their infant's care and that they are important, too. Importantly, nurses also need to convey information and coordinate the data between physicians, social workers, counselors, and other members of the healthcare team who work with the family. Application of the nursing process may sound trite, but it is important in terms of not only collecting data but also using the data to identify problems, make nursing diagnoses, and develop a plan of care before and after discharge. Communication among the healthcare team members, including the parents, has a positive impact on the parents before and after discharge (Discenza, 2012). Collaboration among pediatric medical follow-up, parent support or psychosocial assessments at home, and obstetrical follow-up for the mother is essential. Each healthcare professional has something to contribute to the family's overall well-being. It is essential not to compete but to work with other professionals for the good of the family. It also means that each profession must share information that it receives from the family.

Social and Material Support. After discharge, social support from family members, relatives, and friends (informal social networks) is vital. Social support is an important aspect of coping and managing stress; if support is not provided, family functioning and health may suffer. Once the social support needs of the NICU family have been identified, a plan of action must be implemented. Helpful resources might be parent support groups, parent hotlines, referral to financial resources, or home care agencies. Balancing infant care with other demands is difficult, at best, and maternal fatigue is often a major issue that is associated with depression when the infant comes home (Wilson, Lee, & Bei, 2019). Acknowledgments of the mother's own physical discomfort convey a caring and supportive attitude. The caring attitude by healthcare professionals, the friendly hug, and the taking time to talk with the parents, even if it was about something other than their infant's problems, can have positive effects on parental well-being and ease their stress. Moreover, it has been shown in mothers of healthy infants that provision of psychosocial support in the postpartum period decreased the risks of readmissions (Barilla, Marshak, Anderson, & Hopp, 2010). The availability of a phone number and the potential for a home visit are always viewed as positive by parents. For many parents, the home visit provides a way to vent feelings that otherwise might be suppressed around family and friends; home visits also provide needed reassurance for parents in caring. Unfortunately, with the current healthcare insurance

coverage in the United States, few home visits are actually made, but are still available in some places and countries. In many cases, parents appreciate even a telephone call from NICU personnel.

Screening. Another important aspect of postdischarge care could be screening for depression, PTSD, and parenting disturbances. Screening for postpartum depression (PPD) in NICU parents has been long recommended since depression is a known risk following a high-risk birth (AAP & ACOG, 2017; Barkmann, Helle, & Bindt, 2018; Bergström, Wallin, Thomson, & Flacking, 2012; Gangi et al., 2013). Gray et al. found that parenting stress was heavily influenced by maternal depression (Gray, Edwards, O'Callaghan, & Cuskelly, 2012). As described in this chapter, continued stress, feelings of failure, and grieving for the loss of the fantasy child all have the potential to lead to maternal and paternal depression. Parental anxiety and the depressive symptoms should be assessed in the postdischarge period and be part of routine follow-up care (Enlow et al., 2017); PPD was associated with nonadherence infant feeding guidelines: mothers with PPD breastfed at low-intensity and added solid foods earlier (Gaffney, Kitsantas, Brito, & Swamidoss, 2014). Psychological counseling and other needed treatments should be available for parents: A recent study showed that even after positive screening for PPD, mothers rarely used mental health services (Kallem, Matone, Boyd, & Guevara, 2018). In addition, VCS needs to be considered by those providing posthospital care. Nurses are an integral part in integrating and translating the new National Perinatal Association (NPA) recommendations for psychosocial support of NICU parents into clinical practice (Purdy et al., 2017).

Home Care. With the shift from acute care hospitals to providing home care for infants, even technology-dependent infants, the postdischarge transitions can be even more challenging for parents than before. Some families are expected to set up a "mini" intensive care unit in the home, even providing lung ventilation or intravenous medications. There are several types of home care.

Types of Home Care. Home care, for most practical purposes, is classified as short-term, long-term, or hospice care. Other programs involve respite care, which is relief care for parents; day care, which is at a specialized place that provides care for high-risk infants during daylight hours; and foster care, which refers to a family or individual who takes in a child to live in their house that is not their own when the birth family cannot provide care.

Short-Term Care. Short-term care is considered by many healthcare services to be less than 6 months in duration. Short-term care of an infant at home may include phototherapy for hyperbilirubinemia, administration of supplemental oxygen to treat respiratory distress, home monitoring for apnea of the premature infant, medication administration for various neonatal conditions, and alternative feeding methods such as gavage for nutritional support. The primary caregivers in the home usually attend to these treatment modalities. Parents and families are carefully instructed about the use of any equipment placed in the home to administer healthcare. Extensive teaching before hospital discharge must convey the precise reasons for the therapy, the necessity for close observation of the infant by the caregivers, and the importance of communication and supervision by the primary care physician. In situations of short-term home care, the condition is usually self-limiting, and the home therapy can be discontinued at a predetermined endpoint. Moreover, outpatient management of discharge-delaying ABD events in a late preterm and term population was a cost-effective alternative to prolonged inpatient observation (Montenegro et al., 2017).

Long-Term Care. The point at which care becomes long term is determined by the nature of the healthcare needs of the individual. The providers of extended care and the insurers paying for the care also arbitrarily set the period for long-term care. In general, long-term care indicates that the duration of the condition and the need for care will exceed 6 months. Long-term home care addresses situations for children with disease processes such as bronchopulmonary dysplasia (BPD), short bowel or short gut syndrome, CHD, physical and cosmetic defects, neurological and metabolic disorders, and numerous other prolonged pathological conditions. On discharge, these children may require home care services performed by professional home care agencies or programs. Families gradually become integrated into the healthcare routine. The family's responsibility changes as the infant's condition changes. The primary care physician must be closely involved and should be able to rely comfortably on the caregiver's judgment for making assessments and alterations in the home care plan. Long-term home care requires open communication among the family, community physicians, tertiary resources, community healthcare providers, home medical equipment providers, and financial providers. Many hospital records are now incorporating discharge notes, especially nursing case management notes or orders for the actual discharge and home care follow-up plan. These notes are a good vehicle for communication among the community healthcare providers and the discharging hospital.

Hospice Care. Congenital anomalies are the leading cause of infant mortality in the United States and are also a major contributor to childhood morbidity, long-term disability, and loss of years of potential life. The proportion of infant deaths attributed to birth defects has remained significantly high. The HIV epidemic is improving, but it still takes its toll on the neonatal population. Those infants require specialized home care and, in some instances, palliative care. In addition, with technological advances, the ability to prolong lives has increased. Infants who are born dying do go home, where they need end-of-life (EoL) or palliative care, the care concepts that still require improvement in the neonatal field (E. R. Currie et al., 2016). When it becomes clear that an infant will no longer benefit from acute intervention, plans for healthcare should focus on physical and emotional comfort. The transition from acute care to palliative care involves the concept of hospice. Hospice care is a philosophy of caring when cure is no longer a reasonable expectation. This care is not strictly a kind of terminal care, but rather an effort to maximize current quality of life without giving up all interest in a cure. Hospice provides comfort measures and emphasizes alleviation of symptoms. Whether the infant is terminally or chronically ill, the ultimate goal is to provide an environment that comforts the child and supports the family.

Criteria for Home Care. Some hospitals throughout the country are developing specialized outreach and home care services as an extension of their inpatient services. Regardless of how services are to be provided, the decision to facilitate early discharge from hospital care to home care must be based on standards that are safe and that provide effective ongoing therapy. The infant, the family, the home equipment, and the follow-up healthcare system must meet criteria for discharge to home care.

Infant Criteria. The infant's home healthcare needs must be assessed as to technical feasibility and medical requirements. Nutritional support must be evaluated. How does the infant feed and how frequently? How often does the infant require gavage feedings, and which feeding techniques are required? Pharmacological support assessment must be evaluated. What medication does the infant need and how often? What are the desired and adverse effects of these drugs? Does the infant require supplemental oxygen, respiratory therapy treatments, or chest physical therapy? The assessment of the level of care required

must be matched to the ability and skills of the home care providers. It must be determined before discharge so that care in the home will be safe and meet the needs of the infant and family.

The specific criteria for discharge of special groups of children—such as those with BPD, short bowel or short gut syndrome, neurological disease, cardiac disease, and other pathological conditions—are addressed in the preceding chapters.

Family Criteria. The assessment of the family's commitment to home care is perhaps the most critical factor determining the success or failure of home healthcare. After extensive discharge teaching, skills development, and repeated occasions of caregiving, the family must want the child at home and under their care. They must be willing and able to devote the time and energy required to meet the physical and emotional needs of the child. These factors are essential for the well-being of the family unit. To prepare families for the discharge of their sick or high-risk infant, NICU personnel must begin teaching them as soon as the neonate is admitted to the unit. Once the family is confident and capable of meeting the needs of the infant, a home assessment should be completed. Basic facilities such as heat, water, telephone, electricity, and transportation must be available. Appropriate support systems must be set up in the home, including the technology necessary for the delivery of care. The operation of phototherapy lights or blankets, oxygen delivery systems, portable suction equipment, respiratory and cardiac monitoring systems, ventilators, and numerous other devices must be thoroughly understood by the caregivers. Clear instructions need to be given to the family members by the providers of the home care technology. Ideally, the parents should bring the equipment to the hospital, or the equipment company can help transport it to the hospital before discharge. The rationale is that the parents can be taught on their own equipment. If a problem arises, it can usually be identified before the infant's discharge. The parents should spend at least 24 hours providing total care before discharge. This time under a health professional's supervision helps the family gain confidence in their caregiving abilities. They can also be reassured that they have the proper equipment.

Home Equipment Criteria. The most common equipment needs for neonates are cardiopulmonary monitoring, oxygen, suction, and feeding implements. The family's first decision is how to select a home care equipment company. Hospital discharge planners or the nurse responsible for the discharge can make recommendations. Once the supplier has been selected and the necessary equipment identified, parent education can begin, including neonatal cardiopulmonary resuscitation (CPR). The parents should be given written instructions to take home and a checklist for the CPR procedure that can be clearly posted. If parents cannot read, visual charts outlining the steps should be made available.

A cardiopulmonary monitor is the most common equipment needed in the home. Infants who should be placed on this type of monitoring are those whose sibling died of sudden infant death syndrome (SIDS) or who are at risk for SIDS, such as premature infants. These infants are usually monitored for several months. An infant on home oxygen or one who has neurological impairment is at risk for apneic or bradycardic episodes or desaturation, thus requiring pulse oximetry. Most of the cardiopulmonary monitors have built-in memory or pneumographic capabilities that allow trends and strips to be viewed by home care nurses. Often, parents struggle with alarm limits and sounds, so appropriate teaching should be done before discharge. Online educational modules might be effective and improve parental knowledge on SIDS and promote change in parental behavior (Dowling, Barsman, Forsythe, & Damato, 2018). Parents need to understand alarm delays or oversensitivity, when to change probes, and how to respond.

If parents have an infant who requires home respiratory support, the family will need a ventilator, with oxygen and air tanks. An air compressor and oxygen concentrator may also be needed. Portable or stationary oxygen devices vary in size and the amount of time that they will last. Humidification and suctioning equipment is needed for patients with ventilation support or tracheostomies. Parents should be taught how to perform suctioning, how often, and how to adjust suction when an illness occurs that may put the infant at risk for cross-contamination. Suctioning should be performed according to individual needs of a patient and to the physician or nurse practitioner's orders. Signs that indicate the need for suctioning are the same as those used by health professionals in the NICU: restlessness, decreased color, coughing, increased respiratory effort, or sounds of congestion. Humidification of the airway is necessary for infants with artificial airways, regardless of whether or not they are on oxygen. If the airway is not humidified, mucous membranes may dry and crack, creating areas that may become infected.

These examples of home care and monitoring are the most common. Specific instructions are needed regarding which equipment is necessary and how to use it in each situation; the equipment should be obtained from the home healthcare agency that is to provide care, the hospital equipment vendors, and the home healthcare equipment vendors. Information on home use of ventilators can be obtained from the Home Mechanical Ventilation Resource Center of the American College of Chest Physicians (www.chestnet.org). If parents are primary caregivers, they should keep a log of the timing of the suctioning and the type of secretions obtained. Time of medication administration and feeds also should be recorded. An emergency backup unit must be available—whether it is housed in the home or at immediate dispatch from the equipment company does not matter, as long as it is available for times when equipment failures occur with the portable device. Battery backup is also necessary. Ideally, the nurse should make a home visit before the discharge to assess the home environment for safety hazards. For example, is the house/apartment too hot or cold? Either condition can lead to apneic spells. Are there exposed wires in the house? Peeling paint? Open flames used for cooking when oxygen is going to be used in the house? Are there any strong or chemical odors that may be harmful to a child with respiratory compromise? Is there an emergency phone? Have utility companies been notified? Is there a backup plan in case of a power outage? Is there a plan for continued health promotion, such as immunizations? All aspects of the home and the community setting should be considered when discharging the infant and family.

SUMMARY

Postdischarge care is vital for an infant and family, and no less so than intensive care provided in the hospital. Former NICU infants may suffer from numerous health problems and may have numerous healthcare needs. Parents are in need as well. The crisis of hospitalization and discharge has no time limit because it is so individual. Three major transitions can be identified in parents of former NICU and preterm infants: transition to parenthood, transition to home, and transition to primary healthcare settings; all transitions can bring challenges to the infant and family. Parental role alteration, anxiety, depression, and an increased need for professional and social supports are tremendous. Medical follow-up of NICU infants as well as helping parents to deal with postdischarge challenges are vital in order to promote infant health, development, and family well-being. The outcome of transition (i.e., readmissions, health status of the infant, parenting-style disturbances)

will depend on whether resources are available to support the individuals undergoing postdischarge challenges and may influence the whole life span of the infant and family. Application of the interventions as close to the time of the discharge as possible is vital. The crisis of neonatal hospitalization, difficulties in caregiving, and parenting of an initially sick or small infant can be alleviated by appropriate interventions and strategies. These are appropriate discharge teaching, parental participation in transitional care programs, adequacy and timeliness of follow-up, access and attendance to transitional programs and follow-up, provision of timely and appropriate resources for family and infant, continuity and coordination of care, case management, and access to home care, to name a few. Close collaboration and open communication between healthcare providers and family is required, as well as informational and technical assistance. The absence of these can lead to a less than optimal environment for the infant and child to grow.

CASE STUDY

This case study applies the Kenner Transition Model to the care of a technology-dependent infant.

In recent years, the number of technology-dependent infants discharged home has increased, because of the many early discharge programs available and the survival of extremely low birth weight infants with chronic conditions. Although a fair amount has been written about setting up early discharge programs and the positive financial rewards associated with early discharge, little research is available to look at the effects of having a technology-dependent infant at home.

Spangler-Torok (2001) studied mothers receiving and caring for their technology-dependent infants in the home and applied the concepts of transition to this unique population. The experiential descriptions were from eight mothers, aged 17 to 42, who were the primary caretakers of their technology-dependent infants. All of the mothers were interviewed within the first 4 weeks of receiving their infant into the home. Although this was a phenomenological study, it provides support for the concepts of the Kenner Transition Model.

■ **Information Needs.** Mothers in this study understood the need to learn about care and equipment so that the infant could be discharged. Mothers described moving from learning care to making judgments regarding the infant's health. Gathering information is a way of seeking control of the situation. The mothers in this study sought information to make an overwhelming experience more manageable. The mothers described their initial fear of caring for the infant at home and their ability to move beyond the fear and do what needed to be done. As more information was gathered, mothers described using their judgment in making infant health decisions. When receiving and caring for a technology-dependent infant in the home, more information seems to give mothers more control, confidence, and peace of mind.

■ **Grief.** The mothers in this study feared the infant becoming ill and requiring rehospitalization. Several of the mothers voiced concern that the infant might die. Mothers grieved over the loss of the "ideal" pregnancy and infant. Mothers would report that they were managing the home care experience, "but this is not what I planned for." Mothers grieved about the life their infants would have and vowed to give them "as normal a life as possible." Mothers worried about what others would think: "Will they think it was something I did while I was pregnant that caused this to happen to the baby?" Mothers felt the need to "warn" others that the baby was different before they approached the infant.

■ **Parent–Child Role Development.** Once they were at home, mothers in this study believed that they were getting to know their infants and that their infants were getting to know them as their mothers. Mothers reported learning things about their infants that they didn't know until they were home, such as when their fussy times were. Mothers believed that as they learned more about infant preferences and health-related behaviors, they were able to make appropriate adjustments to infant care. Regardless of whether they had other children, the mothers saw a need to adjust the parenting role and expectation to accommodate the premature infant. They realized that this infant was different and required special care—in some instances, more vigilant care. They discussed how the increased needs of this infant took time away from other children and spouses, but acknowledged that being home was easier than extended hospital visits. Most of the mothers in this study quit their jobs or school to care for the infant, which they would not have planned to do if the infant had been healthy. The mothers discussed lifestyle changes since the infant came home from the hospital, such as decreased number of outings, staying indoors more, and limiting visitors to the home.

■ **Stress and Coping.** Mothers in this study acknowledged that receiving and caring for a technology-dependent infant in the home is a lot of work. One mother stated it is "a ton of work . . . 10 times more work than a normal infant." Mothers report that more time is needed with infant care as well as with supplemental tasks, such as dealing with insurance companies, managing supplies, and checking equipment. A lot of time is required to prepare the infant for outings, and time is needed for the infant to readjust to home after outings. Mothers reported problems with infant digestion and temperament when away from home. "She may require 2 or 3 days to recover from an outing to the doctor's office." All of the mothers described the extra work and time the infant required, but most felt it was worth it to have the infant home with them. This initial anxiety decreases as the infant's respiratory status improves and the infant becomes less dependent on oxygen therapy.

Two mothers described being overwhelmed with infant care in the home and felt they faced too many demands. One mother felt torn between caring for the infant and spending time with her other children. She was "only one person" and could "only be in one place at a time." She appreciated the break the home nurses provided but felt guilty that her infant received care from others. Another mother described frustration in dealing with the equipment. She had a "hard time looking" at the feeding tube but was less bothered by the tracheotomy. She got angry when her husband gravitated toward Holly, the "normal" twin, and left all the work for Grace to her. This mother was afraid that her infant would pick up on her frustration with the equipment and feel that she didn't love her.

■ **Social Interaction.** Several mothers in this study attributed their ability to care for this infant at home to the support of family and friends. Mothers stated they could focus on infant care because others were handling household chores and running errands for them. One mother described how strangers who heard of their situation were delivering food to them. The same mother felt that their experience was probably easier than others because "so many people have pitched in to do things." In describing her experience, one mother stated, "We just needed a lot of family." Having people come and help seemed to make the experience more manageable for some of the mothers. One mother described being supported by the home care nurses. "It's wonderful to have the nursing staff here, because when you want to break down and cry, they're there to tell you, rub your hand, or your shoulder and say, 'you're doing a good job, don't think that you're not; you are.'" She was thankful for them and used the nurses for other things so that she could spend time with the infant.

Although some mothers spoke of the assistance they received, others described the lack of support from family and friends. A mother spoke of being "annoyed" with her husband. She discussed how supportive they were of each other during their infant's hospitalization and that she had assumed that would continue once they were home. She was disappointed by her husband's lack of support and assistance with infant care and home management. "Hey, we have special circumstances here, this isn't just your average baby and you need to help me," she said. Another mother described a lack of support from her husband, children, and friends. She said her husband helped with the cooking, but it took her three times as long to clean up. Although her 12-year-old daughter was old enough to help, she didn't. She also wondered why friends had not come to see her. She believed they were afraid to see the baby and, therefore, did not visit. She sometimes felt alone in her responsibility for the baby.

The experiences of the mothers caring for infants who require technology support lend credence to the Kenner Transition Model. The mothers reported a need for information, grieved for the loss of the healthy child, and found they needed to adjust their parenting roles. They felt stressed and overwhelmed. These are all concepts in the Kenner Model. Other studies report similar findings.

EVIDENCE-BASED PRACTICE BOX

For more than 30 years, issues around the transition home, discharge coordination, and follow-up care have been researched. The reality is that for parents of a premature or sick newborn, life changes with an NICU stay. The discharge, while anticipated, is not easy. The transition to home even with follow-up appointments, programs in place, and written discharge instructions is not easy for most families. There is fear that the baby will become sick again; fear that the baby might die; fear that the health professionals in primary care or the community will not know what to do the way NICU professionals do. Research studies published in 2012 to 2018 continue to support the need for more research in the area of transition from hospital to home and the need for a clearer understanding of the actual follow-up that is being done, including adherence to suggested follow-up visits and programs (Ballantyne et al., 2012; Boykova, 2018; Hutchinson, Spillett, & Cronin, 2012; Lopez, Anderson, & Feutchinger, 2012; Murdoch & Franck, 2011; Smith et al., 2012). Murdoch and Franck (2011) identified six themes from mothers transitioning with their infants to home following an NICU stay: apprehension, confidence, responsibility, awareness, normalcy, and perspective. One or more of these themes have been reported in transition research studies for more than three decades. In light of healthcare reform and the emphasis on health promotion, the time is right to use this evidence to create better follow-up programs.

PARENT VOICES

Deb Discenza

I always tell my families that they should rely on their parent instinct. If something does not seem right with their child, they should absolutely check out the problem with the pediatrician, or with a specialist. Early identification can mean a dramatic change in their child's outcomes and identifiable supports when it comes to developmental delays and diagnosed disabilities. Yet as a parent of a 30-week premature baby girl now 15 years old, I can honestly say that the parent instinct is truly the common denominator among all of the specialties outside the NICU. The parent is the expert of his or her child starting from conception. They notice tiny but crucial nuances where others would assume no general concern mainly because of their continued presence in that child's life throughout every day. And they carry the knowledge with them from doctor to doctor even when the communication between specialists is used.

(*continued*)

(*continued*)

I know this all too well having watched my own daughter's progression from NICU to home and into the school years being challenging at best. Even despite my best efforts to vocalize thoughts while partnering with the pediatrician and with the specialists at hand, no one saw what I saw very early on—concerns about cerebral palsy. At various points throughout my daughter's childhood and early adolescence, I sought out help for her increasingly complicated walk, her difficulty with running. This is a child who went through early intervention, through therapies for other conditions along the way (autism, attention deficit-hyperactivity disorder [ADHD], motor coordination). It was the orthopedic surgeon who fitted my daughter for orthotics (for the "squishy ankles" I noticed as my daughter trained on an elliptical machine) that finally listened and contemplated my concerns. Two years later, at the same practice but my assuming they weren't going to diagnose her, they did. My daughter was 13.5 years old and, while mild, had spasticity and was really struggling. I felt let down by the medical and therapeutic systems in place.

If I as a mother with strong advocacy skills could not get my daughter's diagnosis in place until 13.5 years old, imagine how many families are out there with less capability and no diagnosis. Outcomes data are dependent on many factors, and it should include parent and, at one point, patient's own reporting to help drive better information, better advocacy, and proper diagnoses.

Unit VII: Neonatal Care in the New Millennium: Challenges and Opportunities

CHAPTER 38

Trends in Neonatal Care Delivery

Carole Kenner and Jana L. Pressler

INTRODUCTION

Today's neonatal care is shaped by the onslaught of Institute of Medicine (IOM) reports in the United States on patient safety, quality, technology, consumer involvement, and the need for an interdisciplinary approach to care. Fiscal constraints coupled with fierce competition have made serious dents in the perinatal regionalization model of care delivery with well-defined levels of care. The Affordable Care Act, which became law in March 2010, and now the proposed repeal, threaten to impact coverage for women and children since it changes funding for Medicaid and women's health services at a time when prematurity rates, especially the late preterm, are on the rise in the United States. In 2010, the IOM released *The Future of Nursing: Leading Change, Advancing Health* report (Committee on the Robert Wood Johnson Foundation Initiative on the Future of Nursing, 2010), which clearly identified nurses as the backbone of healthcare delivery and key players in healthcare reform. As McGrath (2011) noted, changes in healthcare will reconfigure neonatal healthcare. One growing area of change is in follow-up and family-centered care that is in line with the IOM's recommendation for patient-focused care (Greiner & Knebel, 2003). Scientific breakthroughs in genetics and technological advances already have pushed the definition of viability and have brought with them the long-term consequences of comorbidities that can last a lifetime. The demand for evidence to support nursing practice is growing expeditiously.

On the global level, many factors are impacting neonatal care. Most prominent are the Millennium Development Goals (MDGs) and the Sustainable Development Goals (SDGs). This chapter will explore the trends in neonatal care and the nurse's role at the forefront of change.

LEVELS OF CARE

In the early 1990s, the report *Toward Improving the Outcome of Pregnancy II: The 90s and Beyond* (TIOPII; Committee on Perinatal Health, 1993) illustrated the need for levels of care and a regionalization plan for education and practice. The need to have high-risk perinatal care that also provided educational outreach to the community was embraced. The definitions for levels of care were incorporated in the work by the American Academy of Pediatrics (AAP) and the American College of Obstetrics and Gynecology (ACOG) in *Guidelines for Perinatal Care* (AAP & ACOG, 2007). *Toward Improving the Outcome of Pregnancy III* (TIOPIII; March of Dimes [MOD], 2010), like TIOPII, emphasized the need for preconception health through infancy to impact maternal infant outcomes. TIOPIII (MOD, 2010) builds on quality, safety, and performance initiatives for health professionals and healthcare delivery systems. Application of evidence-based care guidelines is a cornerstone of this work. Endorsed by the IOM, the theme of quality of care and safety will continue for many years. Similarly, addressing other key themes is dependent on not only healthcare financing but also differing healthcare needs and healthcare providers' understanding of what is needed and ongoing. The five key TIOPIII (MOD, 2010) themes are:

1. Assuring the uptake of robust perinatal quality improvement and safety initiatives
2. Creating equity and decreasing disparities in perinatal care and outcomes
3. Empowering women and families with information to enable the development of full partnerships between healthcare providers and patients and shared decision making in perinatal care
4. Standardizing the regionalization of perinatal services
5. Strengthening the national vital statistics system (MOD, 2010, p. ix)

The AAP Committee on Fetus and Newborn (COFN; Engel et al., 2004, Stark et al., 2004) acknowledges that as the specialty of neonatal care has become more complex and as smaller and smaller infants have survived, and continue to do so, the three levels of care (i.e., primary, secondary, tertiary) are inadequate in describing the care required. Further, some of the most highly specialized technologies are not needed in every community. Uniformity of care and integration of services are critical to the quality and outcome factors today. Four distinct levels of care are defined in the United States by the *Guidelines for Perinatal Care* (AAP & ACOG, 2017). They are described in Table 38.1.

Newborn Screening

Newborn screening is not a new concept but new conditions are being included. Congenital heart diseases screening has been advocated since 2011. The Centers for Disease Control and Prevention (CDC, 2012) identifies CCHD as comprised of seven distinct defects: hypoplastic left heart syndrome, pulmonary atresia

TABLE 38.1

DEFINITIONS, CAPABILITIES, AND HEALTHCARE PROVIDER TYPES: NEONATAL LEVELS OF CARE

Level of Care	Capabilities	Healthcare Provider Types[a]
Level I: Well newborn nursery	• Provide neonatal resuscitation at every delivery • Evaluate and provide postnatal care to stable term newborn infants • Stabilize and provide care for infants born at 35–37 weeks of gestation who remain physiologically stable • Stabilize newborn infants who are ill and those born before 35 weeks of gestation until transfer to a higher level of care	Pediatricians, family physicians, newborn nurse practitioners, and other nursery advanced practice RNs
Level II: Special care nursery	Level I capabilities plus: Provide care for infants born at 32 weeks of gestation or later and weigh 1,500 g or more who have physiologic immaturity or who are moderately ill with problems that are expected to resolve rapidly and are not anticipated to need subspecialty services on an urgent basis Provide care for infants convalescing after intensive care Provide mechanical ventilation for brief duration (<24 hours) or continuous positive airway pressure or both Stabilize infants born before 32 weeks of gestation and weigh <1,500 g until transfer to a neonatal intensive care facility	Level I healthcare providers plus: Pediatric hospitalists, neonatologists, and neonatal nurse practitioners
Level III: NICU	Level II capabilities plus: Provide comprehensive care for infants born before 32 weeks of gestation and weigh <1,500 g and infants born at all gestational ages and birth weights with critical illness Provide prompt and readily available access to a full range of pediatric medical subspecialists, pediatric surgical specialists, pediatric anesthesiologists, and pediatric ophthalmologists Provide a full range of respiratory support that may include conventional ventilation and/or high-frequency ventilation and inhaled nitric oxide Perform advanced imaging, with interpretation on a urgent basis, including CT, MRI, and echocardiography	Level II healthcare providers plus: Pediatric medical subspecialists,[b] pediatric anesthesiologists,[b] pediatric surgeons, and pediatric ophthalmologists[b]
Level IV: Regional NICU	Level III capabilities plus: Located within an institution with the capability to provide surgical repair of complex congenital or acquired conditions Maintain a full range of pediatric medical subspecialists, pediatric surgical subspecialists, and pediatric anesthesiologists at the site Facilitate transport and provide outreach education	Level III healthcare providers plus: Pediatric surgical subspecialists

[a] Includes all healthcare providers with relevant experience, training, and demonstrated competence.

[b] At the site or at a closely related institution by prearranged consultative agreement.

Source: From American Academy of Pediatrics & American College of Obstetrics and Gynecology. (2017). *Guidelines for perinatal care* (8th ed., pp. 28–30). Elk Grove Village, IL: Author.

(with intact septum), tetralogy of Fallot, total anomalous pulmonary venous return, transposition of the great arteries, tricuspid atresia, and truncus arteriosus. According to the AAP (n.d.), 18/1,000 newborns have a critical congenital heart problem. The rationale for including this type of congenital heart disease screening in the universal newborn screening is that the symptoms representative of these conditions might not be apparent in the neonate prior to hospital discharge (CDC, 2012).

New Jersey enacted mandated screening for Critical Congenital Heart Disease (CCHD) in September, 2011. The screening and follow-up program are led by a neonatal nurse. A reference guide has been developed to help the professional community understand this screening and the needed follow-up (Grazel, 2017). This guide is supported by the New Jersey Department of Health (NJDOH), the American Academy of Pediatrics New Jersey Chapter, and Rutgers University.

Another area of significant concern is high-risk follow-up. As more infants are surviving, the relative lack of consistency of how follow-up is conducted or who is eligible to receive follow-up care serves as a gap in care providers' knowledge. Toward this end, in June 2002, the National Institute of Child Health and Human Development (NICHD), the National Institute of Neurologic Disorders and Stroke (NINDS), and the CDC convened a workshop to examine this gap. They also recognized that differences in data collection methods have led to difficulties with comparing outcomes both within and across centers (NICHD, NINDS, & CDC, 2004). To improve long-term developmental and physical neonatal outcomes, neonatal follow-up care must be clearly

defined with levels corresponding to NICU levels of care. In the next decade, this seminal work will shape the post-NICU experience for neonates and their families. Since 2002, many articles have been published on the lack of uniformity of guidelines for hospital discharge for newborns, the lack of qualified providers available for follow-up and early intervention programs, in spite of referrals to high-risk clinics, a lack of parent preparedness for infant discharge, and the need for more research studies on the post-discharge outcomes of infants who were born with extremely low birth weight, were technology-dependent, or who have had surgery (De Jesus et al., 2012; Dobson & Hunt, 2012; Fink, 2011; Pinto et al., 2012; Smith, Dukhovny, Zupancic, Gates, & Pursley, 2012; Trzaski, Hagadorn, Hussain, Schwenn, & Wittenzellner, 2012). In addition, it has been pointed out that often mothers do not bring their infants back for the first neonatal follow-up appointment postdischarge (Ballantyne, Stevens, Guttmann, Willan, & Rosenbaum, 2012), yet the reasons for this lack of follow-up are unknown, creating another knowledge gap (Ballantyne et al., 2012). An additional area of concern is the missed opportunities for immunizing infants prior to discharge. Navar-Boggan, Halsey, Escobar, Golden, and Klein (2012) found that 27% of infants who were discharged from the NICU at or before 2 months of age had not received any vaccinations. While this study was conducted in 2012, the situation persists today. Immigration status has been implicated as one reason for an increase in under-immunized infants. Many undocumented families fear going to a clinic for this type of care. The Children's National Health System has developed guidelines for caring for this population (Gray & Chapman, 2015).

Family-centered care and the need to include the family in care during the NICU stay, as well as the growing recognition for the need to teach families about developmental care both within and outside the hospital, continue to be at the forefront of neonatal care. Schlittenhart, Smart, Miller, and Severtson (2011) have developed an evidence-based, comprehensive teaching tool for parents of infants discharged from the NICU. This tool exemplifies the trend for more evidence-based guidelines for discharge preparedness. It serves as a critical part of developmental care.

DEVELOPMENTAL CARE

Developmental outcomes have been at the forefront of care for many years but today there is also a movement toward supporting and advocating *individualized family-centered care*. This care coincides with the IOM's (2001) emphasis on patient-focused care as a method to increase quality. Another aspect of this care supports IOM's initiative in interprofessional or interdisciplinary care and that is developmentally supportive care. Individualized family-centered care incorporates knowledge of growth and development; factors that interfere with positive growth such as prematurity, environmental noise, and lighting levels; the interface with physiological responses to stress-inhibited growth factors and increases in cortisol levels; and positioning, to name only a few of the focal topics. Chapter 35, Family: Essential Partner in Care gives more in-depth information on individualized family-centered care.

The NICU environment and its impact on development from a long-term perspective have spawned growth in the use of Recommended Standards for Newborn ICU Design (White, 2012) throughout the world (for more information, see Chapter 32, The Neonatal Intensive Care Unit (NICU) Environment). These recommendations come from an interdisciplinary group of architects, institutional planners, developmental specialists, nurses, physicians, and parents. The use of such standards to renovate or build new NICUs will increase, as will the overall incorporation of individualized, family-centered, developmental care. One example is the publishing of an interdisciplinary book on this subject, *Developmental Care of Newborns and Infants: A guide for health professionals* by Kenner and McGrath (2010). This second edition contains levels of evidence to indicate how developmental interventions are supported by scientific studies. The recognition of neurobehavioral stability and the links to developmental care and long-term outcomes are increasing (Montirosso et al., 2012). Follow-up studies of formerly sick and premature infants are important as they are used to examine developmental outcomes, the need for developmental care from the time of NICU admission, and the potential costs associated with physiological complications and sequelae that might be reduced or avoided with developmental care. Developmental surveillance and screenings are needed if problems are to be detected early (Thomas, Cotton, Pan, & Ratliff-Schaub, 2012).

The National Perinatal Association (NPA) developed psychosocial program standards for NICU parents (Hynan & Hall, 2015). This work underscored the importance of families as a part of neonatal care. It emphasized recognizing that having a baby in a NICU creates the potential for post-traumatic stress in families. These guidelines also suggest that family-centered integrative care is the goal, where the family is integrated into the context of neonatal care. Neonatal Intensive Parenting Unit (NIPU) is a new term that reflects this integration (Hall et al., 2017). An interprofessional team led by Drs. Joy Browne and Carol Jaeger as part of the Gravens Physical Environment of Care for High Risk Newborns is developing competencies that are necessary for everyone who touches a newborn. All of this work includes neuroprotective factors of the neonate and family (Altimier & Phillips, 2013). For more information, see Chapter 32, The Neonatal Intensive Care Unit (NICU) Environment, and the protocol on neuroprotective care (see Protocol II).

Trauma-informed care is another trend that is now reaching the neonatal population. It recognizes, as previously noted, that the NICU is stressful for the neonate and the family. Trauma-informed care helps the health professional to recognize these stresses, minimizes them, and prevents reintroducing trauma (Sanders & Hall, 2018). **Quality and Safety: Its incorporation into the NICU environment is aimed at promoting quality and safety** (Sanders & Hall, 2018). There is a working group examining competencies for neonatal trauma-informed care, led by Mary Coughlin, who wrote the book *Trauma-Informed Care in the NICU* (2016). For more information, please see Chapter 34, Touch a Life, Impact a Lifetime: Trauma-Informed Care in the NICU.

NEONATAL STATISTICS

Neonatal statistics are difficult to follow because of the lack of consistent terminology about the age of the fetus, neonate, and infant. To address that problem, the AAP COFN (Engel et al., 2004, Stark et al., 2004) developed definitions of gestational, postmenstrual, chronological, and corrected ages. These definitions are presented in Table 38.2.

Since 2014, the prematurity rate has risen in the United States. The prematurity rate in the United States was 9.85% in 2016 up from 9.57% in 2014 (Martin, Hamilton, Osterman, Driscoll, & Drake, 2018). A number of factors explain this but the rise in the births of late preterm infants (34–36 weeks of gestation) plays a significant role (Hamilton, Martin, Osterman, Driscoll, & Rossen, 2017). Another contributing factor is the use of assistive reproductive technology (ART; Hwang et al., 2018). The proposed changes

TABLE 38.2

AGE TERMINOLOGY DURING THE PERINATAL PERIOD

Term	Definition	Units of Time
Gestational age	Time between the first day of the last menstrual period and day of delivery	Completed weeks
Chronological age	Time since birth	Days, weeks, months, years
Postmenstrual age	Gestational age + chronological age	Weeks
Corrected age	Chronological age reduced by the number of weeks born before 40 weeks' gestation	Weeks, months

Source: From the Engle, W. A., Blackmon, L. R., Batton, D. G., Bell, E. F., Denson, S. E., Kanto, W. P., Jr., . . . Stark, A. (2004). Age terminology during the perinatal period [Policy statement]. *Pediatrics, 114*(5), 1362–1364. doi:10.1542/peds.2004-1915

in Medicaid and insurance funding in the United States that reduces coverage for women's health services may exacerbate the preterm birth rate.

The neonatal mortality rate in the United States was about 4 deaths per 1,000 live births in 2016 (The World Bank, 2018). According to the Central Intelligence Agency (CIA, 2017), the infant mortality rate in 2017 was still high, at 5.8 deaths per 1,000 live births. These data represent a less than optimal outcome for a resource-rich country such as the United States. The factors that impact these data continue to reflect health disparities, lack of access to care, under- or uninsured women, and the rising preterm birth rates (CDC, n.d.).

The MOD, the World Health Organization (WHO) Partnership for Maternal, Newborn and Child Health, Save the Children, and the WHO, published a report, *Born Too Soon* (Howson, Kinney, & Lawn, 2012), endorsed by more than 40 international organizations, including the Council of International Neonatal Nurses, Inc. (COINN). This report represents a landmark collaboration between governmental and nongovernmental agencies whose sole purpose of working together was to address the Millennium Development Goals—especially #4—to improve outcomes for newborns and infants. The statistics are alarming: 15 million infants worldwide are born preterm; over 1 million children die each year due to prematurity, and prematurity is the leading cause of neonatal deaths and the second leading cause of death of all children under 5 years of age (Howson et al., 2012). The importance of these findings is that healthcare professionals must increase awareness of the serious morbidities associated with prematurity as the MOD and others have done and begin to put resources behind preconception health if one believes that maternal health is inextricably linked to prematurity and other complications. There is also growing recognition that late preterm birth (34–36 6/7 weeks) must be treated as a preterm birth, with late preterm infants receiving appropriate care. The Every Woman Every Child initiative launched by the UN in 2010 calls for action on the part of civil society, nongovernmental, governmental, and professional organizations to develop and implement global strategies to improve health outcomes for women, children, and adolescents (Every Woman Every Child, 2018). This work is linked to the UN Sustainable Development Goals (SDGs). The Every Woman Every Child (2017) progress report calls for the end of preventable deaths. One outcome is to reduce newborn mortality to at least 12 per 1,000 live births in all countries (SDG 3.2; Every Woman Every Child, 2017). Achieving this target is critical to under-five mortality as the largest portion of these deaths are related to the newborn/neonatal period.

MATERNAL/FETAL NEONATAL UNITS

Fetal surgery has been performed for more than three decades. The outcomes of these fetuses/infants have improved as best practices have evolved (Partridge & Flake, 2012; Shue, Harrison, & Hirose, 2012). Until recently, fetuses that remained in utero until a viable birth occurred were cared for in an "everyday" NICU. Now there is recognition of the need for more specialized care for infants who received surgery while in utero. Maternal/fetal/neonatal subunits or additions to NICUs have been developed to provide specialized care. Prototypes of this model are found at the Children's Hospital of Philadelphia (CHOP) and Cincinnati Children's Hospital. These units include perinatal/neonatal/pediatric physician specialists who are familiar with fetal surgery, genetics, pediatric surgery, and the needs of the neonate and family after birth (www.fetalcarecenter.org). These units are growing throughout the United States and address the need for more collaboration between maternal/fetal specialists and neonatal/pediatric specialists. There is now a network for support of these units, Maternal–Fetal Medicine Units (MFMU) Networks (www.nichd.nih.gov/research/supported/mfmu). This growing subspecialty is impacting and expanding the role of neonatal nurse practitioners and nurses. For more information, see Chapter 24, Fetal Therapy.

GENETICS

Genetic breakthroughs as a result of the Human Genome Project (HGP) are influencing health and healthcare. Genomics, the term that refers to the interaction between genetic makeup and the environment, is gradually shaping how health is promoted. The U.S. Surgeon General, along with the work of the National Human Genome Research Institute (NHGRI; www.genome.gov), advocate the use of the Family History Tool that incorporates health history in the traditional sense along with genetic history. Use of this tool coupled with knowledge of newborn screening tests will influence how health professionals plan and implement newborn care. One of the newer areas of emphasis by the NHGRI is severe combined immunodeficiency syndrome (SCID), which appears to be related to several genetic mutations that may be preventable in the future (www.genome.gov/13014325). As another example, if an infant is born to a family with a history of diabetes, the development of healthy eating habits to avoid obesity and other risk factors for diabetes need to begin in the neonatal period. A genomics thrust subsequently changes how care is planned and how it needs to be individualized. It also emphasizes the need for individualized family-centered care. A new trend is the use of genetic knowledge, genomics, and lifestyle to tailor medications and therapies to an individual (U.S. National Library of Medicine, 2018). The trend is referred to as precision health or precision medicine. It is possible in the near future that pain medications, for example, will be ordered according to the genetic makeup of an individual. This trend also calls for a customized treatment plan.

Another aspect of genetics is the controversy over the number of tests that a newborn should have, to prevent long-term complications of neonatal conditions and to improve quality of life. The number of conditions screened varies by state (National Newborn Screening & Global Resource Center, 2018). The questions that arise include: Just because the test can be run and is minimally invasive, should it be done? Who decides? What are the ramifications—is there any danger of insurance discrimination? These ethical questions are at the heart of the debate about newborn screening and the intersection with genetic testing. There are websites and organizations dedicated to providing consumer-friendly information for parents on these topics to help them decide a course of action.

Advances in genetic frontiers will continue to change neonatal care and improve outcomes. One area of growing research is gene therapy in neonates who are diagnosed with Hemophilia B (Lizuka, Sakurai, Tachibana, Chashi, & Mizuguchi, 2017). Stem cell research continues to expand to combat the causes of neonatal morbidity and mortality. This research includes conditions such as bronchopulmonary dysplasia and intraventricular hemorrhage (Chang, Ahn, Sung, & Park, 2017). More research is needed in this area since there are many challenges associated with this therapy (Chang et al., 2017).

GLOBALIZATION

Recommendations for NICU standards and professional programs such as Neonatal Resuscitation, S.T.A.B.L.E. (Sugar & Safe Care, Temperature, Airway, Blood Pressure, Lab Work, and Emotional Support [www.stableprogram.org]), and Helping Babies Breathe supported by the AAP (https://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/helping-babies-survive/Pages/Helping-Babies-Breathe.aspx) are being used globally. Neonatal care issues are international. The era of globalization is changing the way care practices and outcomes are viewed. Protocols for care are developed so that they can be adapted for cultural sensitivity, technology availability, and geographic needs. The push toward evidence-based practice and the use of Cochrane reviews, the Joanna Briggs Institute Collaborative Systematic Reviews, and Vermont Oxford materials all are bringing neonatal care to a level that is supported by scientific findings rather than primarily by tradition. This movement is global and is being influenced by hospitals seeking Magnet status; it espouses evidence-based practice guidelines to ensure quality care and more positive outcomes. As this influence continues, there will be shifts in how care is implemented. The COINN (www.coinnurses.org) is partnering with other organizations such as the European Foundation for the Care of Newborn Infants (www.efcni.org), the White Ribbon Alliance for Safe Motherhood (www.whiteribbonalliance.org), and many others worldwide to address policy, care, education, and research initiatives that touch the lives of mothers, fathers, newborns, and their siblings. These collaborations with the use of social media tools, listservs, and blogs will only increase in the next few years. Evidence-based guidelines for care are being adapted for use worldwide. A major challenge for this work, from a nursing perspective, is that there is no consistent definition of a nurse or a neonatal nurse. In some countries there are regulations and consistent education but in others neither of these exist for any level/type of nurse. COINN is working on the development of competencies to define the neonatal nurse. One example of a growing global area of special concern is palliative care for infants.

PALLIATIVE AND END-OF-LIFE CARE

There is an increasing awareness of the need for effective pain management. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has declared pain as the fifth vital sign across the life span. For neonates, pain management is complicated by the patient's nonverbal status and the need to rely on physiological parameters to measure pain and pain management responses. There is a need for more evidence to support pain management as seen in Chapter 23, Pain in the Newborn and Infant. Neonatal palliative care recognition is growing. As part of the National Perinatal Association's (NPA) project on psychosocial program standards for NICU parents, bereavement and palliative care recommendations were included (Hynan & Hall, 2015). Inclusion of this type of care is part of the Quality and Safety movement in neonatal care (Purdy et al., 2017).

Whether anyone wants to acknowledge it or not, some children are born dying. There are infants who cannot be saved despite the availability of sophisticated technology, and others who have life-threatening illnesses and who can survive. Those in the latter group, like all patients, deserve comfort or palliative care. (See Chapter 36, Palliative and End-of-Life Care, for more information.)

Population Health

The National Institutes of Health (NIH) has expanded funding to support development of the Centers for Population Health and Health Disparities. These centers focus on developing strategies to address disparities to include the social determinants of health—social, behavioral, genetic, environmental, and biological. There are many practical applications of population health in neonatal/family care. Population health refers to actions or factors, such as maternal factors, that impact the health outcomes of the infant. Preconception health, factors that relate to prematurity, and neonatal illness are examples of areas that fit within population health. Brindle, Flageole, and Wales (2012) examined maternal factors that might affect the health outcomes of infants with gastroschisis. This study was conducted in Canada and found that younger women who used drugs during pregnancy in rural or very isolated regions of Canada were giving birth to infants with gastroschisis (Brindle et al., 2012). This study is an example of population health and the linkages with social determinants and with specific neonatal conditions for neonates and their families.

The Robert Wood Johnson Foundation awarded grants to support the infusion of population health principles into undergraduate nursing curricula. Healthcare organizations have set up population health departments to address the most costly conditions experienced by patients and families. These usually include asthma, cardiovascular disease, and diabetes. The population health movement has yet to address neonatal health comparable to adult health even though there are some examples as previously noted.

PARENT VOICES

Jennifer Degl

NICU discharge day was something we had dreamed and wished for, yet is was one of the scariest days (aside from my daughter's premature birth) in our journey. For months, we looked forward to the day that we could bring home our baby to join our family. Once we arrived at home, the fear set in. How could we care for this precious baby with complex medical needs? How would we know if she stopped breathing while she slept? How would we know if she was choking while she ate or if she had an episode of reflux while napping? How would we be able to keep her safe and alive? These are all very valid questions since the nurses are the baby's primary caregivers while in the NICU. The fear is real but what is also real is that the hospital staff would not send the baby home if they felt that the baby would not be safe. Most parents begin to isolate themselves and their babies once they are discharged from the NICU because it's very important to keep the germs away. This can cause parents to feel very lonely. Parents should seek online support groups for NICU or premature babies because the members understand and can offer advice on how to manage after discharge. Parents should also be open to counseling. Most parents do not have time to process what has happened while their baby is still in the hospital and often have more time to reflect after discharge. This can trigger a plethora of emotional responses and there is nothing wrong with asking for professional support to help the healing process.

SUMMARY

This chapter has briefly highlighted some of the recent trends in neonatal care. With all the new breakthroughs in care, it is hard to imagine what the next decade will bring.

CHAPTER 39

Neonatal Care Using Informatics

Susan K. Newbold

INTRODUCTION

Hospitals have successfully used information technology (IT) in the past decades to support administrative, financial, and some clinical functions. Recent governmental mandates to reform healthcare have awakened the interest of many hospitals and provider practices to the value of using IT to support patient care. Effective use of IT in neonatal intensive care units (NICUs) or any intensive care unit (ICU) may greatly improve patient care and patient outcomes, reduce clinician workload, and decrease costs. Adoption of computerized technologies holds great promise as computer systems improve each year. Full functionality requires the integration of healthcare systems through adherence to emerging industry standards for computer-to-computer communication, healthcare data vocabularies, and quality management. This chapter focuses on the current status and near-future advances of NICU IT and provides guidance for evaluating and choosing information systems (IS) for the NICU.

BACKGROUND INFORMATION

The evolution of informatics began in the late 1950s as healthcare and computer technology began to blend. According to Collen (1995), the term *medical informatics* first appeared in 1974 and became pervasive in the 1980s with the introduction of microcomputers and networked computers. Some suggest that informatics was created as a new field with the first computerization of a cardiac catheterization laboratory by Dr. Homer Warner, Sr. Informatics expanded quickly as external technological innovations diffused throughout the heathcare environment. Informatics pioneers were first classified as a subgroup of bioengineering. Many new names for the field appeared: medical computer science, medical information processing, and medical computer technology. Over time, healthcare professionals began substituting the term *medical* with *health* because informatics is a broad term that pertains to many healthcare disciplines, not just medicine. By the 1980s, the terms *clinical*, *health*, and *nursing* informatics had surfaced. Saba and McCormick (2015) assert that the field of informatics exploded in nursing in the 1980s. The nursing profession needed to update its practice standards and determine the data standards, vocabularies, and classification schemes that could be used for electronic patient record systems.

Nursing informatics (NI) has evolved rapidly from the predominantly physician-populated field of medical informatics. Nurses Graves and Corcoran, authors of "The Study of Nursing Informatics," defined NI as "a combination of computer science, information science, and nursing science designed to assist with the management and processing of data, information, and knowledge to support the practice of nursing and the delivery of nursing care" (Graves & Corcoran, 1989, p. 227).

Graves and Corcoran's classic definition considered functional components (i.e., management and processing), combined with conceptual components (i.e., data, information, and knowledge), and then recognized the *process* whereby the functional components operate on the conceptual components. In short, Graves and Corcoran believe that NI should be more concerned with how the data is structured and organized than with the content of the data.

In this early stage of development, informatics continues to morph and to grow rapidly. The two strongest influences on the informatics field are evolving healthcare and advances in technology. Informatics attempts to merge these two dynamic influences to better the delivery of healthcare.

A workgroup sponsored by the American Nurses Association (2015) utilized the Graves and Corcoran concept to create this definition of NI, well accepted in the United States:

> Nursing informatics (NI) is a specialty that integrates nursing science with multiple information and analytical sciences to identify, define, manage, and communicate data, information, knowledge, and wisdom in nursing practice. NI supports nurses, consumers, patients, users, the interprofessional healthcare team, and other stakeholders in their decision-making in all roles and settings to achieve desired outcomes. This support is accomplished through the use of information structures, information processes, and IT. (p. 1)

Landmark legislation in 2010 advanced electronic health records (EHRs) extensively in the United States. The Health Information Technology for Economic and Clinical Health (HITECH) Act, passed in 2009, offered financial incentives for meeting the first of a series of tests of the *meaningful use* of healthcare IT. It was expected that there would be three stages to be achieved to realize maximum incentive payments to eligible providers and to avoid financial penalty. As of this writing, the requirements for Stage II have been adopted. In Stage II, the goal is to increase health information exchange between providers and promote

patient engagement by giving patients secure online access to their health information.

The Healthcare Information Management Systems Society (HIMSS) Analytics (2018) offers an eight-stage U.S. EMR Adoption Model[SM] that reveals how facilities have progressed with the implementation of EHRs. As of the end of 2017, 83.3% of the 5,487 facilities reporting indicated they have IS that support computerized physician order entry (CPOE) with clinical decision support, nursing and allied health documentation, and basic business continuity (HIMSS Analytics, 2018). Only 6.4% of facilities have reached the highest level with a complete electronic medical record; external health information exchange, data analytics, governance, disaster recovery, privacy, and security.

SPECIAL CONSIDERATIONS FOR THE EHR IN SUPPORTING PEDIATRIC AND NEONATAL PATIENT CARE

Lowry et al. (2012) published "A Human Factors Guide to Enhance EHR Usability of Critical User Interactions When Supporting Pediatric Patient Care" highlight clinically important special considerations for pediatric patients that are often not understood by those selecting IS for the adult population.

- Weight-based dosing in the NICU is far more complex and difficult to standardize.
- Sophisticated rounding strategies and accurate weight measurements are used to avoid over- or underdosing, especially for infants who weigh less than 1,000 g.
- Patients can share the same birth date with multiple siblings, so identification can be an issue.
- Alerts can be challenging due to the need for both age- and weight-based alerts. Age-based dosing considerations in neonates must also consider gestational age, elapsed days since birth, and *adjusted chronologic age* for growing very low birth weight babies.

TYPES OF INFORMATION SYSTEMS

According to McGonigle and Mastrian (2018), the term *information system* refers to "the manual and/or automated components of [sic] system of users or people, recorded data, and actions used to process the data into information for a user, group of users, or an organization" (p. 568). Others argue that IS also include those manual data management systems that still exist in parallel today. More specifically, clinical IS are IS that provide access to and methods for recording and managing clinical data. Examples include paper and electronic flow sheets, daily notes, physician orders, and pharmaceutical systems.

FLOW SHEET REPLACEMENT AND CLINICAL MONITORING

Critical care bedside clinicians are *hands-on* providers. The care environment is complex and filled with many simultaneous processes that inform medical decision making. ICUs are often crowded with both people and devices. Care providers are often summoned from one task to a more urgent one in seconds, making computer use/access/log off difficult or impossible with existing systems. Clinical data acquisition and integration at most ICU bedsides still depend on pen-and-paper flow sheet methods and workarounds. This practice is very time consuming and creates an *information overload* of poorly organized, often illegible data that can lead to oversights and potentially avoidable errors (Palma, Brown, Lehmann, & Longhurst, 2012; Salanova, Llorens, & Cifre, 2012).

Real-time integration of machine and ancillary data into a user-defined presentation format to support bedside patient care is an unmet dream of most intensive care doctors and practitioners. Past attempts to computerize aspects of ICU bedside physiologic data management have led to sophisticated, freestanding commercial bedside physiologic monitoring and treatment systems (monitors, ventilators, pumps, and flowmeters). Each machine relates to a subset of the patient's overall problems (cardiac, respiratory, brain, etc.). Unfortunately, these existing bedside machines have no formal open communication standards with today's computers, although we are moving toward adopting standards.

A challenge for NICU computerization is acquiring and integrating important off-site ancillary data such as that from laboratory, pharmacy, and radiology departments. Computer tools to obtain, analyze, and present patient data trends and information important for clinical caregivers in complicated ICU situations are emerging and are becoming commercially available, usually as *templates* that require local programming.

As flow sheet replacement systems evolve, more complete solutions are being developed to reduce the drawbacks that have prevented the adoption of many of the early electronic flow sheet systems. The more complete solutions enable real-time temporal integration and storage of clinical patient information derived from many different clinical data sources. They have effective interfaces to analyze and display this data both for immediate patient care and for clinical research and quality assurance initiatives. Some of these new systems have touchscreen interfaces available that provide a single point of contact for viewing patient data that is stored in EHR systems, laboratory systems, and pharmacy systems along with data collected from the output of attached bedside machines. This type of automated integration greatly reduces the amount of bedside clinical patient data that must be reentered by the bedside nurse. Time-sensitive graphical displays provide a convenient mechanism for caregivers to review current and historical data about the patient so clinicians can quickly grasp a more complete picture of a critical care patient's status. With real-time integrated systems, many critical transients (e.g., apnea and bradycardia episodes) or trends (e.g., loss of heart rate variability) are harder to overlook in situations where multiple simultaneous events compete for a caregiver's time, such as crisis situations during transport or in the ICU. The most complete of these automated flow sheet systems improve upon current practices by means of the following:

- Integrating important data from the EHR, laboratory, pharmacy, and bedside devices, then displaying the temporal information clearly and compactly at the patient bedside or point of care
- Capturing and integrating patient parameters (vital signs, labs, etc.) into a daily note system
- Enabling remote access to integrated patient data, just as if the clinician were at the point of care
- Interfacing patient data collected during transport with the patient electronic record
- Providing deidentified or scrubbed patient information securely to a data warehouse for supporting a broad range of quality assurance, medical, pharmaceutical, and bioinformatics research activities
- Utilizing the automatically captured, integrated data to suggest diagnostics, suggest protocol adherence, and provide smart alert notifications.

Current paper-based flow sheet standards have been seemingly adequate throughout history. It is evident, however, that a properly

designed automated flow sheet system could decrease time collecting, communicating, and analyzing patient data. This saved time can then allow clinicians to focus more on treatment and patient care.

INTERDISCIPLINARY NOTES: DAILY DOCUMENTING CHALLENGES

Every day, in every ICU, many different notes must be generated that outline the care being provided for the patient by the nurse, the doctor, the respiratory therapist, and others on the care team (pharmacists, social workers, physical therapists, etc.). Generating these notes, from the initial history and physical (H&P), to the daily progress note, to the final discharge note, has often been problematic and is very time consuming.

The information contained in many of these notes is used for both communicating and documenting daily care and eventually for billing. Over the years, attempts to generate a *readable* note have taken on several forms. Traditionally, a clinician would record a few key words when moving from patient to patient or use a preprinted card with check boxes to record appropriate information. Later, in a more private, less chaotic space, the clinician may try to recall everything about the encounter and create a narrative note. The clinician might type the note, but this data entry method has slowed, and often disgruntled, clinicians. More often, the clinician would dictate the encounter narrative to a dictation service. Some number of hours or days later, a complete note would appear for the clinician to sign and place in the chart, as a prerequisite for reimbursement. The dictation is expensive for the hospital. The delay in returning the dictation to the care venue, plus the delay in signing, compounds ongoing operational problems of timely coordination of daily communication between different caregivers, especially in a cross-disciplinary, teamwork-based NICU.

Several companies have developed voice recognition systems to overcome the delay-related issues. In disciplines with *limited* vocabulary and quiet work environments (e.g., radiology), voice recognition systems have achieved some popularity. If voice recognition systems can be made to work well, the daily note is theoretically available as soon as the clinician finishes speaking; edits can be made immediately. The usual drawback of such systems is that the *vocabulary* to be recognized must be greatly restricted in order for the system to work well. In addition, each clinician using the system must *train* the system to recognize his or her personal speech patterns. Extraneous noise can greatly influence the accuracy of the word recognition, so the dictation must be done in a relatively quiet environment, which is difficult to attain in the daily life of most NICUs. To achieve this, the clinician must, once again, be removed from the point of care to record the encounter. This can lead to errors and often requires first written, then verbal narration of facts in hopes of precisely recording the encounter. Increasing point-of-care clinician absence can lead to team communication gaps, errors, and redundant *documentation*, potentially causing decreased accuracy and wasting precious time duplicating facts. This dysfunctional workflow situation leads to increased caregiver frustration, and therefore decreased product usage. When used in an optimal setting, however, voice recognition systems often excel.

Daily note systems based on templates are gaining popularity. A template is a document in either paper or electronic format that contains commonly used clinical data elements in a predefined format. The idea behind these templates is that the format of the template (e.g., daily note) is fairly static for a given patient type (neonate, cardiac, transplant, etc.). One of the more tedious tasks when using this writing system is gathering parameters (such as blood pressure, O_2Sat, and heart rate from the flow sheet) and retyping them. Another downfall is that the users could begin to rely only on those predefined elements within the template, thereby potentially missing unusual findings or situations. Templates that utilize a note system configured to accept bedside data from an automated data acquisition system can greatly reduce the time needed to generate daily notes and can often increase completeness and comprehensibility of the daily note.

COMPUTERIZED PROVIDER ORDER ENTRY/MANAGEMENT

Meaningful use and the HITECH legislation have significantly advanced CPOE. The promise of these systems includes reduction in errors through improved legibility, immediate cross-checking for prescription interactions, other error alerts, and more immediate fulfillment of orders. Currently 83.3% of 5,487 hospitals are using CPOE, which is a significant jump from 2012, when only about 13.3% of hospitals were using CPOE (HIMSS Analytics, 2018). Poor training and system usability seem to be the root causes of problems with the early use of CPOE (Kuperman & Gibson, 2003). Although some hospitals have experienced failures implementing CPOE systems, there are also many hospitals with successful implementations. Among these success stories, studies have indicated benefits such as a reduction in medical errors, improved quality of patient care, and a positive effect on costs of healthcare are directly related to CPOE systems (Chapman, Lehmann, Donohue, & Aucott, 2012; Mekhjian et al., 2002; Saathoff, 2005). For neonates, the CPOE systems were rudimentary and often required extreme caregiver time and attention to dealing with difficult computer system navigation and workarounds, including defining pharmacy compounding, details that are usually unfamiliar to bedside clinicians. CPOE implementations themselves are often locally adapted from adult systems, leaving gaps and internal coding (e.g., rounding rules for 500 g infants) that may be inconsistent with optimizing clinical care in the NICU.

Chapman et al. (2012) studied the implementation of CPOE in an NICU. The researchers conducted a one process-focused hospital study to determine if CPOE impaired or enhanced workflow in the NICU. By comparing the timing of administration of antibiotics before and after CPOE implementation, they concluded that CPOE in the NICU did not significantly improve antibiotic administration times, but the time to pharmacy verification was improved. This suggested further work was needed to investigate admission workflow, which they deemed to be a complex process.

Unintended consequences of EHR use including CPOE have been studied among physicians but few studies focus on nurses in the neonatal intensive care. Dudding, Gephart, and Carrington (2018) examined the unintended consequences of nurses' use of EHRs and included neonatal nurses in the sample. They defined unintended consequences as "unforeseen events, change in workflow, or an unanticipated result of implantation and use of electronic health records" (p. 167). Interruptions, a heavier workload due to the EHR, changes to the workflow, and altered communication patterns were the most frequent unintended consequences cited.

PHARMACY

Pharmacy-related electronic IS have been introduced in recent years that have reduced medication errors, thereby preventing harm to our tiniest patients. Many ICUs have adopted electronic dispensing systems to help ensure that the ordered medicine is given to the correct patient. Barcode medication administration is in the

process of being widely adopted and the level of adoption stands at 33.8% in 2018, up from 11.5% in 2012 (HIMSS Analytics, 2018). With such a system, barcode labels on the medication (including breast milk) are scanned along with a barcode identification band on the patient, ensuring that the appropriate medication is given to the appropriate patient in the right dose at the right time and through the correct route. If all is correct, the nurse or other healthcare professional gives the medication and records the event in the electronic record. These systems require barcodes to be assigned to a patient and to each prescription filled by the pharmacy. In order for these systems to be most effective, a medication history must be made available to the pharmacy plus someone must be available to enter the historical data, both at admission and after every *transition of care* (e.g., a trip to the operating room and back).

OTHER SYSTEMS

In addition to the systems outlined, many other computerized systems exist within hospital settings that provide data regarding a patient's condition. Imaging systems to store and display x-ray, CT scan, and MRI results are widely available. Laboratory systems that can send information to the EHR or store the results locally are being used by modern hospitals.

More and more NICUs are utilizing telehealth technologies to allow virtual visitations of the infant by family members. A study of the impact of web cameras advises that disruption of the nurse workflow has the potential to decrease the quality of care for infants. Researchers suggest that, to mitigate for the disruptions, training sessions should be held with nursing staff prior to system implementation (Joski, Chyou, Tirmizi, & Gross, 2016).

An underlying layer of complexity with all of the aforementioned systems is the hardware that is used to display the data. For example, most hospitals' IS are *hardwired*, requiring a clinician to view and document patient data at a stationary computer. A rapidly emerging option is to make most interfaces *wireless*, allowing mobile access to patient information. Wireless solutions include laptop personal computers, tablets, personal computers, and smartphones.

The problem with having so many different IS is that ensuring accurate communication between systems is difficult. Such difficulties as terminology differences among systems, multiple log ins, variable security protocols, and reducing data redundancy all point to a more complex integration problem. Lack of computer communication standards to express the broad spectrum of neonatal and perinatal diseases and transitional difficulties compounds the problem set.

Interoperability (HIMSS, 2018) "describes the extent to which systems and devices can exchange data, and interpret that shared data. For two systems to be interoperable, they must be able to exchange data and subsequently present that data such that it can be understood by a user." The Centers for Medicare and Medicaid Services (CMS) has renamed the meaningful use EHR Incentive Programs as Promoting Interoperability (PI) Programs (CMS, 2019).

INTEGRATING COMPUTERS

Integration issues can be likened to language barriers. Suppose the organization's flow sheet system was in Spanish, the daily notes system in Russian, and the pharmacy system in Chinese. Obviously, communication would be difficult unless one spoke all three languages or had interpreters. In informatics, the *interpreter* that would make the aforementioned systems communicate is called an *interface*. Currently, interfaces are necessary because independent systems (flow sheet, daily notes, pharmacy, laboratory, etc.) within a hospital need to communicate patient information with each other and the end users. Although interfaces are currently necessary as an interim solution, they are not perfect. In ICUs, optimal clinical care depends on clear integration of many different kinds of time-stamped clinical data. The data needed to support bedside clinical decision making is generated in many departments throughout the hospital. Caregivers—including nurses, respiratory therapists, doctors, social workers, and physical therapists—all contribute a specific set of important clinical observations to the overall clinical data matrix.

Current hospital IS integrate critical clinical information and convey it to the caregiving team via a myriad of ways. Communication efforts are evolving, using both formal and informal methods, including charting on large paper flow sheets, printed laboratory reports, verbal reports, dictation, and handwritten/typed progress notes, to name a few. Interestingly, some of these methods that are paper based exist within a partially computerized system due to poor integration and virtually no interface capability between departments. Current practices using paper are notorious for being time consuming, illegible, and laborious. They are also error prone, allow only limited access (only one user can view at any one time), create storage nightmares, and have data redundancy. The problem is complicated because any new computer systems installed are often not able to integrate with the original or *legacy* systems, some of which were developed as far back as the 1970s. Thus, in many complex cases, the daily paper flow sheet creates a compact visual document that can be scanned in seconds for emerging and multisystem problems by experienced criticalists. Existing computer systems' screen displays require much clicking, rolling, and scrolling, which often obscures the temporal relationship of complex patient condition changes (*crashes*). Optimizing future systems with a higher level of integration and more cognitively appropriate and compact screen display would obviously work to correct many of these problems (Palma et al., 2012).

The ideal future method of communication would automate and integrate, in real time, all bedside monitoring information, laboratory results, medications, daily notes, alerts, reminders, and order entry directly into a centralized system. This centralized system would also have a decision support element that notices trends occurring in the patient, alerting the clinician, and recommending possible interventions. Additionally, this type of system provides data to hospital administrators so that optimizing decisions can be made regarding staffing, billing, materials management, and quality assurance, to name a few. This same system could also be used to push data to registries to assist hospitals with compliance mandates as well as in identifying the best treatment patterns.

To make the leap from current to future systems, hospitals are faced with hundreds of different products from which to choose. Prior to 1996, many of the larger products boasted they were a *complete system*, but they did not use standardized communication methods. The companies creating these products were unable to come to an agreement as to a unified common standard, and as a result, the government created laws and national standards in an attempt to mandate that a common communication standard be developed.

CONNECTIVITY STANDARDS AND THE HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT

Background

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 (P.L. 104–191, Title II, Subtitle F) is one of the largest pieces of healthcare legislation in U.S. history. According to

Friedrich (2001), HIPAA was passed with three main goals: (1) improve access to health insurance, (2) reduce fraud and abuse, and (3) increase the efficiency and effectiveness of the healthcare system. The initial goal of increasing accessibility is twofold. One aspect is related to making health insurance portable and continuous for those changing employment locations. The second aspect deals with deterring insurance companies from rejecting individuals with preexisting health conditions. Friedrich also explained that the second goal of HIPAA, related to fraud and abuse, and the third goal, related to increasing the efficiency and effectiveness of healthcare, fall under the Administrative Simplifications section of Friedrich (2001). The Administrative Simplifications involve the development of standards and regulations for accessing, transmitting, and storing medical data. Friedrich (2001) states that there are two broad types of regulations: standards related to electronic transmission of data and those intended to ensure the security and privacy of patient information.

The HIPAA mandated that specific code sets and computer communication strategies (both called *standards*) be decided and implemented by specific dates, now all past. The start dates for use of HIPAA-mandated coding and interconnection strategies were between 2003 and 2005. The foundational work for completing healthcare computer communication standards is in progress now. No one *standard* was, or is, completely finished. Standards-setting groups meet regularly. These groups are mostly voluntary. Overcoming the proprietary interests of vendors that have a large vested interest in proprietary (owned by the individual or company with restrictions on use) software, communication strategies, and clinical expression codes did require the federal HIPAA. New systems are required to be *HIPAA compliant*.

HIPAA Mandates: Codes Set Standards

Before HIPAA, there were no mandatory communication standards in place for healthcare providers and payers to transfer information electronically from one facility to another or from one facility to a payer. More than 400 different formats for electronic transactions had been created for communications between providers and health plans (Office of the Assistant Secretary for Planning and Evaluation [ASPE], 2000). HIPAA reduced the number to eight clinical code sets and two electronic transaction/computer communication standards for healthcare administrative and financial communications (ASPE, 2000). Congress made major operational modifications to the original plan in response to comments, problems, and evolving situations in May 2002 (U.S. Department of Health and Human Services [HHS], 2003).

Codes in HIPAA-defined healthcare rules are precisely formatted numbers and letters that match some clinical concept such as a diagnosis, medication, or treatment. Communication standards provide a specific place assignment where programmers insert needed coded information, such as a patient identifier, whether they are writing a lab system, a clinical system, or an administrative system.

The Health Level Seven International (HL7) and American Standards Committee (ASC) X12N computer communication standards provide a uniform programming structure, so different vendors of clinical, lab, or hospital IS can send medical and administrative information to each other, without data loss and with clearly defined meaning. The Fast Healthcare Interoperability Resources (FHIR) standards framework is a promising development that leverages web technology to access and exchange data across electronic systems (HL7, 2017).

A *code set* is any organized system of codes for listing data elements, such as tables of terms, or codes for medical diagnosis and medical procedures (HHS, 2003). Code sets, now defined under the HIPAA, are considered code set standards. Examples of these include the *International Classification of Diseases, Tenth Revision* (*ICD-10*); Healthcare Common Procedure Coding System (HCPCS); *Current Procedural Terminology* (CPT); *Code on Dental Procedures and Nomenclature* (CDT Code); and National Drug Code (NDC). The ICD-10-CM (*International Classification of Diseases, Tenth Revision, Clinical Modification*) is used for diagnoses and hospital patient services codes. Due to the American Recovery and Reinvestment Act (ARRA) of 2009, the Stage II Meaningful Use aspects of the HITECH legislation included converting from *ICD-9* to the more complex *ICD-10* by October 2014. To report supplies, durable medical equipment, and generic drugs under Medicare plans, HCPCS is employed (HHS, 2003). CPT is mandated for coding physician services. Dental services are coded under CDT, and NDC is used only for medications and drug systems for retail pharmacies (HHS, 2003).

Computer communication standards defined under HIPAA include ASC_X12N and HL7. ASC_X12N, Version 4010 (X12, n.d.) is used for health claims, attachments and encounters, payment and remittance advice, claim status, eligibility, referrals, healthcare enrollment, health plan premium payments, and first report of injury. This communication standard condenses more than 400 transaction formats, with one set of specific transaction standards that are formatted in one language (ASPE, 2000). HL7 is an accredited standards developing organization (SDO) that produces standards (sometimes called *specifications* or *protocols*) for a particular healthcare domain such as pharmacy, medical devices, imaging, or insurance (claims processing) transactions. HL7's domain is clinical and administrative data (HL7, n.d.).

As one can see, the elements defining the aforementioned code set standards are independent, not interdependent. Problems, therefore, quickly arose with initial attempts to apply HIPAA administrative code set standards to computerized clinical medical records. According to Chute (2002), most HIPAA approved code set standards, such as *ICD-9* and *CPT*, could lose more than half the underlying, detailed clinical information because these code sets were originally established for billing purposes. Loss of pertinent clinical details needed for bedside care and communication can be detrimental for the patient, the providers, and the institution. Because of the obvious need for standard vocabularies in the clinical setting (medical, nursing, and laboratory), the Office of the National Coordinator for Health Information Technology (ONCHIT) was established in late 2004 to coordinate these efforts (www.healthit.gov). The hoped-for outcome of these efforts is rapid development of complete clinical code set standards for care-based computerized patient records.

Different from the aforementioned HIPAA-defined code set standards, clinical code set standards in use are Systematized Nomenclature of Medicine Clinical Terms (SNOMED), Nursing Intervention Classification (NIC), Nursing Outcome Classification (NOC), North America Nursing Diagnosis Association (NANDA), and Logical Identifier Names and Codes (LOINC). "The SNOMED CT core terminology contains over 366,170 health care concepts with unique meanings and formal logic-based definitions organized into hierarchies" (SNOMED International, 2018). NIC, NOC, and NANDA are independent code sets used for nursing diagnoses, treatments, and outcomes documentation. Each of the three has issues such as an inability to combine and link unique concepts as a single concept, poor coding, and an inability to reduce concepts to an anatomic level. Informatics nurses are currently working to harmonize several terminologies so that nurses can document the nursing processes in a standard manner. Lastly, LOINC, which facilitates "One of the main goals of LOINC is to facilitate the exchange and pooling of results for clinical care, outcomes management, and research" (Logical Observation Identifiers Names and Codes, 2018).

HIPAA Mandates: Identifiers

Identifiers are numbers assigned to healthcare providers (individuals, groups, or organizations) that deliver medical services, other health services, or medical supplies. The final rule for the national provider identifier (NPI) was published in January 2004 (Centers for Medicare and Medicaid Services, 2005). The proposed rules for assigning unique identifiers to employers and health plans are, however, not yet fully operational. Employee identification numbers (EINs) are under scrutiny because the number to be used was determined by the Internal Revenue Service (IRS) to be the taxpayer identifying number, also known as the Social Security number (SSN). This was thought to be a good idea since most employees should already have an SSN assigned prior to being hired in an organization. The use of the SSN has, however, caused controversy because health information and financial information will be directly linked to the same number. Additionally, there are duplicate SSNs. National health plan identifiers (NHPIs) are also undetermined at this time (CMS, 2005).

HIPAA Mandates: Privacy

Before HIPAA, legal protection of patients' privacy and confidentiality was fragmented across state, federal, and commercial insurance systems, which left many gaps in patient privacy (Hebda, Hunter, & Czar, 2019). Evolving, implementing, and testing patient privacy rules under HIPAA is an ongoing process. The effective compliance date was April 14, 2003.

The Privacy Rule was constructed with hopes of protecting verbal, written, or electronic personal health information (PHI) that can be traced to an individual. This PHI refers to any record containing any of the 18 elements defined as personal health data (e.g., name, birth date, SSN, address). The rule protects PHI not only within the walls of the hospital but also while it is in transit to other locations (Friedrich, 2001). The rule applies to health plans, healthcare clearinghouses, and those healthcare providers who electronically conduct financial and administrative transactions (ASPE, 2001). Consent must be obtained from the patients prior to any release of their private information for treatment, payment, or other healthcare operations. Patients will have the right to restrict the use and disclosure of their information, and the option to file formal complaints if their privacy has been violated. All shared data must be stripped of PHI information unless sharing is authorized by the patient. In addition, patients must have full access to their medical records (ASPE, 2001). Since some of these elements are also vital statistics (e.g., date and time of birth) that are a matter of public record, and of extreme clinical importance for babies' healthcare management (e.g., developmental milestones), the problem for follow-up, other communication, and research is obvious to pediatricians. Since adults have no such issues, however, the situation in standards' setting groups is stalled, because vendors of adult systems would have difficulty and expense *retrofitting* their software to support the date/time aspect for neonates. Currently, progress toward full utility for neonates is slow and/or stalled.

HIPAA Mandates: Security

Security regulations refer to technical protection of computerized PHI transmitted electronically within and among provider and payer organizations. Security standards have three categories: (1) administrative security (e.g., access controls and contingency plans), (2) technical security (e.g., authorizations and audit controls), and (3) physical security (e.g., limit physical access to workstations; Hirsch, 2003). Although these three categories are different, the security measures proposed in each category require similar forms of intervention.

For clinical users, HIPAA has created a very unstable and tenuous balance between security and usability (Dawes, 2001). For example, many paper-based units have removed all charts from the bedside, including flow sheets, to keep the patient's data more secure. This poses a workflow problem, especially in an ICU, because that information is needed at the bedside. In computerized systems, excess security has become a burden because hospitals are requiring excessive password usage to gain access to EHRs. In an emergency this process tends to delay patient care when it is needed most. Log-in times range from 30 to 75 seconds in usual times, across most NICUs. A nurse accessing the computer for charting and so on may thus *waste* about an hour a day simply waiting for computer access.

HIPAA Mandates: Penalties

According to HHS, there are two types of penalties: civil and federal criminal (ASPE, 2001). For a civil penalty, the minimum fine for failure to comply with a standard is $100 per violation with a maximum of $25,000 for identical violations per year for each requirement violation. Criminal charges start at $50,000, with a maximum of 1 year in prison for wrongful disclosure (ASPE, 2001).

HIPAA Update 2013

HHS announced a final rule on January 25, 2013, that implemented a number of provisions of the HITECH Act to strengthen the privacy and security protections for health information established under the HIPAA. Since that time fines have been issued for violations of this rule.

Clearly, there are numerous layers of complexity when considering clinical IS. There are various types of IS available for all aspects of the delivery of patient care. When reviewing any IS, it is critical to consider if and how these systems communicate or integrate with one another. Whether the NICU is in the process of replacing an entire EHR, or a smaller change such as an automated flow sheet, it is important to use a formal process to evaluate options and select the system that is the best fit for the organization.

IS EVALUATION, SELECTION, AND IMPLEMENTATION

Bedside caregivers in the NICU need to have an understanding of general guidelines for evaluation, selection, and implementation of IS within their hospital organization. Bedside caregivers, not just administrative staff, must play an integral role in the extensive and elaborate process of hospital IS selection and installation. Bedside caregivers who interact with the clinical IS on a daily basis are called end users. End users help to define the requirements of the system in the early stages of evaluation and to give input during the selection process. End-user satisfaction is the key to the successful implementation of a system. A brief overview of these important processes follows, to ensure that modern-era bedside caregivers have an understanding of their roles and expectations during an NICU IS selection and implementation.

RESEARCHING IS SOLUTIONS

Many hospital organizations are either initiating the switch from paper-based charting systems to electronic charting systems or are moving from one electronic system to another. Some facilities currently have systems and are changing vendors, hardware, and/or

software. This type of project is a massive undertaking for a hospital—financially, logistically, and culturally. For future purchases, therefore, most hospitals are beginning to develop structured planning, purchasing, and implementation processes in an effort to avoid project failures.

The first stage in the system evaluation/selection process is to logically identify and list the problems with the current system in a structured format (e.g., a spreadsheet). It is important to research alternative technological solutions or enhancements to the identified problem(s). Often a multidisciplinary (IT, clinical, and administrative representation) approach to these early *brainstorming* sessions yields enough ideas to structure a more substantial search. Initially, a request for information (RFI) can be directed to vendors that specialize in clinical IS. The vendor will in turn reply with introductory product information. An RFI is a standard and affordable business process that is used to collect information about the capabilities of various products. The RFI is normally formatted so it can be used as an initial assessment tool for comparing vendors (Hunt, Sproat, & Kitzmiller, 2004).

Once the vendor list is at a manageable size, a more detailed comparison process begins, using a request for proposal (RFP). The main purpose of the RFP is to document the vendor's claims in terms of system functionality, support, training, cost, and implementation approach, including staff education and post-installation support plans for the early months of the *go-live*. The hospital's IT or IS department will likely compose this document with input from all affected parties. Some organizations elect to use an outside consulting firm to help with RFP development and system selection. At this step, input from the end users (practicing clinicians) is vital. An RFP should be created for each individual unit and should include its unique workflow issues. When you use an individualized approach, it is harder for the vendor to provide broad, generic solutions that may be technically capable, but do not really address the NICU's specialized requirements, and ultimately may be either unusable or unsafe, or both.

One of the most essential sections of the RFP describes the system's functional and technical requirements. Functional requirements are developed using input from bedside caregivers on the basis of the daily workflow needs and data management goals for the specific unit. These detailed requirements are listed by the requesting hospital in a table/database format. Technical requirements pertain to issues such as network and hardware specifications that are required to make the system run (Hunt et al., 2004). Vendor response columns should be provided so that the vendor can specifically address each requirement in terms of the technical details, defining how the system meets each specification. Each requesting hospital should provide a predetermined response key for the vendor to use. The preestablished response key assists the purchasing team in cross-vendor comparisons.

In addition to the functional and technical requirements, the implementation and maintenance plan for the proposed system should be requested of the vendor. In the RFP response, the vendor should provide, in writing, their plan for implementation, training, and support of the system (Hunt et al., 2004). These components can make or break the success of the system. Finally, the RFP should request a detailed cost matrix of all aspects of the vendor's system and its implementation, including costs, plans, and options for go-live testing and tuning and rollout staging.

The completed RFP is sent out to prospective vendors, and formal proposal replies are expected within weeks. If composed appropriately, the RFP will require the vendors to confirm that they meet the details of the request. Their responses will contain information that will allow a thorough evaluation and selection process.

EVALUATION AND SYSTEM SELECTION

As the vendor proposals are received, the informatics department and selection team will begin the evaluation process. A metric scoring scale can be applied to the objective sections of the submitted proposals. The objective sections include the functional, technical, and financial requirements. The scoring scale allows the hospital to evaluate the vendors' systems objectively and consistently. A numerical weight value will be assigned to each response. For example, a response of "Not available" should receive a weighted score of zero, whereas a response of "Available and already successfully installed in a similar healthcare facility" should receive the highest weight on the response key scale. All objective sections of each vendor's proposal are scored on the basis of his or her responses. Then a summary table can be created to display the final numeric results and ranking of each vendor.

Financial comparisons evaluate whether the requesting hospital can afford the high-scoring vendors. Typically, the financial department of the hospital assists in this phase. Several financial evaluation tools are commonly used. A cost–benefit analysis (CBA) is traditionally done by comparing the cost of each system with the proposed benefits. The CBA is, however, purely an estimation approach and incorporates such concepts as *intangible* benefits that are difficult to quantify for parallel comparisons. A second approach is a cost-effectiveness analysis (CEA), including a payback analysis, a return on investment (ROI) estimation, and a net present value (NPV) assessment. The ROI and payback analysis are both methods that determine the time for each system to repay its costs. Once a system pays for itself, cost savings for the hospital will begin. The NPV calculates the value of each system at any given time, thus determining the profitability in current dollars. Typically, the financial department performs these analyses. End users who are active in the selection process should be familiar with commonly used comparison methods.

Once the objective scoring is complete and the cost analyses are done, vendors should be ranked according to their scored percentages. This ranking acts as a consistent comparison tool to determine which vendor best meets the hospital's desired criteria. This process is important because the purchasing organization must be able to quantify necessary functions for their desired system.

Finalist vendors' products (usually two to three) can be further evaluated in many ways. Reference checks by telephone interviews of the specific vendor's clients to get an overall feel of client satisfaction with the vendor's installed system is one way to evaluate a finalist (Hunt et al., 2004). A standard questionnaire is another useful telephone tool that can again compare client feedback on an equal basis. There are several web-based agencies that conduct and publish results of satisfaction surveys for a fee that can be helpful to a buyer.

The next step is to organize on-site vendor demonstrations. Demonstrations are necessary for end users to test whether their functional requirements can actually be met. A demonstration evaluation test tool should be created to assess how each system functions in the context of actual daily workflow for the particular unit. Part of the tool should use test case scenarios that are unique to the unit and also taxing to a system. An example of such a scenario may be to "demonstrate the admission of unnamed triplets where two were born before midnight and one was born after midnight." The demonstration tool should also assess usability and functionality of clinical documentation. For example, "What happens if a nurse is documenting an assessment but gets called away from the bedside before finishing? Is his or her work saved and time stamped?"

The final step of product evaluation is to conduct site visits at other hospitals. Select similar hospital units that currently use the IS of interest. To obtain a true picture of how the system functions, it is best to conduct these site visits without the vendor present, which also allows the end users to express how they feel about the system and how it will fit into their workflow (Hunt et al., 2004). The site visit team should be multidisciplinary for gathering feedback from various perspectives, including different types of end users (i.e., nurses, respiratory therapists, doctors, informatics specialists). The site visit team should use the same evaluation tools that were used in the vendor demonstration to observe and evaluate the installed product function during real-life scenarios in real time. It is also important for the site visit team to note the physical layout of the unit and how the system fits into the staff's workflow. For example, is there a computer terminal in each patient room, or do the staff share one terminal per several patients? If the computers are mobile, do they easily fit into each patient room, or do the visitors have to leave before they can pass through the door? The site visit team can apply the on-site observations to their own NICU. In addition to environment and workflow observations, a site visit questionnaire can be created to gather more structured information from current end users.

As the evaluation process closes, a final decision-making team should review (a) subjective and objective information, (b) reference telephone interviews, (c) demonstration evaluation tool results, and (d) site visit feedback from questionnaires. Hospitals usually select a finalist and a runner-up vendor. The two finalist vendors' supporting information is presented to the project steering committee (i.e., the final decision makers.) This committee will likely include representation from high-level executives (CEO), financial personnel (CFO), nursing (CNO), medical (CMO), IS/Informatics (CIO), chief medical information officer (CMIO), chief nursing informatics officer (CNIO), and so on. Once the selection is made and contract negotiations are finished, the implementation phase will begin.

IMPLEMENTATION

The key to a successful system conversion (i.e., switching the old system out and bringing the new system in without clinical disruption) is a well thought out implementation plan. A project implementation team should include end-user representation from every shift, IT personnel, and vendor representation. Administrative representatives who are people-oriented problem solvers are valuable team members. End users who are bedside caregivers are integral to the installation process because they provide functional knowledge for both the system design team and the training team. IT team members can provide technical services and schedule planning tools to ensure a smooth transition. Team members from the vendor facilitate local customization efforts and training on the basis of their full understanding of their system's inner workings.

The implementation team is responsible for (a) educating themselves with 100% of the system's functions, (b) installing hardware and software, (c) customizing the system, (d) testing the system, (e) creating implementation and user documentation, (f) educating users hospital-wide, (g) overseeing the actual system conversion, and (h) conducting the post-implementation evaluation. Typically, the first five steps precede the live conversion. These steps make the system mesh with the subtle nuances of the hospital and/or the particular unit (i.e., the NICU). The last three steps rely heavily on end-user participation. The success of the system conversion is based on actual usability by the intended users in the clinical environment.

Before the installation of the hardware (monitors, keyboards, etc.) and software (instructions for the computer), the IT staff on the implementation team should verify the physical layout of the unit and check and supplemental power sources, lighting, noise, and privacy limitations. IT staff should walk through the unit with all end-user representatives while they visualize and verbalize issues unique to the unit. This step (*cognitive walkthrough*) helps prevent surprises and delays during the system-wide installation process.

Meanwhile, the system vendor representative responsible for implementation should initiate system education and training of the end users who are on the core team. The first end users trained will eventually become the trainers (Hunt et al., 2004). The end-user trainers need to know the operation of the system, its limitations, and backup plans in the event of an unexpected system shutdown. They must also understand how to log formal *issues and complaints* across all shifts to ensure continuous system quality improvement.

System customization, the third responsibility of the implementation team, ensures that the system is tailored to meet the unit's workflow needs. For example, the NICU may want to integrate the hospital laboratory list within the new system, so it can view the results of ordered laboratory tests and specifically and concisely check only *abnormal values* across a 60-patient census list. It is important for the implementation team to determine that all customization/modification requests are sensible. Sometimes the customization process becomes unrealistic as individual end users' desires expand. For example, one user may want to view vital signs with heart rate as the initial value, while another user may prefer the temperature first. A few systems reaching the market allow individual customization at this level, without changing the overall configuration for others. Currently, an entire NICU usually must form a consensus of how the standard data is to be represented. Keep in mind that many small modifications to the system usually are needed within the first 6 months of the installation. Expect to give the vendor reasonable time to make those changes.

System testing is a very important responsibility of the implementation team and the vendor, working together. As customization occurs, it is important to verify the system is working properly with the new changes. The testing should be carried out by members of the team not affiliated with the vendor. Each module of the system should be thoroughly tested for functionality using formal scenarios from actual clinical situations. Outlier management is important. Most NICU patients are *outliers* compared with the larger child and adult population. Thus, scenarios should include a sample of the most complex as well as common cases managed on the unit. Technically, the flow of data between modules should be verified and validated. System response times should be tested at peak volume of staff using the system simultaneously and should be monitored and tuned at intervals. Performance tends to degrade as use and data intensity increase over time. All system tests must be fully documented for historical and legal purposes.

As the system is being customized, modified, and thoroughly tested in the NICU, the implementation team begins to create and revise the system's documents. User guides and educational material are created during this phase. Typically, materials already supplied by the vendor will need to be updated/modified due to local changes made to the product. The hospital education department should be included at this phase to aid with hospital-wide training and 24/7/365 educational dissemination.

The hospital-wide end-user education phase should start a few weeks before the go-live (conversion) date. The users need to know what to expect of the system, the rollout, and the testing and tuning processes. They should feel prepared for the upcoming change. Choose several *super users,* who are computer savvy end users, who are eager to help roll out the new system, and who are liked and respected by colleagues. In terms of system training, a diffusion

approach tends to be the most successful. With the diffusion approach, super users, once trained, can train their coworkers with enthusiasm and during real-life scenarios/situations. It is best if the initial exposure to the system is in a quiet, comfortable, and well-lit area. Distractions should be kept at a minimum so that the training material can be fully absorbed. This session should not exceed 2 to 3 hours. If more time is needed, then subsequent sessions should be scheduled. After their exposure to the system, move the users to the patient care setting. After go-live (see the following paragraph), trainers should be available in the unit around the clock until the end users are comfortable navigating and using the system. Overtime pay for off-hours training builds positive attitudes.

When the implementation team has completed all planning, testing, documentation, and training steps, it is time for the final conversion or go-live step. There are several types of go-live options that have led to successful system conversions, including (a) parallel conversion, (b) pilot conversion, (c) phased conversion, and (d) big bang conversion. The parallel method involves running both the old and new system at the same time until the users are comfortable with the new system. This approach is time consuming and expensive, but is safe in terms of bridging documentation gaps. The pilot conversion involves changing only one unit at a time. This approach is timely and effective for some organizations. The phased conversion involves installing application modules individually throughout the hospital. This phased conversion takes a considerable amount of time, but may ease the users into the system at a more comfortable rate. The big bang approach involves shutting off the old system and turning on the new system overnight. This approach can be quite stressful for the end users and may lead to poor patient care. If the staff are adequately trained and are comfortable with the new system, however, this approach may be optimal, especially if the new system solves many preexisting problems. Each hospital should weigh the pros and cons of each approach heavily before choosing the best go-live scenario. Do not attempt massive inpatient conversions over holiday weekends, unless the hospital 24/7 critical care services can be closed down, or shifted to other hospitals for the duration.

There should be a post-implementation evaluation immediately and several months after the system conversion. Samples of the people directly involved in the conversion should provide feedback on the go-live process and on the system performance. This feedback may uncover gaps in the system use or performance. Structured feedback may also aid in the redesign of subsequent system conversion approaches. The post-implementation evaluation results should also be analyzed for operating costs, benefits, and system stability.

The implementation process requires careful planning and much work. Without a solid multidisciplinary implementation team the system conversion could fail, costing the hospital millions of dollars. The implementation team's stepwise responsibilities are critical to the ultimate success of the system. By following the eight aforementioned implementation guidelines, a hospital should be able to avoid pitfalls and complete a successful implementation.

FUTURE TRENDS AND NURSING IMPLICATIONS

Health IT is not yet at the point where data flows from monitors into the EHR documentation systems, synchronizing with all medical technologies and systems. Due in part to the HITECH Act, we now have information that can be analyzed to make predictions and improve patient care. For example, considering the current opioid crisis, with babies born with neonatal abstinence syndrome, how can we use predictive analytics to model an algorithm to predict when withdrawal is going to occur? Can we alert the bedside team in enough time to preempt the withdrawal from happening by medicating earlier?

McCartney and Drake (2016) offer an action plan for practitioner involvement with health IT. They suggest that nurses initiate an action plan, tackle current challenges, and transform practice.

SUMMARY

The intensive care environment has always depended on the most advanced technologies to care for patients. Traditionally, these technologies have been limited to bedside devices. It is inevitable that the device-based technology expand to include IS. Systems such as the electronic medical record are necessary to capture the data that these devices report throughout the ICU. With the help of advanced computer systems we can view and analyze patient data in ways that traditional paper-based methods cannot permit. As we evolve into the information age in healthcare, it is important that bedside caregivers have an understanding of the pros and cons of various types of IS, the importance of an integrated system, as well as the complexities that arise when implementing them within the NICU.

PARENT VOICES

Rosie Moore, DNP, RN

The specific gap in practice in the NICU is the challenge that parents face when they are discharged home. The underlying assumptions of these issues include a lack of confidence to be able to take care of the baby, not enough information to understand the machines, a lack of practice time, and increased readmission rates to the hospital within 30 days of discharge from the NICU. Regarding the population parents of premature babies, the argument that is most often heard from the nurses and the NICU team is that the parents have been in the NICU watching the nurses for the last 5 to 7 months and they should be able to take care of their infant (Hutchinson, Spillett, & Cronin, 2012).

The parents of premature babies have a higher stress level when the babies are discharged due to not receiving specific education to ease the transition home (Busse, Stromgren, Thorngate, & Thomas, 2013). In Miles and Huberman's

(*continued*)

(*continued*)

(1994) study conducted via the patient reported outcomes measurement information system (PROMIS) following a discharge from the NICU, it was proved that there was a higher stress level for parents when they were discharged home. Premature infant readmissions were analyzed, and it was determined that there was a 31% readmission rate to the NICU. The parents needed to be taught skills on how to avoid a rehospitalization (Hutchinson et al., 2012).

Premature babies were being born daily with multiple medical conditions that carried on long term through the span of their lives. When they were transitioned to their homes, they required management of their special needs in the home setting. The transition program began 30 days before the baby was discharged to the home. If the teaching was not done prior to the discharge home, then when they went home, the baby was susceptible to errors made at home with medications, infection control, or treatment in general.

When a baby is taken home from the regular nursery it is noted to be a scary time for parents due to the newness of being a parent. For a parent of a premature baby, the anxiety increases, especially if the baby had a long NICU stay. The parents are accustomed to having the nurses there for support but when they go home, they feel alone.

The proposed solution for this gap in service is the implementation of an NICU navigator toolkit. The toolkit is designed to help hospital nurses, doctors, therapists, social workers, and parents communicate more effectively toward reducing the parents' anxiety surrounding their baby's discharge to the home. The presentation of the NICU patient navigator toolkit contains evidence-based studies and real-life examples to demonstrate the toolkit's necessity in the NICU.

CHAPTER 40

Human Genetics and Genomics: Impact on Neonatal Care

Robin Dawn Clark

INTRODUCTION

Genetic disorders contribute significantly and disproportionately to the morbidity and mortality of newborns. Although congenital anomalies affect 2% to 3% of all newborns, they are present in 13% of infants admitted to intensive care units in developed countries. Chromosome anomalies and congenital malformations alone are responsible for 20% to 34% of infant mortality in the United States. About 10% of all live-born infants incur significant health consequences in childhood due to congenital anomalies, chromosome anomalies, neuromuscular and neurodevelopmental disorders, or intellectual disabilities (Toufaily, Westgate, Lin, & Holmes, 2018). Pathogenic variations in over 3,000 genes cause about 5,000 single-gene or Mendelian disorders that follow well-described patterns of inheritance. Online Mendelian Inheritance in Man is a curated and updated catalog of information about single-gene disorders (www.omim.org). More commonly, the accumulation of many small effects from the interplay of multigenic inheritance and environmental factors results in multifactorial traits that have a genetic component but usually do not follow Mendelian inheritance patterns. The true incidence of genetic diseases in the neonatal intensive care unit is unknown because ascertainment is incomplete.

In recent decades, remarkable improvements in genetic technology have reduced the cost and turnaround time for genetic testing and widened the scope of testing from the single gene to the genome. As these advances are implemented by clinical geneticists and other practitioners with expertise in their use, they have the potential to dramatically change the course of diagnosis and therapy for the sick neonate and expand the role of newborn screening for the well-baby. These advances improve the rate of diagnosis in infants with multiple congenital anomalies as well as in newborn babies with dysmorphic features, low birth weight, or neurologic impairment. Genetic analysis is now routine in infants with isolated birth defects and babies who feed poorly without explanation. This chapter summarizes commercially available genetic and genomic techniques, nomenclature, and vocabulary and provides a guide for the clinical application of these new technologies. Some definitions are provided but interested readers can also refer to the Talking Glossary of Genetic Terms maintained by the National Human Genome Research Institute at www.genome.gov/glossary/index.cfm.

GENETIC AND GENOMIC CONCEPTS AND TERMINOLOGY

A gene is the basic unit of hereditary information encoded in a sequence of nucleotides, composed of four bases (A for adenine, T for thymidine, C for cytosine, G for guanine) that make up the "alphabet" of DNA. In humans, over 20,000 gene pairs are inherited. Every child receives one copy of each gene from both parents: one copy of each gene in the egg and another copy in the sperm. Genes are composed of exons, sequences that are transcribed into RNA and then translated into proteins and introns, and noncoding DNA that separate exons and that are spliced out of the final RNA message. Intervening DNA sequences that separate genes actually make up the majority of human DNA. Noncoding DNA figures in the important and complex regulatory functions that control gene expression patterns in different tissues at different times. In humans, the nuclear genome refers to the totality of all 20,000+ genes, including all exons, introns, and intervening DNA sequences that separate the genes. The exome refers to the total of all coding regions, all exons, without intronic sequences or intervening sequences. Almost all genes are located in the nucleus, but specialized genes are located in the mitochondria; organelles that produce energy are located in the cytoplasm of the cell. Mitochondria have their own genome, which consists of multiple copies of circular DNA. They are exclusively transmitted from mother to child in the cytoplasm of the egg.

A specific version of a gene, an allele, can be common or rare. The Human Genome Project produced a reference map of the human genome, which is still being revised and amended as different populations are studied and more information about normal and abnormal genetic variation is gathered. When a gene sequence varies from the reference data, that change is called a variant. Common genetic variants that occur in 1% or more of the population are polymorphisms. Variants that cause disease, whether common or rare, are pathogenic, whereas variants that do not cause disease are benign. The status of some variants is unclear. A variant that is unique or about which little is known is called a variant of unknown significance (VUS). The status of a VUS can be revised as more information becomes available about its effects.

The phenotype is the outward or clinical expression of a genetic disease, whereas the genotype is the variation or change identified

in the genetic information responsible for that disease. The phenotype may not always be predicted from the genotype because a genetic variant may cause a disease in some but not all individuals who harbor it. Other genetic or environmental interactions may modify the phenotype. The lack of a genotype–phenotype correlation can make it challenging to interpret some genetic test results.

A genetic disorder is an autosomal trait when the responsible gene is located on one of the 22 numbered chromosomes or an X-linked trait when the responsible gene is located on the X chromosome. Few Y-linked genetic traits are associated with disease. Dominant traits are genetic disorders that are expressed when only one of the two alleles is pathogenic. These disorders may be familial, transmitted from a parent to a child across the generations, or sporadic and de novo, occurring for the first time in a family. A heterozygote has one normal (sometimes called wild-type) allele and one pathogenic allele. Affected individuals with a dominant trait have one pathogenic variant; they are heterozygotes. A recessive trait is expressed only when both alleles are pathogenic. Remember that genes themselves are not dominant or recessive; these terms apply to genetic disorders.

A careful family history is critical to the assessment of genetic disorders in the newborn. Family history information available in the maternal record is often copied and pasted into the infant's record to little effect, because the information gathered (about adult onset diseases, for instance) may not be relevant to the infant's problems. It is better to interview the family independently and ask questions pertinent to the baby's condition. Families may not volunteer information about a consanguineous relationship unless the question is put to them directly: "Could you and your partner be related to each other, from the same family?" Ask whether they have a grandparent or great grandparent in common, or whether they share a surname or come from a small isolated region. Ask about the health status of other offspring, living and deceased. Clarify the relationships between full siblings and half siblings. Ask about infertility and reproductive losses and most importantly whether other family members have been affected similarly to the baby. The family tree can be drawn out in a pedigree to visually represent the family members, usually through at least three generations. A list of symbols used to represent family members and instructions on how to draw a pedigree can be found at https://medicine.uiowa.edu/humangenetics/resources/how-draw-pedigree/instructions-how-draw-pedigree.

Unaffected individuals who have one copy of a pathogenic allele for a recessive trait are heterozygous carriers for that trait. Individuals who are affected with a recessive trait have two pathogenic variants: They are homozygotes when they have two alleles with the same pathogenic variant, which occurs in the majority of infants with sickle cell disease, and they are compound heterozygotes when they have two different pathogenic alleles, which often occurs in infants with cystic fibrosis. Both parents of a child with an autosomal recessive condition, such as cystic fibrosis or sickle cell disease, are almost always heterozygous carriers of a pathogenic variant in the responsible gene.

Males have one X chromosome and females have two. An affected male with an X-linked trait is hemizygous for the responsible pathogenic variant, whereas a female with one pathogenic X-linked allele is a heterozygote, because she also has one copy of a normal allele. Although females have two copies of the X chromosome, one copy is randomly inactivated in each cell. The inactive regions of the X chromosome do not express any gene products. X-chromosome inactivation is usually a random process and the ratio of the activity of the two X chromosomes is equal at about 50:50. However, occasionally, the ratio is skewed in favor of one or the other X chromosome. This explains why heterozygous carrier females sometimes express an X-linked trait, although when this happens the phenotype is usually milder than in affected males. Mild hemophilia in the mother of a boy with severe disease can be explained by the phenomenon of X-chromosome inactivation.

Gene expression can be modified by changes in chromosome structure that make genes more or less available for transcription. These epigenetic changes include methylation and acetylation that affect how tightly or loosely DNA is coiled around histone proteins. Tightly coiled regions of DNA are not actively transcribed. These epigenetic changes are influenced by environmental factors that can exert their effects during the formation of the egg or sperm, during pregnancy, and throughout infancy and early life. Exposure to adverse environmental factors in fetal life, such as malnutrition, pollution, environmental toxins, trauma, and stress, can alter the pattern of gene expression throughout life. Dr. David Barker proposed the Barker hypothesis, which traces the fetal origins of adult disease, such as obesity, coronary artery disease, and type 2 diabetes, to gene expression patterns set in motion by maternal malnutrition that produced low birth weight and other stressors in pregnancy. The socioeconomic implications of these effects can extend trans-generationally. Consider that a baby born today was conceived from an egg that was formed in her mother's ovary, when her mother was herself a fetus in the grandmother's womb. Thus, a grandmother's diet during her pregnancy decades earlier is expressed in epigenetic changes in the third generation and beyond.

Some chromosome regions are differentially methylated based on the parent of origin. These chromosome regions are imprinted with a methylation pattern that differs depending on whether it was laid down in an egg or a sperm. This maternally derived or paternally derived methylation pattern is maintained after fertilization and during each subsequent cell division. Usually the genes in the transcriptionally active regions are unmethylated, and the genes in the silenced areas that are not transcribed are methylated. About 50 imprinted genes within the differentially methylated regions on chromosomes 6, 7, 11, 14, 15, and 20 are expressed only from the actively transcribed chromosome from one parent. For instance, a microdeletion on chromosome 15q11.2 causes Prader–Willi syndrome when the deletion occurs on the paternally derived chromosome 15. Angelman syndrome, a different condition, results when the same region is deleted on the maternally derived chromosome 15. Uniparental disomy (UPD) refers to the situation in which both copies of a chromosome pair originate from the same parent. If the chromosome is an imprinted one, then some genes will not be expressed at all and others may be overexpressed. UPD can be caused by trisomy rescue. In this situation, a trisomic conception occurs, which makes the fertilized egg nonviable. However, during cell division, one of the three chromosomes is lost, and viability is restored with the correct number of chromosomes. However, when the lost chromosome came from the parent who contributed only one of the original three chromosomes, then the two chromosomes that remain both came from the other parent. This causes uniparental inheritance rather than biparental inheritance of a chromosome pair. When UPD is associated with advanced maternal age, trisomy rescue is the likely mechanism. Maternal UPD for chromosome 15, designated as matUPD15, causes Prader–Willi syndrome in about a quarter of affected children. UPD is always significant when it involves an imprinted chromosome region, but it can also cause genetic disorders when non-imprinted chromosomes are involved. This occurs when the parent of origin is also a heterozygous carrier of an autosomal recessive disorder. When that parent contributes two identical copies of the same chromosome (isodisomy) that contains the pathogenic allele, the child is

homozygous and affected. This explains the rare situation in which a child is affected with an autosomal recessive disorder but only one parent is a carrier.

PRENATAL SCREENING AND DIAGNOSTIC TESTS

When assisted reproductive technology is used to create embryos in vitro, the opportunity to screen the embryos for common chromosomal disorders, called preimplantation genetic screening (PGS), allows only those embryos to be selected for implantation that are most likely to result in a successful continuing pregnancy. However, this technique does not guarantee that the infant will have a normal chromosome complement at birth because only three to five cells are collected from the early blastocyst stage at day 5 of development. The biopsied embryos are frozen, and only some of them are used for implantation later. The fetus derives from the inner cell mass of the blastocyst, whereas the placenta and membranes derive from other regions. Therefore, the few cells that are obtained for PGS testing may not reflect the chromosome complement of the region from which the fetus eventually arises. Preimplantation genetic diagnosis is a similar technique that utilizes embryonic DNA to detect a particular genetic disorder for which the fetus is at risk.

Until recently, the offer of prenatal diagnosis was limited to high-risk pregnancies at risk for familial genetic disorders, those with confirmed fetal anomalies on ultrasound, and women of advanced maternal age, typically those who would be over 35 years of age at delivery, because of the known increased risk for fetal aneuploidy in this group. High-risk women were offered an invasive procedure, chorionic villous sampling (CVS) or amniocentesis for diagnostic testing of fetal or placental cells. The small risk for pregnancy loss, 1/200 to 1/500, following these procedures increased anxiety and decreased their utility.

Meanwhile, low-risk pregnant women were screened for congenital anomalies and aneuploidy. Detailed fetal ultrasound examination in the second trimester detected many, but not all, congenital anomalies. Screening for aneuploidy involved first- and second-trimester tests: a nuchal translucency measurement at 11 to 13 weeks gestation and first- and/or second-trimester maternal serum analysis of pregnancy-associated plasma protein A (PAPP-A), free beta–human chorionic gonadotropin (beta-hCG), alpha-fetoprotein (AFP), inhibin-A, and unconjugated estriol (uE3).

AFP levels are elevated in both maternal serum and amniotic fluid when a fetus has an open neural tube or abdominal wall defect. The relationship between low maternal serum AFP level and Down syndrome, which was recognized in the 1980s, was the basis for early maternal serum screening programs for Down syndrome.

A first-trimester screen (nuchal translucency, PAPP-A, beta-hCG) detects 85% of fetuses with Down syndrome at a 5% false-positive rate. The chance of Down syndrome (trisomy 21) is also increased when the second-trimester quadruple or quad screen reveals a pattern of low AFP and uE3 and elevated hCG and inhibin. The quad screen alone detects 81% of Down syndrome fetuses at a 7% false-positive rate. When first- and second-trimester maternal serum screens are integrated with a nuchal translucency measurement, the detection rate for Down syndrome increases to 95% with a 5% false-positive rate. Incorrect gestational dating reduces the efficacy of maternal serum screening because these analytes are reported as multiples of the median value for a given gestational age in an unaffected population (Ngo et al., 2018). Incorrect gestational dating can affect the interpretation of results by changing the comparison group to a younger or older fetal age. Other obstetric conditions such as multiple gestation or a deceased co-twin also complicate the interpretation of the analytes.

Trisomy 18 is associated with a high likelihood of fetal congenital anomalies on ultrasound and low AFP, low hCG, and low uE3 in the second-trimester maternal serum screen. In the absence of fetal chromosome anomalies, abnormal maternal analytes (low PAPP-A and low free beta-hCG in the first trimester, and low estriol and high AFP, hCG, and inhibin in the second trimester) are associated with adverse obstetric outcomes including prematurity, fetal demise, miscarriage, preeclampsia, and low birth weight (Harris, Reed, & Vora, 2018).

The prenatal testing paradigm shifted early in the 21st century, when noninvasive prenatal screening tests (NIPS/NIPT) for aneuploidy became commercially available (Renga, 2018). NIPS/NIPT offers higher detection rates for the most common fetal aneuploidies than screening with maternal serum analytes. While NIPS/NIPT cannot replace amniocentesis and CVS, it has drastically reduced the need for invasive diagnostic testing in the unaffected fetus. NIPS/NIPT analyzes small cell free DNA (cfDNA) fragments derived from the fetus that are normally present in the maternal circulation during pregnancy. Fetal cfDNA, which is present in maternal supernatant, is derived mostly from the normal degradation of trophoblasts in the placenta. It accounts for 10% to 15% of all cfDNA in maternal serum. The amount of fetal DNA is compared with that of the maternal DNA, which is present in both the supernatant and the white cells that make up the Buffy coat. Several techniques for analyzing cfDNA are employed by different laboratories. One common method assesses the relative amount of DNA contributed by the chromosomes of interest to the total amount of fetal DNA with a high degree of accuracy; a variation in the expected ratio is an indicator of the risk of aneuploidy. The results are not reliable when the fetal fraction, which is the proportion of total cfDNA that derives from the fetal placenta, is 4% or less. This is more common in obese women in whom the turnover of adipose tissue contributes to the higher maternal fraction of cfDNA.

Although the best screening parameters with cfDNA testing for the aneuploidies are achieved for Down syndrome (trisomy 21) with a detection rate of 99.7% and a false-positive rate of 0.4%, the clinical significance of a positive test for an individual patient varies with the prior (pretest) probability of fetal aneuploidy. It is less predictive for young mothers and becomes increasingly predictive as the maternal age increases. In the general obstetric population, a low-risk group, the positive predictive value (PPV) of a cfDNA test with an abnormal Down syndrome (trisomy 21) result ranges from 45% to 76%. A PPV calculator is available at www.perinatalquality.org/vendors/nsgc/nipt. For this reason, NIPS/NIPT must be considered a screening and not a diagnostic test, and abnormal results should always be confirmed. False-negative results for Down syndrome (trisomy 21), which are rare, can often be explained by mosaicism for a normal chromosome cell line in placental tissue. Fetal cfDNA testing for sex chromosome aneuploidy can be confounded by undiagnosed sex chromosome aneuploidy or mosaicism in the mother.

Professional guidelines for the use of cfDNA testing in pregnancy have evolved beyond high-risk pregnancies (women aged 35 years and older, pregnancies with documented fetal congenital anomalies). Now women may choose cfDNA testing regardless of their risk status, although testing in certain situations, such as multiple gestations and pregnancies conceived with donor eggs, is not recommended because it is less reliable. Testing options have expanded to include common microdeletion syndromes and some genetic disorders (Shaffer & Norton, 2018). In the future, cell-free RNA tests may be able to assess gene expression patterns in

mother and fetus and predict preterm delivery, preeclampsia, and other obstetric and neonatal complications.

NEWBORN SCREENING

Newborn screening tests are performed on infants within the first days of life to detect serious health disorders presymptomatically and prevent avoidable health problems. The prototypic newborn screening test, the Guthrie test, was implemented in the mid-1960s to detect phenylketonuria, an inborn error of metabolism that was successfully treated with dietary protein restriction. After blood from a heelstick was applied to circles on a filter paper card, the dried blood spots were sent to a regional laboratory. Discs punched out from the dried blood spots inhibited bacterial growth when the phenylalanine level was elevated in the sample. This simple concept has evolved in scale and complexity to detect over 50 conditions. In the 21st century, tandem mass spectrometry (MS/MS) and related techniques have expanded newborn screening test algorithms to detect a great number of abnormal molecules with the first- and then second-tier analysis (Ombrone, Giocallere, Forni, Malvagia, & la Marca, 2016). Hearing loss, hypothyroidism, congenital adrenal hyperplasia, hemoglobinopathies, cystic fibrosis, organic acidopathies, amino acidopathies, fatty acid oxidation disorders, and dozens of other metabolic disorders are now routinely included in newborn screening programs.

Each newborn screening test algorithm has a different sensitivity and specificity rate, designed to detect affected infants, but false-positive and false-negative results occur for all diseases that are screened. False-positive newborn screening tests for aminoacidopathies are common in premature infants and babies fed with elemental formulas or total parenteral nutrition. When retested later, after the babies are feeding regular formula by mouth, the repeat results are usually negative. However, it should never be assumed that a positive test in a premature infant is falsely positive. Always complete a repeat test when advised to do so. Similarly, a normal newborn screening test reassures but it does not guarantee that the child is unaffected. A small percentage of newborn screening tests are falsely negative. In California, for instance, newborn screening for cystic fibrosis fails to detect about 5% of affected infants who have two rare pathogenic alleles in the *CFTR* gene.

In successful newborn screening programs, timely and accurate laboratory results are supported by a robust program of patient and medical provider education, prompt and efficient clinical follow-up of abnormal results, and responsive program administration and development. Public health agencies vary in their ability to deliver high-quality newborn screening programs due to challenging social, economic, health, and political environments in which they operate. Lack of government support limits the success of newborn screening in many developing regions of the world. Although legally required in the United States, newborn screening is fee-based in some states, which may limit utilization. Newborn screening is less effective when blood is collected too early or in quantities insufficient to complete the analysis, when infants are born outside of the hospital system, or when babies are discharged early from hospitals. Measuring the efficacy of newborn screening programs is hampered by differences in data collection and program design between and even within countries, as different states and provinces maintain their own budgets and infrastructure.

There is no agreed universal newborn screening policy. Throughout the world, newborn screening programs are heterogeneous and lack consensus (Therrell et al., 2015). In the United States, the U.S. Congress passed legislation supporting national screening efforts that was signed into law in 2008. This created a Secretary of Health and Human Services Advisory Committee on Heritable Disorders in Newborns and Children. This committee has worked with the American College of Medical Genetics and Genomics (ACMG) to develop a Recommended Uniform Screening Panel (RUSP; www.hrsa.gov/advisory-committees/heritable-disorders/rusp/index.html) of 32 conditions that now include severe combined (T-cell related) immunodeficiency syndromes, critical congenital heart disease, and the lysosomal storage disorder (Pompe disease). Other diseases are being nominated for inclusion in the RUSP as treatment becomes available or as the cost of detection is reduced. Laboratory screening methods for X-linked adrenoleukodystrophy, Fragile X syndrome, and spinal muscular dystrophy are being developed and tested. In the future, newborn screening may adopt a genomic approach.

CHROMOSOMAL ANALYSIS

Chromosome anomalies affect about 1 in 150 live-born infants, but not all of them will be detected in the newborn period. The first step in conventional chromosome analysis is tissue culture. Intact cells are cultured over several days to stimulate cell division. Typically a blood sample is collected and the white cells or lymphocytes are cultured in the cytogenetic laboratory, but any viable tissue type can be analyzed including amniotic fluid cells (amniocytes), placental tissue, bone marrow, and skin biopsies (Malam et al., 2017). After these cells have been coaxed into dividing, the cell division process is arrested during metaphase when the chromosomes have condensed in the nucleus and are visible under the microscope. The matching chromosomes that make up a chromosome pair are homologs. These 23 individual chromosome pairs can be identified by their size and unique banding patterns after staining with Giemsa. An experienced technologist then photographs the chromosomes, evaluates their morphology, and arranges them from largest to smallest in an ordered display of all chromosome pairs, which is called a karyotype. Results are reported with the chromosome number first, followed by the type and number of sex chromosomes, for example, 46,XX and 46,XY. Euploidy refers to the correct number of chromosomes (46), referring to the 22 numbered chromosome pairs and the sex chromosomes, XX or XY. Aneuploidy refers to any other number of chromosomes. Monosomy refers to the absence of one chromosome from a chromosome pair. Turner syndrome is caused by the lack of a second sex chromosome. Monosomy X refers to a 45,X chromosome complement. Similarly, trisomy 21 refers to an extra copy of chromosome 21 in every cell, causing Down syndrome, and is written as 47,XX, + 21. Triploidy refers to the addition of a complete extra set of chromosomes in every cell (69,XXX or 69,XXY or 69,XYY).

With some miscalculations along the way, the chromosome pairs were numbered from largest (chromosome 1) to smallest (chromosome 22 was mistakenly thought to be the smallest, but in fact chromosome 21 is smaller). The short arm of the chromosome is oriented up, toward the top of the page, and is referred to as the p arm. The long arm of the chromosome, oriented down toward the bottom of the page, is the q arm. The centromere separates the p and q arms and provides the microtubular attachment site for each chromosome during cell division. Light- and dark-stained bands are numbered from the centromere out to the tip or telomere. The lower the band number, the closer to the centromere. Longer chromosomes have more visible bands. Del refers to a deletion and dup refers to a duplication of chromosome material. Acrocentric chromosomes (13, 14, 15, 21, 22) have centromeres placed nearer to one end, with vestigial short arms that are highly variable in size and contain few genes. A Robertsonian translocation occurs when

two acrocentric chromosomes have lost most or all of their short arms and fused, long arm to long arm, at their centromeres to produce a derivative chromosome (designated der). A Robertsonian translocation can involve chromosomes within the same acrocentric chromosome pair; for instance, an unaffected female carrier whose pair of chromosomes 21 have joined together would be denoted as 45,XX,der(21;21)(q10;q10). It can also occur between different acrocentric pairs, such as in 46,XY, + 13,der(13;14)(q10;q10), indicating an affected male individual with three copies of chromosome 13, one of which is a derivative chromosome composed of the long arms of chromosomes 13 and 14 (in addition to two free-standing copies of chromosome 13). A reciprocal translocation involves breakage in chromosomes from different chromosome pairs, swapping of the broken pieces between them, and reunion of the chromosome fragments to form two (or rarely more) derivative chromosomes. A reciprocal translocation is designated first by a lower case t, followed by the numbers of the affected chromosome pairs in the first set of parentheses, followed by their respective breakpoints in another set of parentheses, for example, 46,XX,t(5;12)(q11.2;p13). Reciprocal translocations are balanced, when all chromosome material is present, or unbalanced, when only one of the two derivative chromosomes is present. Conventional chromosome analysis is the only test that confirms the number and morphology of individual chromosomes and identifies structural chromosome rearrangements such as inversions, translocations, and rings. The method is time-consuming and requires a high degree of expertise. Finally, and most importantly, the resolution is limited by what the human eye can see with a microscope, making this test less sensitive for the detection of small deletions and duplications of 10 megabases (Mb) or less. Chromosome analysis is no longer the preferred first-line diagnostic test for infants with congenital anomalies. However, it is still the preferred test when Down syndrome, Turner syndrome, or a balanced translocation is suspected.

Fluorescence In Situ Hybridization

Fluorescence in situ hybridization (FISH) testing identifies the number of copies of specific DNA regions that bind with a single-stranded DNA probe that contains a fluorescent marker, which makes it visible under the microscope. Rapid FISH test results are available within a few hours. Because dozens or hundreds of individual cells can be scored quickly, this is a useful technique for detecting mosaicism, when there are two or more cell types such as 45,X/46,XY. FISH is the preferred first test when trisomy 13 or trisomy 18 syndrome or sex chromosome aneuploidy is suspected. FISH tests require intact cells and prior knowledge of the region of interest.

Microarray Analysis

G-banded chromosome analysis detects discrepancies in chromosome number, size, or banding pattern by directly visualizing chromosomes in the metaphase nucleus of intact cells using a microscope. A major disadvantage of this method is that structural changes must be at least 3 to 10 Mb in size to be detected. Chromosome microarray analysis (CMA) utilizes DNA-based techniques to detect much smaller chromosome microdeletions or duplications. Because microarray is able to detect smaller chromosomal variations that are beyond the resolution of microscopy, it produces a diagnostic yield that is about 10% higher than conventional G-banded chromosome analysis (Ronan, 2018).

The first step in this process is the extraction of DNA from the intact cell. Small pieces of the patient's DNA are hybridized to a target, or array, that contains a reference sample of DNA from all the chromosome regions of interest. By comparing the patient's DNA with the reference sequence, a chromosome microdeletion or microduplication can be detected with much greater sensitivity than with conventional chromosome analysis, which is limited by the resolution of the human eye and the magnification power of a microscope. By analyzing these small pieces of DNA, microarrays detect copy number variants (CNVs) at the level of the chromosome. They do not detect DNA sequence variants. The chromosome microarray is the first-tier test for the infant with congenital malformations or dysmorphic features (Bachman, DeWard, Chrysostomou, Munoz, & Madan-Khetarpal, 2015). Easy to understand information about many rare CNVs and numerical chromosome anomalies, appropriate for both families and medical professionals, is available at www.rarechromo.org.

Microarray Nomenclature

Microarray and chromosome abnormalities are described using the International System for Human Cytogenomic Nomenclature, which is regularly updated, most recently in 2016. Normal microarray results indicate that the expected chromosome pairs are present in two copies. Normal female and male results are reported, respectively, as arr(1-22,X)x2 or arr(1-22)x2,(X,Y)x1. Abnormal microarray results are expressed in terms of the genomic position of the copy number change within a specific version of the genomic map. Over 3 billion nucleotides in the human genome have been assembled into a map, but this map continues to be refined and updated with new revisions. Not surprisingly, reference points change with different versions. Microarray results refer to the version of the human genome map that was used to generate the coordinates that are being reported, usually in hard brackets: [hg19] for human genome map 19 or [GRCh38/hg38] for Genome Reference Consortium Human Genome Build map 38. The map version is followed by the chromosome bands for the region involved. This is followed by two 9-digit (usually) numbers, separated by a dash, and enclosed within a set of parentheses, followed by the times symbol ("x") and the number of copies identified. For example, arr[hg19]4q32.2q35.1(163146681-183022312)x1 describes a deletion of the long arm of chromosome 4 from band 4q32.2 to 4q35.1, using coordinates from Human Genome map 19. The large numbers refer to the genomic position of the nucleotides that mark the start and stop positions of the CNV. The length of the CNV can be determined by subtracting the smaller parenthetical number from the larger one: in this case, the deletion size is 19.8 Mb (1 Mb = 1,000,000 nucleotides). By inputting the map version, chromosome number, and genomic coordinates into a genome browser, a list of genes within the CNV can be obtained. This genome browser is maintained by the University of Miami (http://firefly.ccs.miami.edu/cgi-bin/ROH/ROH_analysis_tool.cgi).

Using Microarray and Conventional Chromosome Analysis

CMAs have become the first-tier test replacing conventional chromosome analysis in most cases and especially in the evaluation of infants with multiple congenital anomalies of unclear etiology. However, there are some structural anomalies that can only be detected with conventional chromosome analysis. Although there are various microarray techniques, all of them analyze small pieces of DNA rather than intact chromosomes. This means that chromosome morphology, including structural anomalies such as inversions and balanced translocations, cannot be assessed with microarrays. Chromosomal mosaicism, in which there are two or more cell lines with differing chromosome complements, may not be detectable with CMA.

Both techniques have advantages and disadvantages, and neither test can detect all types of chromosome abnormalities. Bi et al. (2013) compared the effectiveness of conventional chromosome analysis and CMA, which when performed simultaneously in 3,710 consecutive patients identified a smaller number of abnormalities that were detected only with one of the two techniques. About 1% of patients with a normal CMA test had a chromosome abnormality that was detected with conventional chromosome analysis. The chance of missing an abnormality is low if CMA is the first-line test, but when clinical suspicion is high, chromosome analysis should be considered even when the CMA test is normal.

For some indications, such as suspected Down syndrome (trisomy 21), conventional chromosome analysis is the preferred test because the main objective is distinguishing between trisomy 21 in which there is an extra chromosome 21 (and 47 chromosomes) and a low risk of recurrence, or a translocation involving an extra copy of chromosome 21, which can be familial with a higher risk of recurrence. The microarray detects an extra copy of chromosome 21 in the patient with Down syndrome (trisomy 21) but does not distinguish between these two types. For the indication of recurrent miscarriage, in which the concern is that one member of the couple may have a balanced translocation, chromosome analysis is the method of choice. There are also situations when both tests are needed to clarify the nature of a complex chromosome anomaly.

CNVs and Other Microarray Abnormalities

The human genome tolerates quite a bit of variation and many healthy, apparently normal people have benign CNVs. The clinical significance of CNVs is an area of active clinical investigation. When a CNV of unknown clinical significance is identified in a child, parental studies are often recommended. As a general rule, microduplications are more often benign and tolerated and microdeletions are more likely to be pathogenic and disease causing. Regions of the genome that are studded with repetitive elements or inversions can become error-prone because it becomes difficult for chromosome pairs to line up exactly side by side during the formation of the egg or sperm, when chromosome material is normally exchanged between homologs. These regions are the sites of recurring CNVs such as the deletion of chromosome 22q11.2 associated with conotruncal cardiac defects and cleft palate or the deletion at chromosome 15q11.2 that causes Prader–Willi syndrome.

The clinical significance of a CNV may not be clear if it is small or unique, without precedent in the medical literature. Some CNVs have to be investigated further to determine their significance. The recommendation is often made for parents to be tested for the same CNV found in their newborn. CNVs that are de novo, occurring for the first time in the egg or the sperm during gametogenesis rather than inherited from a parent, are more likely to be pathogenic. This is how a CNV can occur for the first time in a family. A familial CNV that is present in an unaffected parent or sibling is less likely to be pathogenic.

Rarely, an affected parent transmits a familial pathogenic CNV to his or her child or an unaffected parent has a mixture of affected and unaffected cells and is mosaic for the trait. Typically, parents are tested with a blood sample. A normal result is reassuring; however, it may not be adequate to detect low-level mosaicism in blood or mosaicism that is confined to another tissue, including gonadal tissue. An unaffected parent with a normal blood test for the CNV identified in his or her child still has a small residual risk to be a gonadal mosaic for the CNV, and this confers a small risk of recurrence for a similarly affected child in a future pregnancy. Hence, genetic counseling and prenatal diagnosis in future pregnancies are offered to families after the birth of an affected child with a CNV, regardless of the parental testing results.

The single-nucleotide polymorphism (SNP) microarray technique evaluates thousands of common SNPs that are present in the genome. SNPs vary between individuals and do not cause disease. Most individuals have inherited different SNPs from each parent, making them heterozygous for some SNPs and homozygous for others. By comparing the two SNP alleles at thousands of SNP sites throughout the genome, SNP microarrays can detect regions of homozygosity (ROHs), in which the same SNPs are present in both alleles for long stretches of the DNA sequence. When an ROH, also called a region of loss of heterozygosity (LOH), is confined to one chromosome or a chromosome region, it may be caused by UPD. When both the size and the number of regions of LOH are large, they indicate consanguinity, a familial relationship between the parents, such as first cousins, which is common in many cultures around the world. When the regions of LOH are fewer or smaller, a more distant relationship based on shared ethnicity or a distant common ancestor is more likely. More significantly, when regions of LOH make up a major component of the total DNA, an SNP microarray can identify an incestuous relationship between the parents. In the context of incest, especially when the mother is a minor, the possibility of sexual abuse by a male relative could be the basis of a broader investigation by police, social services, or child protection agencies.

GENE AND GENOME TESTING

Most pathogenic genetic variation is present in the coding sequence of genes, and genetic testing focuses on sequencing the nucleotides that make up exons and intron–exon boundaries (Berg et al., 2017; Petrikin et al., 2018). The original method for gene sequencing, and still considered the most accurate, the Sanger sequencing method, is time-consuming and expensive. It requires isolating the genetic material to be sequenced first and then separating and ordering the sequence fragments that are generated from the smallest to the longest, based on the identity of the final nucleotide. Even after automation improved the efficiency of this technique, it was too slow and costly for large-scale gene analysis. The so-called next generation sequencing (NGS) techniques reverse the Sanger workflow by sequencing many genetic fragments first, and then matching the sequencing products, called "reads," which are of varying lengths and with variable overlaps, to a reference sequence afterward (Boemer et al., 2017). There is not one but many NGS techniques, and all of them rely on massive parallel sequencing of many different genetic regions at the same time and powerful computational algorithms that process large amounts of complex data to complete the analysis. Using NGS techniques, large panels of genes can be sequenced at the same cost and turnaround time as a single gene could be analyzed using the Sanger method. The quality of NGS sequencing is less robust than Sanger sequencing, but the difference is small. Nevertheless, the quality of NGS sequencing data can affect the interpretation of results. These data are critical for accurate interpretation of results: how many exons are captured by the test, the number of times each nucleotide is sequenced (the number or "depth" of reads), and the sensitivity of the computer algorithm that is used to identify variant signals or "calls" and interpret them. A low read-depth increases the chance that only one allele was sequenced or "read" several times rather than both. NGS techniques may not reliably detect a mosaic pathogenic variant. Some variants that are located deep

within introns may not be detected at all because these techniques focus on exonic variants.

The ACMG recommends using standard terminology for the interpretation of DNA variants: pathogenic, likely pathogenic, VUS, likely benign, and benign. The interpretation of a variant can change over time as more information becomes available about its pathogenicity.

Certain types of pathogenic variants, such as gene rearrangements, deletion or duplication of a single exon, or expansion of regions with runs of triple-nucleotide repeats (e.g., increased numbers of CGG repeats in Fragile X syndrome), are not reliably detected with NGS techniques. Special deletion/duplication testing, such as multiplex ligation-dependent probe amplification, should be considered when sequencing does not detect a pathogenic variant in a patient with a convincing phenotype. Methylation-sensitive sequencing test detects genes that are silenced by hypermethylation.

EXOME AND GENOME SEQUENCING

Exome sequencing, which includes all exons from the human genome, is the ultimate gene panel. The exome encompasses about 1% of the human genome but captures about 85% of the pathogenic variants (Borghesi et al., 2017; Hayward & Chitty, 2018; Meng et al., 2017). The test costs thousands of dollars and takes weeks to months to return results. The detection rate varies from 25% to 40% depending on the phenotype. Higher detection rates can be achieved by including tissue samples from both parents, known as a trio test, to act as comparators. The informed consent process is extensive because parents need to be aware of the chance of detecting variants of unknown significance, results that are inconsistent with the child's phenotype, or unanticipated significant pathogenic variants unrelated to the phenotype, such as a cancer predisposition trait, that could affect one of the parents.

The more extensive genome sequencing test, which includes all coding and noncoding DNA, offers a higher detection rate at a higher cost. New rapid techniques for trio whole genome sequencing are being investigated in randomized controlled trials for accelerated diagnosis in critically ill infants where they show improved rates of diagnosis in selected populations of infants.

CHALLENGES OF INTERPRETING GENETIC OR GENOMIC TESTS

When results are clear-cut, either pathogenic or benign, and the pathogenic variants are associated with a phenotype that matches the patient's features, genetic testing can enhance medical care and family genetic counseling, eliminate unnecessary testing, and provide timely information and support (Lalani, 2017). However, this scenario is not universal. Some genomic test results are uninformative or equivocal or do not correlate with the patient's phenotype. Genetic tests can be difficult or impossible to interpret when the patient's phenotype has not been adequately defined.

Sometimes even extensive testing reveals only one pathogenic mutation in an autosomal recessive trait that matches the patient's phenotype. In this situation, the challenge is to identify the second pathogenic variant with another testing modality. Sanger sequencing, deep intronic sequencing, and/or specialized deletion/duplication testing can be considered in those situations. Sometimes a nongenetic test can confirm the diagnosis even when genetic testing cannot detect the second variant. For instance, a positive sweat test confirms the diagnosis of cystic fibrosis in a symptomatic child in whom only one variant in the *CFTR* gene can be detected (Rosenfeld, Sontag, & Ren, 2016).

As more genes are tested, the likelihood of finding one or more VUSs increases. VUSs are time-consuming to evaluate and difficult to interpret. They cannot be ignored because they may hold the clue to a diagnosis but neither can they be relied upon as evidence of a diagnosis. Family testing and careful examination of the parents and other relatives are needed to establish a relationship between the presence of the VUS in a family member and any associated phenotypic features. This clinical information should be shared with the laboratory that performed the testing. Over time, the laboratory may update the status of a VUS to benign or pathogenic as more information about the gene variant, its population frequency, and associated phenotypes becomes available. In the meantime, VUSs should not be considered diagnostic, and they should not be used for prenatal testing or presymptomatic testing. Secondary findings, also called incidental findings, in genes unrelated to the original phenotype must be shared with the family if they are of medical consequence. Such pathogenic variants may put a parent or other relative at increased risk for a disease and possibly increase anxiety about their own health.

Optimizing Utilization of Genetic Testing

Although faster and cheaper gene sequencing offers many advantages, it does not inevitably lead to improved clinical care. There are thousands of genetic tests to choose from, and new genetic tests are entering the market every day. Clinicians may misuse or overuse genetic tests because of the relative ease of ordering a blood test and the time it takes to order the correct test. Larger gene panels or exome tests are not always the preferred testing strategy. Limited genetic testing for a known familial variant can be performed in a way that significantly reduces costs by ordering a targeted test for that particular gene variant rather than ordering the same large gene panel that was used to identify the variant in the index case (Geddes, Basel, Frommelt, Kinney, & Earing, 2017). Choosing the best test can be difficult even for experts in the field. Some hospital laboratories are employing genetic counselors to review genetic test orders, whereas others are implementing best practice guidelines or contracting with genetic case management consultants to optimize utilization of genetic testing. Genetic laboratories, genetic counselors, and insurers are working together to optimize utilization through professional engagement at Patient-centered Laboratory Utilization Guidance Service (PLUGS; http://www.schplugs.org/).

Choosing the Best Person in the Family to Test

Genetic testing is more meaningful when a pathogenic variant is identified first in an affected person. Then subsequent relatives who test negative know that the variant in their family is detectable with the technique that is being used. However, when the genetic testing process begins with an unaffected person, a negative test is uninformative and cannot be used to counsel that person that his or her risk of disease is reduced, because the pathogenic variant has not been identified and may in fact not even be present in the gene that is being studied. It is always best to start genetic testing with an affected person rather than an unaffected one.

Finding a Genetic Testing Laboratory

The National Center for Biotechnology Information maintains the Genetic Testing Registry, an international database of genetic tests and genetic laboratories (www.ncbi.nlm.nih.gov/gtr).

ETHICAL CONSIDERATIONS OF GENETIC AND GENOMIC TESTING

Special considerations should be given to avoid presymptomatic testing in childhood for adult onset disorders for which no treatment is available. This practice is not recommended because of the psychological burden that such information poses for a child and his or her family, including guilt, blame, shame, denial, and survivor guilt among unaffected children. By testing children presymptomatically without offering treatment, at-risk children lose their autonomy including the right to decide for themselves whether and when they wish to be tested as adults. Presymptomatic testing also allows the possibility of future employment and insurance discrimination.

Genetic and genomic testing, such as the exome or genome sequencing trio test, may disclose sensitive information about family relationships including nonpaternity, conception with donated gametes, and adoption. It may reveal a disease state in a relative who is unprepared for such information. These possibilities reinforce the reasons that pretest informed consent is recommended for families of children undergoing genomic testing.

Even the hypothetical use of genome sequencing in healthy newborns as a possible technique for newborn screening raises concerns that should be examined carefully before implementing such a strategy, even in a limited way. Genetic information may have potentially damaging psychosocial effects within the family if it interferes with parent–child bonding or fosters the parent's perception of a child with a genetic variant as fragile or vulnerable (Frankel, Pereira, & McGuire, 2016). An individual's right to privacy and related concerns about access, storage, and security of genomic information and the chance of misuse of genetic information by corporate or government agencies must be weighed against the benefits to society that public health programs can deliver when they can efficiently and effectively screen and treat a population for preventable diseases.

RESOURCES ABOUT GENETIC DISORDERS FOR CLINICIANS AND FAMILIES

When a rare genetic diagnosis is made, treating providers need to become familiar with the disorder quickly and families need reliable resources. GeneReviews is a frequently updated and well-researched website that provides an excellent source of clinical information about specific genetic disorders (www.ncbi.nlm.nih.gov/books/NBK1116). The American Academy of Pediatrics has produced health supervision guidelines for achondroplasia, Down syndrome (trisomy 21), Fragile X syndrome, Marfan syndrome, neurofibromatosis type I, Prader–Willi syndrome, sickle cell disease, Turner syndrome, and Williams syndrome. They can be accessed by searching for "Health Supervision Guidelines" at https://aap.org. Information on many syndromes that is appropriate for families can be found at the Genetics Home Reference page, a site maintained by the National Institute of Health at https://ghr.nlm.nih.gov. The website maintained by the National Organization for Rare Disorders offers many resources for families and patients with genetic disorders in the United States at (https://rarediseases.org).

SUMMARY

Remarkable progress in the field of molecular genetics has improved the ability to diagnose critically ill newborns with neurobehavioral disorders, dysmorphic features, Mendelian disorder, intrauterine growth restriction, and congenital malformation syndromes. These advances bring with them the opportunity to diagnose more children at younger ages and improve medical care for a fragile and vulnerable population. However, genomic tests also have unique disadvantages and limitations. Some types of variants cannot be detected with NGS techniques. VUSs limit the utility of results. Families should receive informed consent about the unique aspects of genomic tests including their potential to reveal unsettling information about family relationships and predisposition for late-onset diseases. Our challenge as medical providers is to use these complex tools in the best interest of our patients by making informed and cost-effective choices. When we do our job well, the patient will receive the right test at the right time for the right reason.

CHAPTER 41

Trends in Neonatal Research and Evidence-Based Practice

Jana L. Pressler and Valerie Boebel Toly

INTRODUCTION

The focus of this chapter is on connecting neonatal nursing practice and research in such a way that the most valid and reliable knowledge available is translated into practice—known as best practice. The chapter presents knowledge on five distinct areas: (1) the basis of evidence-based practice (EBP), (2) models of evidence-based quality improvement, (3) clinical problems amenable to research, (4) various research-related roles for neonatal nurses, and (5) current trends in neonatal nursing research.

There is a growing call for nurses to lead quality improvement and transformation of healthcare through research and EBP. Experts point to the critical role that nurses have in leading interprofessional groups in producing safe, quality healthcare (Institute of Medicine [IOM], 2001, 2011). Conducting research and integrating results into clinical decision making are vital to this task.

Some type of knowledge and/or tradition guides every clinical decision and action taken by a nurse. The underlying rationale for a nursing intervention may be based on past experiences, trial and error, authority, a nursing procedure manual, textbook(s), or, most reliably, science produced through systematic inquiry (research). Nurses, along with most health professionals, have endorsed EBP as the knowledge foundation assuring the greatest likelihood that interventions will produce the intended outcome for the patient or the most accurate diagnosis of the condition. Progress, however, is sometimes held back by deeply rooted conventions in clinical decision making. In the past, nursing care policies often represented tradition ("we have always done it this way"), a source of knowledge known as "authority," the policy makers' own clinical experience, internal or external benchmarks, and information retrieved from textbooks. Moving from rationale grounded in tradition to EBP will increase the success of nursing care in assisting patients and families to better health.

Quality of care and resulting patient outcomes improve when interventions are selected based on research findings. Quality of care is defined as "the degree to which health care to individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge" (IOM, 2013). "That definition implies the nurse's application of cause-and-effect interventions known to be effective in resolving health issues." That definition also underscores key challenges in proceeding from research to evidence to practice. Specifically, there must be an available body of research-produced knowledge; intervention research needs to validate the likelihood that a given nursing intervention will produce the health outcome(s) desired; and care provided must align with what is known to be effective, as demonstrated through research in proceeding from research to practice.

THE BASIS OF EVIDENCE-BASED NEONATAL NURSING PRACTICE

Not all sources of knowledge are highly reliable nor does care based on various sources consistently produce the desired patient outcome. Experience and trial and error can be helpful; however, the knowledge gained through these approaches contains bias. That is, it is unknown whether results are due to the intervention or to something other than the intervention that is outside of the nurse's awareness. Additionally, results from one situation may not be generalizable (that is, applicable) to another situation or client for a variety of reasons. Clinical decisions drawn on experience and trial and error will not likely be the most effective in producing the patient outcome desired because these sources do not expose the entire truth or validity of broader reality. Also, knowledge resulting from trial and error (experience), not framed in explanatory models or theories, provides little to advance the scientific foundation for practice.

The underlying premise of EBP is that research studies produce the most valid and reliable source of knowledge on which to base clinical decisions. Today, the measure of "best practice" is that interventions are based on "best evidence," referring specifically to scientific findings. However, translating research into practice is fraught with obstacles. The work within the EBP paradigm itself has overcome a number of hurdles in applying research results in practice. EBP has established ways of applying research evidence in clinical decision making to ensure producing the best outcomes from scientific findings. Individual clinician decisions about care, as well as agency policies about care standards, should reflect the best evidence produced to date. The end result of applying state-of-the-science patient care is that healthcare status goals are effectively and efficiently met within the context of preferences of the patient, his/her family or significant others, and healthcare providers (Sackett, Straus, Richardson, Rosenberg, & Haynes, 2000). This rapidly advancing EBP movement comprises new methods and represents a new paradigm of research application in clinical care. The care environment in neonatal nursing exhibits many aspects of EBP whereby the entire neonatal healthcare team is engaged.

What Is EBP?

EBP is a process through which scientific evidence is identified, appraised, converted, and applied in healthcare interventions (Stevens, 2004). A widely accepted definition of EBP is that it is the integration of best research evidence, clinical expertise, and patient preference. The objective of EBP is the application of the best available evidence in clinical care in order to increase the likelihood that the desired patient outcome is achieved.

Although evidence and knowledge can be drawn from a variety of sources, the best evidence is specifically identified as evidence drawn from competently conducted (or robust) scientific investigation, or research (Guyatt, Rennie, Meade, & Cook, 2008). Using robust research evidence as the basis for care is best because it allows the nurse to gauge the certainty and predictability of the care in producing the intended outcome. Implementation of evidence into clinical decision making produces more accurate diagnosis, maximally effective and efficient intervention, and most favorable patient outcomes. These ends can be accomplished through EBP methods, processes, and models.

Using the keywords of "evidence-based practice" and "neonate," 119 publications were recently retrieved from Cumulative Index to Nursing and Allied Health Literature CINAHL) stemming from January 2010 to June 2018. These publications were grouped into nine broad categories (Table 41.1), beginning from most to fewest publications: infection ($n = 28$), caregiving ($n = 19$), feedings ($n = 15$), blood transfusions ($n = 14$), quality of care ($n = 12$), respiratory related ($n = 11$), drug studies ($n = 10$), birth experience ($n = 6$), and safety related ($n = 4$). Knowledge gleaned from these publications could comprise a succinct neonatal textbook in and of itself.

Because EBP findings might not be generalizable outside of the context or location of where studies were conducted, the publications were categorized by geographic origin of the publication. U.S. authors had the most (62) and Australia/New Zealand had the second most (15) publications. The origin of the other publications were broken down as follows: Europe (13), the United Kingdom (UK; 12), Asia (8), Canada (6), South America (2), and Africa (1). Two unexpected findings in completing this CINAHL search were that there were not more EBP publications emanating from Canada

and Asia, where research appears to be heavily pursued and highly regarded, and the fact that there were quite a few published EBP articles involving neonatal blood transfusions. Only one publication was focused on EBP for developmental care of neonates.

As is summarized in Table 41.2, some geographic areas originated very few EBP publications over the past 8 years. Thus, caution must be used when considering EBP findings from other geographic areas and when planning care using EBP findings in these less published geographic areas. It is especially important to consider individual provider and organizational factors that influence the adoption of practice evidence when the evidence was generated in very different healthcare environments or contexts. It might not be effective, for example, to apply practice guidelines that were developed in the United States to neonatal units in South America or Africa because psychosocial and healthcare delivery systems vary in such a way that knowledge is not generalizable.

MODELS OF EVIDENCE-BASED QUALITY IMPROVEMENT

Evidence-based nursing practice is the process of establishing research-based practice (RBP) by transforming research knowledge into practice and patient outcomes. Over 14 years ago, nurse scientists developed the ACE five-point Star Model of Knowledge Transformation to explain the conversion necessary to enhance the clinical utility of research results by reducing the volume and complexity of research knowledge, converting one form of knowledge to the next, and incorporating a broad range of sources of knowledge throughout the EBP process (Stevens, 2004). Stevens's five-point Star Model provides a framework for considering the transformation that takes place from a single research report in a form with low clinical utility (e.g., statistical test results in a primary research report) into a form that has high utility in clinical decision making and that is firmly integrated into clinical practice. Knowledge transformation through five related forms is depicted as a five-point process (Figure 41.1). The forms of knowledge in this transformation are (a) primary research, (b) evidence summary, (c) translation, (d) integration, and (e) evaluation (Stevens, 2004, 2012; Stevens, Pepper, Horn, & Mitchell, 2017). Each form moves progressively forward in its usefulness for clinical decisions at the point of care, ending with measuring the impact of the evidence-based improvement.

Point One of Stevens's Star Model is represented by single, primary research studies. This is the knowledge form with which nurses are most familiar—individual reports of research studies. Over the past 50 years, nurse researchers have conducted thousands of research studies on a wide variety of nursing clinical topics. Although primary research is requisite to EBP, such research does not hold a great deal of stable, accessible usefulness in clinical decision making. The body of primary research on any given topic will likely include both a variety of study designs, small and large samples, and conflicting or converging results, leaving clinicians uncertain about which studies are the best reflection of cause and effect in selecting effective interventions. In addition, the body of research on a given clinical topic might include hundreds of studies and, as such, not be useful for clinical decision making. In considering the form of knowledge on Star Point One for clinical decision making, two major challenges exist: (1) volume and (2) complexity of research literature.

In **Point Two of Stevens's Star Model**, single research studies are transformed into clinically useful knowledge using an evidence summary approach. In this second stage of knowledge transformation, all primary research on a given clinical topic is systematically gathered, screened, and summarized into a single statement about the state of knowledge on the topic. This summary step is considered the key step for moving research into practice (Eden, Wheatley, McNeil, & Sox, 2008). Systematic reviews (SRs) transform research knowledge in numerous ways and offer advantages, as summarized in Box 41.1. Evidence summaries present the latest

Box 41.1

ADVANTAGES OF SYSTEMATIC REVIEWS

A systematic review accomplishes the following:

Reduces large quantities of information to a manageable form

Integrates existing information for decisions about clinical care, economic decisions, future research design, and policy formation

Increases efficiency in time between research and clinical implementation

Establishes generalizability across participants, settings, treatment variations, and different study designs

Assesses consistency and explains inconsistencies of relationships across studies

Increases power in suggesting cause-and-effect relationship(s)

Reduces bias from random and systematic error, improving true reflection of reality

Provides better continuous updates of new evidence

SR, systematic reviews.

Source: Adapted from Mulrow, C. (1994). Rationale for systematic reviews. *British Medical Journal, 309*, 597–599. doi:10.1136/bmj.309.6954.597

scientific findings in an accessible form, both for the clinical nurse to readily apply in clinical decisions and to also create clinical unit policies. When developing an evidence summary, reviewers must keep in mind that nonsignificant findings can be as important to practice as statistically significant findings. However, nonsignificant findings tend not to be regarded as worthy of publication and, subsequently, are underrepresented in the literature.

Evidence summaries are developed by various groups and referred to using several terms: evidence synthesis, SRs, and integrative reviews. The most widely used methods in rigorous evidence summaries produce a SR that reflects the SR methods established in the mid-1990s (Higgins & Green, 2011). A SR is a type of evidence summary that uses a rigorous scientific approach to combine results from a body of primary research studies into a clinically meaningful whole. SR involves a research design that produces new knowledge through synthesis. SR typically uses the statistical procedure of meta-analysis to combine findings across multiple studies. Meta-analysis removes voluminous and rapidly expanding bodies of literature from the findings. SRs are rated as the strongest evidence for best practice. In addition, if summaries are not systematically developed, there is a risk of drawing erroneous conclusions about whether or not an intervention actually works. If this is the case, nurses may select interventions that do not work as intended, or be unaware of interventions that do work as intended.

Developing sound evidence summaries requires time—often over a year's worth of scientific teamwork, specialized scientific skill, and extensive resources. If an evidence summary is completed to meet rigorous standards, evidence summaries will

- Include research that has been reviewed from all relevant disciplines and across the globe
- Screen studies for quality of design and relevance
- Use multiple reviewers to abstract the findings
- Analyze the results to combine findings and examine extent of bias in the set of research studies

Therefore, evidence summaries are often conducted by scientific and clinical teams who are specifically prepared in evidence summary methodology.

Point Three of Stevens's Star Model occurs through translation of resulting knowledge once an evidence summary is conducted. In this stage, content experts are called upon to review the evidence summary, fill in gaps with consensus expert opinion, and merge research knowledge with expertise to produce clinical practice guidelines (CPGs). This translation process converts the research evidence into clinical recommendations.

New standards for developing CPGs specify processes that will produce high-quality, trustworthy guidelines, assuring that recommendations reflect current knowledge. A number of clinical specialty organizations produce these types of clinical guidelines. For example, the Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN) developed an excellent example of a CPG for late preterm infants (AWHONN, 2010). The association combined research evidence and clinical expertise to produce evidence-based guidelines on assessment and care of the late preterm infant. This was achieved by (a) locating and explicating the evidence, (b) rating the strengths of evidence (including evidence-based recommendations), and (c) publishing the guideline.

Trustworthy CPGs reflect several characteristics:

1. A specified process is followed during guideline development.
2. The guideline identifies the evidence on which each recommendation is based, that is, specifically whether it is research or expert opinion.
3. The evidence is rated using a strength-of-evidence rating scale (Graham, Mancher, Wolman, Greenfield, & Steinberg, 2011).

Once such guidelines are produced, integration is accomplished through change at both the individual clinician and the organizational levels. Other, less rigorously developed guidelines are present throughout healthcare in the form of **clinical pathways, nursing care standards, and unit policies**. However, because they are believed to be more valid and reliable, CPGs should be used as the guidelines of choice to the extent that it is feasible.

Point Four of Stevens's Star Model encompasses integration of a CPG into practice at individual provider, microsystem, and system levels. Planned change approaches often are used to overcome

resistance and move the individual and organization to a higher standard of practice based on evidence. Guidance for planned change is provided by principles and theories. For example, first, because quality is a system property, systems must be changed with EBP; and second, adoption of new practices can be amplified using principles from theories—such as Rogers's theory of diffusion of innovation (Rogers, 1995). As advances unfold in neonatal nursing, it is essential that all members of the healthcare team be actively involved in making quality improvement changes in caregiving. Nurses will serve as leaders and followers in contributing to such improvements at the individual as well as the system level of care.

Point Five of Stevens's Star Model is evaluation. Practice changes are followed by evaluation of the impact on various outcomes, including effectiveness of the care in producing desired patient outcome; population outcomes; efficiency and cost factors in the care (short and long term); and satisfaction of providers' and patients' families. Evaluation of specific outcomes has risen to a high level of public interest, given people's awareness that American healthcare might neither be safe nor effective (Kohn, Corrigan, & Donaldson, 2000). As a result, quality indicators have been established for healthcare improvement and for public reporting (e.g., Agency for Healthcare Research and Quality [AHRQ], 2012a, 2012b).

Major Features of EBP

Barriers to implementing EBP are removed by using evidence syntheses as the basis for clinical recommendations. SRs "efficiently integrate valid information and provide a basis for rational decision-making" in clinical care (Mulrow, 1994). Only in rare instances will a single research study offer highly reliable answers to a clinical question (Eden, Levit, Berg, & Morton, 2011). It is most feasible for nurses to use research evidence that has been summarized in the form of a SR. Because conducting evidence syntheses is a new, resource-intensive, labor-intensive, and rigorous process, it is beyond the capacity of and time allotted to most clinicians in their daily routine. For those reasons alone, it is critical that clinicians be aware of existing sources of synthesized evidence. Box 41.2 presents examples of evidence summaries from the *Cochrane Library of Systematic Reviews*. In addition, Table 41.3 describes other credible sources for evidence summaries. In some cases, conclusions from the evidence summary support current practice and increase confidence that nursing care will produce the desired outcome. In other cases, the evidence points to a needed change in practice. In either case, examining current practice in light of the state of the science is becoming expected in healthcare.

Sources of Evidence for Nursing Practice

Recognizing that considerable work needs to be done to translate research into practice, a number of entities are adding to the collection of forms of knowledge available to clinicians. These EBP points are now populated by several resources, guiding nurses to useful forms of knowledge for clinical decision making. Synthesis work is conducted by several organized agencies. Because the conduct of a SR requires specialized scientific methods and significant resources, it is usually a sponsored work activity spurred by influential agencies such as the IOM and AHRQ. Each point of Stevens's Star Model is conducted by groups of scientists. The leading agencies pursuing this work are the Cochrane Collaboration (a global collaborative headquartered in the United Kingdom) and the AHRQ (a federally funded agency in the United States). Another source of evidence summaries is the Joanna Briggs Institute (JBI), headquartered in Adelaide, South Australia. The JBI has centers for EBP and conducts SRs around the world. In turn, these agencies disseminate the evidence summaries for use by clinicians, health policy makers, and consumers of healthcare (Table 41.3).

Point Three of Stevens's Star Model is populated by several agencies that develop or provide large collections of CPGs. The AHRQ supports the National Guidelines Clearinghouse, a searchable collection of almost 2,000 CPGs, most with strong evidential

TABLE 41.4

THE FIVE POINTS OF THE STAR MODEL AND SAMPLE COMPETENCIES FOR NURSES

Star Point	Competency
1. Original research	Recognize ratings of strength of evidence when reading literature including web resources
2. Evidence summary	List advantages of SRs as strong evidential foundation for clinical decision making
3. Translation	Use specified databases, access CPGs on various clinical topics
4. Integration	Assist in integrating practice change based on EB CPGs
5. Evaluation	Participate in EB quality improvement processes to evaluate outcomes of practice changes

CPG, clinical practice guidelines; EB, evidence-based; SR, systematic review.

foundations. In the United Kingdom, the National Institute for Health and Clinical Excellence (NICE; www.nice.org.uk) develops evidence-based guidelines for healthcare providers, as well as for patients and caregivers. There is growing interest in promoting global collaboration in the development and evaluation of EBP guidelines. One organization that has formed to promote such collaboration is the Guidelines International Network, with members from 46 countries and an international guidelines library that contains more than 7,400 documents (Guidelines International Network, 2012). Another excellent resource for evidence-based neonatal care is the Vermont Oxford Network that was established in 1988 and now includes 9,000 neonatal units worldwide. Member institutions participate in research and also have the option of participating in a quality improvement neonatology collaborative to identify and implement best practices in neonatal care (Vermont Oxford Network, 2012).

Point Four of Stevens's Star Model is now populated by the AHRQ Healthcare Innovations Exchange, with the goal of speeding integration of new and better ways of delivering and improving quality of healthcare. Almost 600 innovations are profiled, along with adopter's guidelines and tools for adopting and sustaining the innovation. Additionally, Point Five, evaluation, is populated by a number of initiatives to measure and track the quality and safety of care. Quality indicator initiatives include the AHRQ National Healthcare Quality and Disparities Reports and National Database of Nursing Quality Indicators. System-level indicators include surveys of the agency's culture of patient safety and attainment of "never" events.

Essential Skills in Using EBP

The skills required to accomplish EBP range from the frontline clinician's openness to credible changes in practice to the statistician performing meta-analysis. At each clinician level and discipline, there are crucial competencies needed in terms of skills, attitudes, and actions. Although the principles and goals of EBP are readily apparent, the paradigm requires a shift in the way that nurses have traditionally perceived research and clinical decision making. Through an iterative process with an expert panel, national consensus about essential competencies for EBP in nursing has been established (Stevens, 2009). Table 41.4 provides examples of these competencies for the staff nurse level, organized by the five points contained on the Star Model. The competencies are organized across three levels of clinical practice: (1) entry (staff nurse), (2) intermediate (e.g., CNS or midlevel manager), and (3) advanced (e.g., doctoral nurse participating in a SR team). In addition, the competencies span the five points of the Star Model.

How to Integrate EBP in Nursing Practice?

With the new insights into effective clinical decision making that EBP has provided, the question becomes "How is EBP employed?" Although a number of methods are being developed, tested, and adopted, several guiding principles are apparent. In today's trends, adoption of EBP is connected to clinical effectiveness and patient safety. EBP is connected to the agency's goal of improving care and outcomes. In clinical settings, often the administrative and managerial teams come to a conclusion that the agency will adopt an initiative: to employ EBP throughout their healthcare. The commitment requires time, leadership, engagement across all stakeholders, and resources; so, several planning stages help make the initiative a success. These planning stages are as follows:

1. The plan for employing EBP may initially include announcements, persuasion for buy-in from all vested interests, and identification and mobilization of resources. Of the many resources needed, *time* in the clinician's workday is a key resource. Other resources can be drawn from existing departments such as the quality assurance department, the medical librarian, and academicians from collaborating universities.
2. To focus the EBP effort, clinical priority topics are identified and set out as the first targets for evidence-based quality

improvement. To be successful, the organization and healthcare team are involved. Criteria useful for selecting priority topics are those established by the IOM to identify national priorities for healthcare improvement (Adams & Corrigan, 2003). These are (a) *impact* in terms of burden on patient, family, healthcare system, and society; (b) evidence that already exists for *improvability* but is not yet used in standard care; and (c) *inclusiveness*, reflecting applicability to patients across the life span and settings.

3. Evidence is located. A comprehensive search is essential, and professional information management skills are valuable. Beginning with a search for evidence summaries is often productive in locating reviews that have already been completed. Locating other forms of knowledge, such as primary research and CPGs, is also important in this step.
4. Critical appraisal of the evidence can be accomplished by an evidence team. Using existing checklists, the validity and strength of the evidence are rated.
5. An evidence-based CPG is adapted from an existing one or developed by the team. This CPG development process should be standardized to ensure that evidence is explicated and rated in all CPGs that are introduced into practice.
6. Quality indicators are selected, and baseline assessments are made.
7. A comprehensive plan for change, adoption of innovation, and integration into practice is developed and implemented.
8. The targeted quality indicators are measured again and then compared to baseline assessment. These outcome measures should include patient outcomes, health status (population) indicators, and cost impact. The impact on the care process is also measured to determine if clinical practice has been true to the prescribed CPG. Feedback from quality audits is effective in stabilizing the change to the new standard of care.

Global Considerations to Be Made in Using EBP

Implementing EBP may be challenging to nurses who live in low-resource countries that have limited access to the Internet and thus have limited opportunities to review the literature or identify evidence to guide practice. One resource that can help to improve access to information resources is the eGranary database of digital resources (www.widernet.org/eGranary). eGranary was founded in 2001 to provide access to Internet resources for the estimated seven out of eight people worldwide with limited Internet access. With support from numerous partner institutions and volunteers, digital and web-based resources are copied onto the eGranary server (after securing copyright permission), and these resources are then available to those who purchase the reasonably priced server. As an example of the capability of eGranary to disseminate knowledge, the University of Alabama at Birmingham Sparkman Center for Global Health has worked with numerous partners to develop a portal of more than 500 resources. This portal supports evidence-based nursing practice in Zambia and other English-speaking countries (eGranary Digital Library, 2012).

Another resource to improve access to evidence for nurses in low-resource countries who have Internet access is the Health Internet Access to Research Initiative (HINARI) Access to Research for Health Programme, set up by the World Health Organization (WHO) together with major publishers. HINARI enables developing countries to gain access to one of the world's largest collections of biomedical and health literature. It provides free or low-cost Internet access to more than 8,000 journals and online resources to not-for-profit institutions in low-resource countries (HINARI Access to Research for Health Programme, n.d.).

CLINICAL PROBLEMS AMENABLE TO RESEARCH

Neonatal nurses can use findings from research as well as other evidence to improve and change neonatal nursing practice. As previously noted, the first step in developing an EBP protocol or procedure is the identification of a clinical problem to be addressed.

Nurses might start by identifying a problem of concern in their individual clinical setting. Nurses in the clinical setting are often in the best position to identify and articulate highly relevant research questions and, through partnering with scientists, are able to carry out research studies that directly improve the delivery of nursing care. The types of questions posed by clinical nurses range from basic physiologic mechanisms in neonatal health to comparisons of efficacy between various interventions to identification of new phenomena as the topic for new programs of research. Ideas for research come from many different sources, including an individual nurse's experience, the nursing or health literature, discussions of social or health issues, or theory (Burns & Grove, 2009). With today's increased emphasis on quality and safety, research topics also emerge from quality assurance audits in the clinical unit, agency-wide interest in system support for quality and safety, and national recommendations for healthcare delivery changes.

Researchers and professional organizations sometimes conduct surveys or convene expert panels to identify research priorities. These priorities can also help researchers identify researchable problems. For example, the Strategic Plan for the National Institute of Nursing Research (NINR) identified four areas that will be the focus of research investment between 2016 and 2021: (a) symptom science: promoting personalized health strategies; (b) wellness: promoting health and preventing disease; (c) self-management: improving quality of life for individuals with chronic illness; and (d) end-of-life and palliative care: the science of compassion. In addition, the NINR included two crosscutting topics vital to the advancement of nursing science: (a) promoting innovation: technology to improve health; and (b) 21st century nurse scientists: innovative strategies for research careers (NINR, 2016). NINR promotes interdisciplinary research using a variety of methods including intervention studies, translational research programs, and research to evaluate costs, outcomes, and quality of care (NINR, 2011). In parallel, the Improvement Science Research Network (ISRN) established research priorities in improving healthcare delivery that works in tandem with the NINR clinical research topics (ISRN, 2010). The ISRN research priorities underscore a new goal for nursing research, that is, to discover which improvement interventions are effective in changing healthcare delivery. The broadly stated ISRN research priorities include (a) transitions and coordination in care across healthcare delivery segments; (b) high-performing clinical systems and microsystems; (c) evidence-based quality improvement and best practices; and (d) learning organizations and culture of quality and patient safety (ISRN, 2010).

Box 41.3 lists topics of current research interest questions for neonatal nurses. Many of these research questions are derived from the concern about the prevention of iatrogenic complications of treatments. Others emerge from systematic observation of clinical phenomena or from frustration with current practices.

The Role of Neonatal Nursing Organizations

Neonatal nursing organizations also assist with the identification of neonatal research priorities and development of EBP guidelines. For example, in 1990, the AWHONN convened a panel of nurse experts to identify areas with sufficient research to develop

Box 41.3

SOME CURRENT NEONATAL NURSING RESEARCH QUESTIONS

Skin Care

How can epidermal damage from tape removal be reduced?

Can the permeable skin of preterm infants be used to deliver medication?

How can the barrier properties of the skin be improved to prevent infection and water loss?

Which cleansing agent and bathing techniques are best for preterm and full-term infants?

Do emollients prevent transepidermal water loss and dermatitis in premature infants?

What is the reliability and validity of the neonatal skin condition score?

Nutrition

How can breastfeeding practices be promoted among mothers of premature infants?

What are the most effective methods of feeding preterm infants?

What are the effects of kangaroo care on breast milk production?

What is the relationship between preterm infant behavioral states and feeding efficiency?

What is the effect of side-lying position on oral feeding outcomes in preterm infants?

What are the supports and barriers to the provision of human milk by mothers of preterm infants?

Instruments and Procedures

What is the effect of routine care tasks, such as bathing, suctioning, on cerebral blood flow velocity?

Which pulse oximeters are most effective in reducing the effects of motion artifact?

Do temperature probe covers contribute to nosocomial infections by providing an environment for skin microbe colonization?

What is the effect of draw-up volume on the accuracy of electrolyte measurements from neonatal arterial lines?

What are the indwell time and catheter-associated complications among EPIV, PICC, and PIV catheters?

Effect of the Environment and Supplemental Stimulation

What is the impact of light, noise, and handling on infants in the NICU?

What is the appropriate level of stimulation for preterm infants?

What is the effect of supplemental massage and gentle touch on preterm infants?

What are the effects of music therapy on preterm infants?

What is the effect of cycled lighting on preterm infants?

What is the most appropriate method of positioning preterm infants to promote neuromuscular development?

Extracorporeal Membrane Oxygenation (ECMO)

Is the initial training and ongoing education of ECMO specialists sufficient to maintain emergency management skills?

What are the long-term effects of ECMO use?

What are the neurodevelopmental outcomes of infants who were treated with ECMO?

Endotracheal Tube Stabilization and Maintenance

How can slippage of the endotracheal tube within the trachea be measured?

How can movement of the endotracheal tube be minimized?

Is there a difference in the incidence of nosocomial infections, bronchopulmonary dysplasia, or frequency of suction when using closed versus open tracheal suctioning in neonates?

Management of Pain

How can neonatal pain be assessed?

When is pharmacologic treatment appropriate?

What factors influence preterm infants' responses to painful procedures?

Are there long-term consequences of unrelieved pain experienced in the neonatal period?

What is the most effective method for weaning the infant from analgesics?

(*continued*)

Box 41.3

SOME CURRENT NEONATAL NURSING RESEARCH QUESTIONS (*continued*)

Management of Pain (*continued*)

Does the use of premedication prior to intubation result in fewer signs of physiologic distress during intubation compared to intubation without premedication?

What are effective nonpharmacologic pain-management techniques for use with neonates?

What are the analgesic effects of oral sucrose and pacifier use on preterm infants during painful procedures?

Thermoregulation

Which techniques are most effective in minimizing insensible water loss and maintaining thermoregulation in the extremely premature infant?

What are the optimal procedures for maintaining thermoregulation when transferring infants from incubators or warmers to open cribs?

What are the effects of skin-to-skin holding (kangaroo care) on thermoregulation of preterm infants?

Positioning and Holding

Which positions are most effective in promoting optimal oxygenation and in minimizing postural deformities?

What are the effects of skin-to-skin holding on high-risk infants?

What are the effects of containment and swaddling of preterm infants?

How often should infants' positions be changed?

Under what conditions is the prone position linked to sudden infant death syndrome?

What factors influence parents' decisions about sleep positions of their infants?

Developmental Care

What are the outcomes of developmental care?

What are the effects of developmental care training programs on the care delivered by NICU staff?

What are valid and reliable measures of stress in preterm infants?

Is measurement of heart rate variability or vagal tone a reliable means for assessing stability or stress in preterm infants?

Do nursing interventions have an effect on preterm infant oxytocin release and contribute to preterm infant neurobiology?

Effects of Cocaine

How is the behavior of a cocaine-exposed infant different from that of the nonexposed infant?

What is the appropriate level of environmental stimulation for these infants?

What types of intervention programs are effective for families of cocaine-exposed infants following hospital discharge?

Effective Parent Teaching Techniques

What are the most effective teaching methods for instructing parents in the care of their newborns?

Is computer-assisted instruction effective?

What type of posthospital follow-up is most helpful to parents of infants who are released from the NICU?

Are postdischarge telephone follow-up programs effective in promoting breastfeeding of preterm infants discharged from the NICU?

What are parents' perceptions of a parental care-by-parent program before NICU discharge of their infants?

Family Issues

What nursing interventions help reduce stressors experienced by families who have infants in the NICU?

What is the incidence of depression among parents of preterm infants?

What interventions help grieving parents?

What interventions help to promote attachment and adaptive parenting between parents and preterm infants and between parents and infants with serious health problems?

What are the outcomes associated with participation in a parent support group for parents of preterm infants?

What are parents' perceptions of the NICU follow-up clinic?

(*continued*)

Box 41.3

SOME CURRENT NEONATAL NURSING RESEARCH QUESTIONS (*continued*)

Staff Education

What is the most effective method of orientation of new NICU nurses?

How should formal classroom teaching and clinical preceptorship be integrated?

Are self-paced learning modules an effective teaching methodology for neonatal nurses?

Can neonatal nurses use expert systems to support decision making?

Delivery of Nursing Care

What is the most effective model for delivery of nursing care in the NICU?

Can nonprofessional staff be used in the NICU to support the professional nurse?

Does the use of critical pathways facilitate "costing out" nursing services?

What is the effect of a structured neonatal resuscitation program on delivery room resuscitation practices?

What are the best strategies to promote use of evidence-based practice guidelines in the NICU setting?

What is the prevalence and severity of secondary traumatic stress in nurses caring for critically ill infants in the NICU?

Retention of Nurses in the Critical Care Setting

What are the factors that increase job satisfaction for nurses working in the NICU?

How do NICU nurses cope with stress?

What factors increase the likelihood that nursing jobs will be retained?

Do neonatal nurses perceive technology in the NICU as sources of stress?

What are the stressors, satisfiers, and coping processes of neonatal nurses?

ECMO, extracorporeal membrane oxygenation; EPIV, extended dwell peripheral intravenous; NICU, neonatal intensive care unit; PICC, peripherally inserted central catheter; PIV, peripheral intravenous.

research-based protocols that could be tested in multiple settings (Gennaro, 1994). Members of the AWHONN Research Committee recommended that the organization fund an EBP project to evaluate the best method for transition of preterm infants to open cribs, appointing a group of six neonatal nurse researchers to conduct the project (Meier, 1994). After reviewing the literature on the topic, the group held a series of meetings and ultimately developed a weaning protocol that was subsequently tested with 270 infants from 10 different hospitals (Medoff-Cooper, 1994). The evidence of this project suggested that preterm infants could be moved to an open crib at lower weights than had been suggested by results of previous studies. The AWHONN project is an excellent example of the contributions that clinical professional associations can make to the development of EBP guidelines. That project illustrates several points in the Star Model: evaluation of original research related to thermoregulation, developing a practice guideline based on a review and synthesis of the existing research, and evaluating the outcome of the EBP guideline.

The AWHONN has implemented two other EBP initiatives to enhance evidence-based neonatal nursing care: (1) development of a protocol for neonatal skin care in association with the National Association of Neonatal Nurses (NANN); and (2) development of guidelines for care of late preterm infants (Medoff-Cooper, Bakewell-Sachs, Buus-Frank, & Santa-Donato, 2005). In the neonatal skin care project, a group of researchers reviewed extant literature to develop a CPG and data collection tools that were implemented by 51 sites involving 2,820 infants in all levels of care. Results of their study indicated that the use of the clinical guideline resulted in improved skin condition of neonates in intensive, secondary, and well-baby nurseries. Nurses also were better able to identify risk factors for impaired skin integrity in neonates.

The Late Preterm Infant Initiative (LPTI) project was launched in April 2005 by AWHONN to develop a research-based guideline (RBG) for infants born between 34 and 37 weeks' postmenstrual age. The initiative was based on a conceptual framework that focuses on neonatal physiologic functional status, nursing care practices, the neonatal care environment, and the role of the family (Medoff-Cooper et al., 2005). A sample of 15 geographically and demographically diverse sites participated in implementing and evaluating the RBG. The focus of this initiative was to enhance awareness of the special needs of the near-term infant among healthcare providers and consumers, and promote universal adoption of a practice guideline for care of these infants. For more information on this initiative, readers can go to the AWHONN website at https://www.awhonn.org/page/AWHONNLateInfant/AWHONN-Late-Preterm-Infant-Initiative.htm

The NANN has published position statements on various practice issues on its website (http://nann.org/about/position-statements). Examples include medication safety in the neonatal intensive care unit (NICU), palliative care for newborns and infants, the use of human milk and breastfeeding in the NICU, cobedding of twins or higher-order multiples, and prevention of bilirubin encephalopathy and kernicterus. In addition, and importantly, the Council of International Neonatal Nurses (COINN; Kenner & Boykova, 2014) has united neonatal nurses through policy work, education, research, and conferences. COINN has been involved in sharing EBP findings across the world.

Barriers and Facilitators to Implementing Neonatal Nursing EBP

Several studies have been conducted to evaluate the extent to which neonatal nurses are implementing EBP guidelines such as

the AWHONN/NANN guidelines. For example, Johnson and Maikler evaluated the implementation of the skin care guidelines in a sample of 136 nurses from 26 hospitals, and identified several barriers to implementing the guidelines in practice: perception by some nurses that traditional practices were superior to the practices proposed by the evidence-based guidelines, difficulty in reading and understanding research evidence, lack of authority to implement the protocols, and lack of physician support (Johnson & Maikler, 2001). Wallin, Boström, Harvey, Wikblad, and Ewald (2000) conducted a similar study in Sweden to determine the extent to which national guidelines on evidence-based nursing care were being implemented in Swedish neonatal units. A total of 13 evidence-based guidelines were developed in cooperation with 42 of the 45 neonatal units in Sweden, and the guidelines were presented in a report that summarized the evidence supporting each guideline, as well as suggested measures for auditing the implementation of the guideline. Findings from this Swedish study indicated that 14.3% of the neonatal units were not using the guidelines at all, and there was variable implementation of the guidelines in the other units. Four factors that were associated significantly with guideline implementation were the extent to which the units were using a quality improvement method, the length of experience of the nurse manager, the level of research experience in the unit, and the availability of nursing staff resources.

Melnyk, Fineout-Overholt, Stone, and Ackerman (2000) surveyed 160 nurses and found that only 46% of these nurses identified their current practices as evidence-based. Factors associated with increased evidence-based care were nurses' beliefs about the importance of EBP, knowledge of EBP, length of practice as an advanced practice nurse, use of the *Cochrane Database of Scientific Reviews* and/or the National Guideline Clearinghouse, and having a mentor to model EBP. Barriers to EBP included lack of time and heavy patient loads; lack of appreciation for the value of research; difficulty searching for and retrieving studies; difficulty reading, understanding, and evaluating research reports; institutional barriers; and limited autonomy or control over one's own practice. Institutional barriers included inadequate staffing and failure to reward nurses who initiated change based on findings from research.

To address the barriers to EBP effectively, neonatal nurses must receive education regarding the research process, have the opportunity to participate in research projects (in data collection or as research participants), and participate with colleagues in sessions to stimulate the formulation of questions from their clinical experience. One can begin by asking the question "why?" of every NICU nursing practice. Lack of resources—including time, money, and consultation—can be more difficult to address. In many institutions, the conduct of nursing research continues to be viewed as unnecessary and not central to the delivery of patient care. In such settings, nurses who wish to conduct research initially might need to invest their own time and money. However, once the research process has demonstrated clinical relevance, additional resources are often made available. Collaboration with colleagues within the institution, schools and universities, and industry can enhance resources. Writing grants with colleagues for the purposes of obtaining funding to support research is often the only way that clinical research can be conducted (Holtzclaw, Kenner, & Walden, 2018).

Mariano et al. (2009) evaluated the effects of mentoring on the EBP of a sample of 20 NICU nurses. Although the researchers were not able to demonstrate changes in EBP of the nurses, they did report changes in the NICU as a result of the project.

There is a need for ongoing research to monitor the extent to which neonatal nurses and nurseries use evidence-based guidelines in practice, and to identify facilitators and barriers to such implementation that should be addressed to ensure continuous quality improvement in neonatal nursing care. In order to facilitate data collection for these studies, it is important to first identify core measures that can be collected and recorded by neonatal units and that can be used to evaluate implementation of EBP guidelines. For example, in 2009, Coughlin, Gibbins, and Hoath (2009) developed a set of such core measures that could be used to evaluate the implementation of evidence-based guidelines for developmentally supportive care in neonatal care. The core measures represent five categories of developmental care that were identified based on an extensive literature review of effective developmental care practices: (1) protected sleep, (2) pain and stress assessment/management, (3) developmentally supportive activities of daily living, (4) family-centered care, and (5) the healing environment.

Conducting Research in Neonatal Nursing

Scientific substantiation of neonatal nursing practice and neonatal healthcare requires collaboration with other nurses and health professionals. Clinical nurses are often the first to recognize and identify trends in newborn and infant care problems for which there is no apparent evidential base. With the guidance and assistance of other nurses, nurse specialists, and physicians, a collaborative investigation can be used to explore such care problems. The combination of expertise from multiple disciplines can make a highly effective research team.

Research is a formal, systematic inquiry or examination of a given problem. The outcome or goal of research is to discover new information or relationships or to verify existing knowledge. Other less formal definitions of research focus on the understanding of an event by logically relating it to other events. Some types of research are designed to predict events by relating them empirically to antecedents in time. Still other types of research attempt to control or manipulate an event or procedure to determine its impact on other phenomena (Burns & Grove, 2009). Quality assurance and quality improvement activities often lead to the design and conduct of research. Nurses are often introduced to issues related to objective data collection through quality assurance audits. Issues of clinical consequence that are identified through quality assurance screening can lead to the articulation of research questions. Research principles can also be used in the evaluation of new procedures, protocols, and products. Evaluation is often an integral part of NICU nursing, but it tends to be performed subjectively rather than objectively. Using research methodology to perform evaluation promotes scientific objectivity.

Why Conduct Research?

Using the research process to discover new information or to confirm empirical knowledge allows the growth and evolution of nursing practice. Without research, nursing care would be based on tradition. Without research, the practice of nursing would change slowly and grow little because things would be done the way they have always been done. The failure to conduct research regarding neonatal care has taught nurses some sobering lessons. Judgments of efficacy based on observation of small numbers of infants or of treatments based on the principle "if a little is good, more is better" have resulted in significant morbidity and mortality for neonates. Increasing the risk of dehydration by withholding early feedings, misuse of oxygen therapy, and misuse of vitamin K are examples of failure to conduct research (Ramachandrappa & Jain, 2008). From these experiences, the use of clinical research trials to evaluate new therapies scientifically has become more common in neonatal care before widespread application. The research

process also provides a vehicle for challenging accepted routines and theories. Nurses caring for neonates often identify issues for which adequate scientific information on which to base clinical judgments does not exist.

VARIOUS RESEARCH ROLES FOR NEONATAL NURSES

The many different research roles for neonatal nurses include research consumer, participant, facilitator/coordinator, and investigator (Harrison, 2001). There is variability in the research roles that are considered appropriate for nurses across the globe. In some countries with limited opportunities for nurses to pursue doctoral degrees, nurses prepared at the master's level are expected to serve as research investigators, whereas in the United States, the investigator role is generally reserved for nurses with doctoral-level education (Harrison, Hernandez, Cianelli, Rivera, & Urrutia, 2005a).

In the United States, the American Association of Colleges of Nursing (AACN) has published a series of "Essentials" guidelines that outline specific competencies for nurses in baccalaureate, master's, and Doctor of Nursing Practice (DNP) programs. The competencies related to research suggest that nurses prepared at the baccalaureate level use evidence to guide their practice (AACN, 2008). Nurses prepared at the master's level translate evidence to improve practice (AACN, 2011). Nurses prepared at the DNP level conduct application-oriented scholarly projects, as opposed to the knowledge-generating research expected of nurses in PhD programs. DNP nurses are prepared to lead EBP initiatives (AACN, 2006). The American Nurses Association (ANA) asserts that all nurses are responsible for assuming various research activities and roles as appropriate to their education (ANA, 2010). The ANA has also created a research toolkit that is available online to help nurses provide evidence-based care (ANA, 2012).

All neonatal nurses should be knowledgeable consumers of research, read reports of research, and ensure that their practice is research- or evidence-based. To be a knowledgeable research consumer, the nurse must be a critical reader of research articles. A rigorous critique of research should also be carried out before one tries to apply the findings in a practice situation. Strategies that might be implemented to assist nurses with developing critical appraisal skills include journal clubs or workshops (Horsley et al., 2011).

Another key research role for every neonatal nurse is to serve as an advocate for infants and families who are research participants to ensure that their rights are protected and that their safety is ensured. Thomas (2005) reviewed ethical and safety issues related to research with vulnerable infants and their families, and suggested that neonatal nurses may serve an important role by reporting any safety concerns to the Institutional Review Board (or ethics committee) that originally approved the study.

Neonatal nurses can also participate in research as data collectors or clinical research coordinators (CRCs). CRCs assume primary responsibility for implementing clinical studies and protocols that are critical for the successful implementation of any study (McKinney & Vermeulen, 2000). With the rapid expansion of global research, and translational research, there is a growing demand for well-prepared CRCs, although there is considerable variability in the specific responsibilities, training, and titles of nurses who work in clinical and/or translational research (Jones, Jester, & Harrison, 2006; Jones, Wilson, Carter, & Jester, 2009). The International Association of Clinical Research Nurses (CRNs) was formed to support the professional and educational needs of CRNs, and is working to identify specific competencies and standards to guide the educational preparation of CRNs (International Association of Clinical Research Nurses, 2012). The Association for Clinical Research Practitioners (ACRP) has a certification program for CRCs as well as for Clinical Research Associates. (Refer to the ACRP website at www.acrpnet.org for more information.) Several nursing schools have started master's level programs to prepare nurses for these roles (Harrison, Hernandez, Cianelli, Rivera, & Urrutia, 2005b; see the website for the University of Alabama at Birmingham School of Nursing for a description of one such program).

Another method of participating in the research process is to perform secondary analyses on data that were collected to answer another research question. Often answers to additional research questions can be extracted from a single database without having to collect new data. Caution, however, must be used in the design of secondary analysis studies to minimize threats to validity and reliability inherent in the method. Neonatal nurses also might promote research by coordinating research committees, promoting research utilization, coordinating research activities in the NICU, and providing educational programs to help nurses understand and use findings from research.

CURRENT TRENDS IN NEONATAL NURSING RESEARCH

Over the past 30 years, there has been a tremendous increase in the quantity and quality of descriptive as well as experimental and quasi-experimental studies focused on preterm or other high-risk infants and their families. Holditch-Davis and Black (2003) reviewed nursing research on the care of preterm infants and identified 17 nurse researchers who had developed programs of neonatal research, meaning that the researcher had at least five publications since 1990 and was the first author on at least three of these publications. These programs of research had four themes: (1) infant responses to the NICU environment, (2) pain management, (3) infant stimulation, and (4) infant behavior and development. Holditch-Davis and Black suggested that these research programs had many strengths, including interdisciplinary focus and clinical relevance, but recommended that more studies should focus on critically ill infants and be based on a developmental science perspective.

Another trend in neonatal research is the publication of reports of EBP projects in the NICU. For example, Pollock and Franklin (2004) described an ongoing project to implement developmentally sensitive care in the NICU. Smith (2005) described the process of developing, implementing, and evaluating a feeding guideline for very low birth weight infants. Three other examples of NICU EBP projects are (1) evaluation of the use of heparinized saline versus normal saline for the maintenance of intravenous access in neonates (Cook, Bellini, & Cusson, 2011); (2) evaluation of the effect of toys in the NICU microenvironment on nosocomial infection rates (Hanrahan & Lofgren, 2004); and (3) proposing evidence-based guidelines for kangaroo care in the NICU (Ludington-Hoe, 2011).

An important source of funding for nursing research is the NINR, an institute within the U.S. Department of Health and Human Services (DHHS) National Institutes of Health (NIH). Abstracts of research funded by the NIH can be searched and retrieved in the Research Portfolio Online Reporting Tools (RePORT) database (http://projectreporter.nih.gov/reporter.cfm). A query using the keywords "neonatal nursing" resulted in a listing of 21 abstracts of research funded by the NIH (National Institutes

of Health, 2018b). Table 41.5 lists examples of these funded studies.

There are many opportunities for neonatal nurses to implement EBP projects to improve the quality of care for patients and families. Sharing experiences through presentations at professional meetings or publication in the professional literature will contribute to the growing body of information about EBP and the implementation of evidence-based neonatal nursing practice.

TABLE 41.5

EXAMPLES OF STUDIES RELATED TO NEONATAL NURSING FUNDED BY THE NATIONAL INSTITUTES OF HEALTH IN 2017–2018

Principal Investigator	Organization	Title of Study
Katherine E. Gregory	Brigham and Women's Hospital	The influence of the milk microbiome on inflammation of the preterm infant
Tondi M. Harrison	The Ohio State University	Behavioral and physiological responses to oral feeding in infants with complex congenital heart disease
James L. McManaman	University of Colorado, Denver	Postnatal actions of maternal obesity on neonatal metabolic health
Marliese D. Nist	The Ohio State University	Inflammatory mediators of stress exposure and neurodevelopment in very preterm infants
Jochen Profit	Stanford University	Social disparities in NICU care
Jochen Profit	Stanford University	The WISER study
Lisa S. Segre	University of Iowa	Promoting emotional well-being in distressed NICU mothers: A phase 2 evaluation of a nurse-delivered approach
Heather L. Tubbs-Cooley	Cincinnati Children's Hospital Medical Center	Systems analysis of guideline adherence in neonatal intensive care

NICU, neonatal intensive care unit.

SUMMARY

With more and more hospitals and healthcare organizations striving for Magnet status and the inclusion of evidence-based clinical guidelines for care in these institutions, research, research utilization, and EBP reviews and guidelines will continue to grow. This chapter has highlighted some of the ways neonatal nursing care is being impacted through EBP and research.

EVIDENCE-BASED PRACTICE BOX

For the past 20 years, neonatal researchers have conducted studies to assess the effects of music and music therapy provided to preterm infants in the NICU. Hodges and Wilson (2010) published an integrative review of 35 of these studies, which is an example of an evidence summary (the second category in the five-point Star Model of Transformation). The authors concluded that comparison of results from the studies was difficult because of the wide variations in type of music, volume, duration, and gestational ages of the infants. However, despite the limitations, findings from many of the studies suggested positive effects of music on increasing oxygen saturation levels, reducing heart rates and arousal, and improving parent–infant interaction in hospitalized preterm infants. The authors made specific recommendations about future research to address the limitations of existing studies and provide evidence for practice.

CHAPTER 42

Legal and Ethical Issues in Neonatal Care

Carole Kenner

INTRODUCTION

In the high-technology and often high-tension milieu of the NICU, nurses and other healthcare professionals inevitably encounter ethical issues. However, ethical issues involving neonates are not limited to the NICU. Neonatal nurses are providing comprehensive care in an increasingly complex environment for a very diverse population. These challenges will continue to bring ethical issues to the forefront of neonatal care and will require thoughtful reflection.

Ethical issues are often intertwined with legal considerations, further adding to their complexity. Nurses may experience moral distress related to the complexities of care and associated ethical dilemmas. Neonatal nurses and advanced practice neonatal nurses are well positioned for leadership roles in managing ethical and legal issues in the neonatal care settings. This chapter provides an overview of ethical and legal issues that can arise across the spectrum of neonatal care, as well as approaches to recognizing and managing these issues.

RECOGNIZING ETHICAL ISSUES IN NEONATAL CARE AND THE NICU

The NICU and care of neonates can be laden with ethical issues (Cavaliere, Daly, Dowling, & Montgomery, 2011; Kuschel & Kent, 2011; Orzalesi, 2010). The blurred boundaries for viability, coupled with parental preferences and legal considerations, can lead to ethical issues across the spectrum of neonatal care. One of the challenges faced by neonatal nurses is effectively recognizing ethical issues in the midst of providing complex care.

Some neonatal care issues with ethical implications may be more readily recognizable than others. For example, consider the case of a neonate experiencing deteriorating multisystem organ failure whose parents wish to continue aggressive care. The NICU team may be recommending increased palliative and supportive care measures with a deceleration in other measures. This type of heart-wrenching scenario unfortunately continues to occur and is recognized as a classical NICU ethical issue. Many nurses do not feel they have adequate training/education in palliative care to provide the needed support, and this leads to an ethical dilemma (Gibson, Hofmeyer, & Warland, 2018). It is important for neonatal nurses to examine other neonatal care ethical issues that are not as easily recognizable. If nurses have no role in the team decisions about care, moral distress can occur (Molloy, Evans, & Coughlin, 2015; Thorne, Konikoff, Brown, & Albersheim, 2018).

Parents may express care preferences that are deemed nonpermissible because they fall outside usual care practices and may be believed to be potentially harmful to the neonate. For example, parents may want to burn incense in the mother's hospital room in the presence of their newborn. While hospital policy will likely dictate no candles or other flaming substances for the security of all persons in the building and in consideration of the health of the neonate, it would not be in the family's best interest to end the interaction with a discussion of what is not permissible and why. Rather, it would be important for this neonate's nurse to talk further with the parents about their request. Engaging the parents in dialogue about the issue can provide insight into their beliefs and practice preferences. Through this process, the neonatal nurse and parents together can determine an acceptable alternative. The neonatal nurses' actions will demonstrate respect for their role as parents as well as their preferences. Perhaps most significant, though, is that the neonatal nurses will have established a supportive relationship with the parents as opposed to what could have quickly become an unintended adversarial relationship.

Situations such as the one just described may raise questions among neonatal nurses regarding how to best recognize and manage situations that extend beyond clinical care. To assist in understanding the development of ethical issues, an overview of key ethical principles follows.

ETHICAL PRINCIPLES

It is important for neonatal nurses to understand the ethical principles that can help guide their actions when they encounter an ethical situation. Beauchamp and Childress (2009) specify four key principles for biomedical ethics: autonomy, beneficence, nonmaleficence, and justice. Each of these principles is presented along with examples demonstrating how neonatal nurses can apply them to everyday practice.

The principle of autonomy focuses on an individual's independence and the right to make decisions. In neonatal care, the decision makers are the parents rather than the actual patient. To respect the principle of autonomy, neonatal nurses and other team members should engage the parents in decision making about the neonate's plan of care to the fullest extent possible. For example,

it may be medically indicated for a neonate to undergo surgical ligation of a patent ductus arteriosus. Prior to the surgical team obtaining informed consent for this surgery, the neonatal nurse and other team members can provide ample opportunity for the parents to consider the information provided to them to ensure that all of their questions are addressed.

Beneficence, or doing well, is a principle that along with nonmaleficence (avoiding causing harm) represents optimal nursing care. Neonatal nurses are consistently engaged in care that meets best practice standards for promoting the well-being of the neonate. Adequate positioning, promotion of rest, and other supportive care measures demonstrate care delivery in a beneficent manner. Similarly, the avoidance of causing intentional harm to a neonate illustrates nonmaleficent behavior. Consideration of these two ethical principles provides a supportive foundation for delivering the best possible care.

The ethical principle of justice can be viewed in a multitude of ways in healthcare incorporating varying components of equity, allocation, rationing, and access (Beauchamp & Childress, 2009). An examination of justice in neonatal care can focus on the actual process of care delivery. While neonatal nurses are not responsible for the broader issues of access to care, they are in a position to ensure that the neonates within their care receive similar attention and that the care is prioritized based on need. For example, with the number of neonates experiencing withdrawal symptoms, staffing ratios do not always take into consideration the complexity of this care (Smith, Rogowski, Schoenauer, & Lake, 2018). This scenario requires adjustment of assignments to provide adequate care to a neonate in withdrawal (Smith et al., 2018). Providing care to all neonates without regard for extraneous factors such as socioeconomic status and ethnicity represents an important component of the principle of justice in neonatal care.

MANAGING ETHICAL ISSUES: RESOLUTION STRATEGIES

There are various approaches to managing the types of ethical issues that can arise in neonatal settings. While each neonatal care unit or hospital may have a standardized resolution pathway already in place, it can be helpful to explore alternate approaches. Among the ethical issue–resolution strategies available to neonatal nurses are engaging in nursing and/or healthcare team ethics rounds, debriefing discussions, and consultation and collaboration with hospital ethics committees.

Nursing Ethics Rounds

Among the strategies that neonatal nurses may find helpful when faced with ethical issues are engaging in nursing ethics rounds and team discussions. Nursing ethics rounds (Robichaux, 2012) can assist neonatal nurses to recognize and manage developing issues. Ethics rounds can provide an opportunity for addressing developing issues before they expand in complexity and become emotionally laden for all involved individuals. Additionally, through ethics rounds, neonatal nurses can engage in dialogue and elicit support from team members for any identified issues or care-based concerns.

Debriefing Discussions

Following a particularly complex or emotionally laden care situation, it can be beneficial for all members of the healthcare team to participate in debriefing discussions. These discussions can be requested by any team member, but should be scheduled when the key care providers can be in attendance. It is also helpful to ensure that any providers with dissenting opinions or conflicted views are included in open and nonjudgmental dialogue. The session should include a discussion of the salient ethical issues in the case, allowing all team members to identify their perceived areas of discomfort. For those team members who continue to have unresolved discomfort or distress, additional individualized support needs can be identified and enacted.

Collaborating With Hospital Ethics Committees

Hospital ethics committees generally operate in an advisory capacity and can provide guidance with the ethical issues of cases but not serve in a legal advisory capacity (Mercurio, 2011). In situations where different members of the healthcare team and/or the parents have conflicting perspectives on what will be the best course of action, it can be helpful to obtain the perspectives of individuals not directly involved with the case. Additionally, it is important to consider the perspective of the organization and explore the means to involve others from the organization in the clinical decision-making process as warranted (Bean, 2011).

Aside from providing perspectives on actual cases, ethics committees can assist in a consultative manner to garner perspective on potential issues before they arise. Ethics committees can also assist with reviews of past cases or tenuous situations by examining other pathways than the one taken and laying the foundation for future resolution strategies. Examples of neonatal issues before these committees are use of extracorporeal membrane oxygenation (ECMO) or what constitutes viability—a question that brings many different perspectives to the dialogue (Bucher et al., 2018; Peterec, Bizzarro, & Mercurio, 2018).

SUPPORT FOR THE FAMILY

While neonatal nurses often become engaged in close relationships with families of the neonates they care for, the family may begin to feel isolated when ethical issues arise. During these challenging times, neonatal nurses can exhibit leadership in ensuring that families remain engaged to the fullest extent possible. Supporting families in the NICU encompasses a multitude of actions on behalf of the neonate's parents as well as siblings and extended family members. The neonatal nurse may serve as an advocate for grandparent visitation or assist parents in explaining the complexities of the NICU to the neonate's siblings. Perhaps most importantly, they support parents through ensuring their role in various components of decision making (Kavanaugh, Moro, & Savage, 2010; Sudia-Robinson, 2011b), respecting their role regardless of opposing treatment perspectives (Sudia-Robinson, 2011a), and speaking on their behalf (Spence, 2011) whenever necessary. More research needs to be done to determine how best to involve parents in decision making and to what extent they wish to be included (Richards et al., 2017).

Decision Making

One means of demonstrating respect for parents is involving them in decision making (Rushton, 2007). For parents to truly participate in decision making, they must have the necessary information. Information for decision making should be presented to parents in a manner that is easily understandable, yet at an appropriate level for their education and background experiences. While all parents need baseline information, the kinds of questions that parents ask will provide a good indication of their desire and readiness for additional information. Additionally, by providing information in an objective manner, parents will be in a better position to share their values and perspectives rather than being overly influenced by those of the healthcare team (Kuschel & Kent, 2011). What else would you like to discuss regarding your baby's progress?

Other Open-Ended Questions

What else can I provide more information about?

What questions would you like to ask?

Invitational Statements

This is a lot of information. Let's pause so that you can ask questions.

We presented possible care options. Let's discuss your thoughts about each of them.

Tell me the questions you would like to ask the neonatal care team.

decision making is a cornerstone to family-centered integrative care (Ahlqvist-Björkroth, 2017).

Cultivating an invitational atmosphere will foster dialogue and provide an avenue for parents to be active participants in the decision-making process (see Box 42.1). By assuming that all parents have questions regarding some aspect of their neonate's care, neonatal nurses will keep the door to dialogue open. Invitational atmospheres for dialogue allow parents to ask as many or as few questions as they like. An open atmosphere for questions also provides opportunities for parents to ask questions at a time when they are ready to receive the information. For example, some parents can become overwhelmed when a large amount of information is presented during a single conversation. However, when they are given time to process the information, their questions will emerge and they can further engage in dialogue and decision making. For some parents, the role they play in determining outcomes may not even be as important as the opportunity to engage in the decision-making process (Gallagher, Marlow, Edgley, & Porock, 2011). Ethically sound decisions, collaboratively determined to be in the best interest of the infant, represent best practice (Orzalesi, 2010).

Determining Parental Preferences

While it is important to cultivate an open environment for parental engagement in various aspects of care for their neonate, it is equally important to determine their preferences for such involvement. Some parents will want to be very much involved in decision making while others indicate a preference for varying degrees of delegation. Parental involvement should not be viewed as an all-or-none phenomenon, but rather on a continuum that may change over the course of the neonate's hospitalization (Gillam & Sullivan, 2011). Neonatal nurses can play a key role in assessing parental preferences of involvement in care decisions both at the onset and at key time intervals, such as when the neonate's condition significantly improves or becomes increasingly complex. Communication between health professionals and parents is a critical factor in determining how parents want to be involved in care decisions (Ahlqvist-Björkroth, 2017).

Opposing Points of View

In the increasingly complex care environment of NICUs, there will inevitably be varying perspectives on care decisions between parents and the healthcare team. Parents may hold different points of view regarding the overall treatment plan or specific components of care. Neonatal nurses can assist in bridging these differences by engaging parents in conversation about these issues and their preferences. Learning more about their perspective and desired outcomes can lead to improved communication and enhanced decision making (Ahlqvist-Björkroth, 2017; Gillam & Sullivan, 2011; Sudia-Robinson, 2011b).

In situations where parents and the healthcare team are in disagreement about major care issues, it is important for the neonatal nurse to foster continued parental engagement in decision making to the greatest extent possible. For example, a situation may arise where despite the parents' expressed preferences, continued aggressive care is deemed appropriate. The parents can still be encouraged to be involved in other decision making about the care of their neonate such as touch time scheduling. Neonatal nurses can ask parents about their preferences in the scheduling of limited touch times, ensuring that some of those times are when the parents indicate that they can be present at the bedside. Sometimes even relatively minor decision-making opportunities can help restore respect for their role as parents and enhance feelings of connection with their neonate.

SUPPORT FOR THE NEONATAL NURSE

While neonatal nurses are actively engaged in supporting neonates, their parents, and their extended family members, they may neglect their personal needs for health and well-being. Attention to personal care needs is especially important for nurses working in settings that can be physically, mentally, and emotionally challenging. Neonatal nurses need to advocate for their own needs just as they do for the needs of the neonates and families they care for. Actively expressing their needs and taking steps to support themselves, colleagues, and other members of their team are key components of self-sustainability and effective care delivery. Without adequate support, untoward issues can arise for neonatal nurses and other team members. Additionally, during particularly challenging patient and family situations, neonatal nurses may find themselves feeling undue stress with related manifestations, such as compassion fatigue and moral distress.

Compassion Fatigue

Compassion fatigue and emotional exhaustion among nurses have been attributed to a variety of factors including stressful work environments, additional nursing care responsibilities and priority conflicts, extensive and intensive work hours, role responsibilities, and emotionally laden patient care situations (Boyle, 2011; Garcia & Calvo, 2011; McGibbon, Peter, & Gallop, 2010; Potter et al., 2010; Yoder, 2010). This is an evolving area of interest among both nurse administrators and researchers as they strive to develop interventions to support nurses who have experienced compassion fatigue and to develop preventive measures. For neonatal nurses, potential mitigating interventions include on-site professional counseling services, art therapy, rotating patient assignments, extra days off, spiritual support, grief resolution, and self-care goals with specified plans to achieve them (Boyle, 2011; Coetzee & Klopper, 2010; Yoder, 2010). When there is self-compassion, a strong relationship between the nurse and family, and interprofessional–physician nurse collegiality, there is less compassion fatigue (Sano, Schiffman, Shoji, & Sawin, 2018). Strategies to encourage

these attributes may decrease the exhaustion and compassion fatigue nurses often feel.

Moral Distress

Moral distress among nurses and other healthcare professionals can occur when they cannot enact what they perceive as the right or correct thing to do (Callister & Sudia-Robinson, 2011; Pauly, Varcoe, Storch, & Newton, 2009). Acknowledging feelings of moral distress in oneself as well as recognizing moral distress among team members is an important component in the process of ethical care delivery. Signs of moral distress can include feeling conflicted about care decisions and uncomfortable with a lack of involvement in care decisions. Moral distress is linked with the development of depression (Lamiani, Dordoni, & Argentero, 2017). Attention to these feelings is important for both the neonatal team morale and overall care delivery (Janvier, Nadeau, Deschenes, Couture, & Barrington, 2007).

The American Association of Critical-Care Nurses (AACN, 2008) presented a framework for nurses to manage moral distress, referred to as the four A's: ask, affirm, assess, and act. The first A, ask, focuses on the nurse asking oneself questions to determine if distress is present within oneself and/or the healthcare team. Next, through affirming, the nurse validates the feelings of distress by exploring with others. The third step involves assessing the source of the distress and determining that an action plan is needed. Through the fourth step, the nurse develops and implements an action plan. The four A's framework is circular rather than linear, indicating the need to revisit steps as the plan unfolds and to develop additional strategies as needed. One book that addresses moral distress is *Moral Distress in the Health Professions* by Ulrich and Grady (2018).

Strategies that neonatal nurses can utilize to manage moral distress within themselves and team members include verbalizing their concerns and feelings of distress through story telling (Austin, Kelecevic, Goble, & Mekechuk, 2009) and other means of sharing with team members. Further, journal clubs focused on the review of ethical issues, as well as case studies, can help neonatal nurses be better prepared when confronted with ethical issues (Garity, 2009).

LEGAL ISSUES

Neonatal nurses, as well as staff nurses and the nurse practitioner, may be involved in malpractice suits. Most of these instances involve a perinatal event, a neonatal event, or a combination. The types of cases range from a medication error to catastrophic outcomes—death or lifetime disabilities. The cause may be a perinatal event whose effects are not seen until the infant is in the NICU. It could also be a high bilirubin that is not aggressively addressed, or signs of temperature, heart or respiratory rate, or oxygen saturations that are outside of the normal range for a while. Other potential possibilities include a prolonged resuscitation with bad neurological outcomes or a failure to provide an adequate airway (Giuseppe, Riccardo, & Del Sordo, 2018). The lawsuit generally includes the physicians, nurses, and the hospital. Although hospital malpractice does cover all employees, nurses can also obtain their own malpractice insurance; that attorney will then be charged with looking out solely for the nurse's best interests. The choice of whether or not to have personal insurance is left up to the individual nurse. So how does a nurse protect against a lawsuit? The nurse should make sure the policies and procedures of the institute are followed and that there is good documentation of what is done. If there appears to be a problem, the nurse should document and follow the chain of command, as this will record that the nurse has notified others of a situation. If a mistake is made, the nurse should follow the institutional policies for such events and get advice from risk management if that is possible. If a lawsuit is brought and involves the nursing care, the nurse should make sure to know his or her rights and seek legal advice. Remember that emails are discoverable, so nurses should be careful what is put in an email. Nurses can also make notes for themselves to document details that might not be in the chart—impressions they may have at the time. Nurses should keep them in a secure place for their own use.

SUMMARY

Neonatal nurses are uniquely positioned to serve as leaders and supporters of all aspects of ethical care delivery. Assisting parents to express their preferences for care delivery and providing support for those preferences to the greatest extent possible are components of practicing within an ethical context. Through the delivery of highly skilled bedside care to facilitating parental involvement in care-based dialogue and decision making, neonatal nurses enact key advocacy roles for neonates and their parents.

CHAPTER 43

Neonatal Care From a Global Perspective

Carole Kenner and Marina V. Boykova

INTRODUCTION

In 2005, *The Lancet* published the "Neonatal Survival" issue (Lawn, Cousens, & Zupan, 2005). This report called for action worldwide to address the United Nations Millennium Development Goals, especially #4 to reduce mortality of children less than 5 years of age. Why a call for action by perinatal and neonatal specialists who care for children in the first year of life? Why call this edition the Neonatal Survival and not child survival? The reason is that almost 50% of the deaths of children under 5 years of age is attributable to the neonatal period (Lawn et al., 2005). Most of the causes, including infection, intrapartal complications, and prematurity, are preventable (Lawn, Kerber, Enweronu-Laryea, & Cousens, 2010). In 2010, a progress report was released stating that the deaths in this population had been reduced from 4 million annually to 3.6 million (Lawn et al., 2010).

To combat these outcomes, the global community responded by producing an action plan for implementation of strategies that would continue the progress. The World Health Organization (WHO, 2012), specifically the Partnership for Maternal Newborn and Child Health–WHO, led the Child Survival Call to Action. This initiative was in collaboration with UNICEF. Over 700 leaders participated in Washington, DC, in this historic meeting (www.who.int/pmnch/media/news/2012/20120614_childsurvival_call/en/index.html). Over the past decade, one key ingredient in improving health outcomes has been nursing. It is recognized that a strategy is to strengthen the education and training of neonatal and pediatric nurses. The March of Dimes, the Partnership for Maternal, Newborn, and Child Health, Save the Children, and the WHO issued a report in 2012, *Born Too Soon* (Howson, Kinney, & Lawn, 2012). In that report, there is also a call to action citing that, to date, 15 million babies worldwide are born prematurely, with 60% of these births occurring in Africa and South Asia. The United States is in the top 10 countries that are the highest contributors to preterm births (Howson et al., 2012). The call to action lists four shared actions. **Invest:** Ensure preterm interventions and research are given proportional focus, so funding is aligned with health burden. **Implement:** Plan and implement preterm birth strategies at global and country levels and align on a preterm mortality reduction goal. Introduce programs to ensure coverage of evidence-based interventions, particularly to reduce preterm mortality. **Innovate:** Perform research to support both prevention and treatment agendas. Pursue an implementation research agenda to understand how best to scale up interventions. **Inform:** Significantly improve preterm birth reporting by aligning on a consistent definition and more consistently capturing data. Raise awareness of preterm birth at all levels as a central maternal, newborn, and child health issue. The overarching message is continued support for "Every Woman Every Child" and other reproductive, maternal, newborn, and child health efforts, which are inextricably linked with preterm birth. Ensure accountability of stakeholders across all actions (Howson et al., 2012, p. 7). The Every Woman Every Child global strategy continues and the Every Newborn Action Plan is now in the implementation phase (Every Woman Every Child, n.d). This plan provides a roadmap to end preventable neonatal deaths (Every Woman Every Child, n.d.). Endorsed in 2014 by the World Health Assembly, this work now includes a Quality of Care Network, Partnership to Prevent Preterm Birth, and Breastfeeding Advocacy Initiative (Every Woman Every Child, n.d.). At country level, there is now a commitment to track neonatal health outcomes including barriers to providing care (Every Woman Every Child, n.d.).

This work is improving outcomes but not fast enough. According to UNICEF (2018), in 2017 the neonatal mortality rate was 18 per 1,000 live births, which translated to 7,000 deaths daily, and 2.5 million deaths per year. WHO (n.d.-a) cited that in 2016 there were approximately 2.6 million neonatal deaths annually. This constitutes 46% of all under-five deaths. The top 10 countries for neonatal, maternal mortality and stillborn rates are India, Nigeria, Pakistan, China, Democratic Republic of the Congo, Ethiopia, Bangladesh, Indonesia, Afghanistan, and Sudan (Bhutta, 2018). The highest neonatal mortality rates occur in Africa—Somalia, Mali, Democratic Republic of the Congo, Sierra Leone, Central African Republic, Burundi, Angola, and Chad—and two countries outside Africa—Afghanistan and Pakistan (Bhutta, 2018). Preterm birth constitutes about 35% of this mortality (Bhutta, 2018). Most neonatal deaths occur on the first day of life (WHO, n.d.-a). There is much work to be done globally to decrease morbidity and mortality of mothers, neonates, and children. Nurses are key to making a difference. Nursing Now (n.d.) has declared 2020 as the year of the nurse to coincide with Florence Nightingale's 200th birthday. This initiative is supported by WHO and the International Council of Nurses (ICN) to empower nurses (WHO, n.d.-b).

Raising awareness of the factors that contribute to these rates, improved education and training of health professionals and community health workers, and a commitment to raise the standards of maternal–child care are the cornerstones to changing the global picture. To this end, this chapter is dedicated to the efforts that are at work to change neonatal nursing and neonatal and child outcomes. It also presents exemplars of neonatal nursing and its struggles as well as its opportunities.

A STRONG GLOBAL VOICE FOR NEONATAL NURSING

The Council of International Neonatal Nurses (COINN) was founded in 2005 by national neonatal nursing organizations that believed that a strong voice for neonates and their families was essential. These national members felt that already strong organizations needed to work together to help nurses in countries where there were no national organizations. Many times, there were only a few nurses, and obviously they could not be trained or specialized in just neonatal care. These nurses, so few in number, needed to provide care across the life span. The founding groups were the National Association of Neonatal Nurses (NANN) in the United States; the National Neonatal Association (NNA) of the United Kingdom; the Australian College of Neonatal Nurses (ACNN), formerly the Australian Association Neonatal Nurses Association; the New Zealand Association of Neonatal Nurses (NZANN) or Neonatal Nurses College of Aotearoa; and the Canadian Association of Neonatal Nurses (CANN). Over the next 7 years, other national organizations joined, including the Danish Neonatal Nurses, Netherlands Innovation and Research-Dutch NICUs, Finnish Society of Neonatal Nurses-Finland, and Sociedad Española de Enfermeria Neonatal (SEEN), Spain. COINN helped launch organizations in Southern Africa—the Neonatal Nursing Association of Southern Africa (NNASA); India—the Indian Association of Neonatal Nurses (IANN), Rwanda—the Rwanda Neonatal Nurses Association (RANN) in 2016; the Japanese Academy of Neonatal Nurses joined COINN in 2016, the Kenya Neonatal Nurses Association (KNNA) launched in 2018, a network formed in Russia, and COINN is beginning to discuss such work in Burundi, Democratic Republic of Congo, and Brazil. Other areas of the world have offered regional representatives who can link nurses together in their region of the world. Through these efforts, over 70 countries are now represented by COINN. Why is this type of nongovernmental, nonprofit organization important?

COINN'S Role in Global Health

COINN has joined forces with many partners worldwide to address the issues of newborn health standards, neonatal nursing recognition as a specialty, and the need for lifelong learning for those caring for mothers and babies. COINN's partners are the 99nicu Forums, Caring Bridge, European Foundation for the Care of Newborn Infants (EFCNI), the Healthy Newborn Network, as an affiliate of the International Council of Nurses, the Partnership for Maternal Newborn and Child Health–WHO, and the White Ribbon Alliance for Safe Motherhood, to name a few. COINN has issued position statements on the Care of the Late Preterm Infant, Care of the Well Term Infant, Child Health, Poverty and Breastfeeding, Ethical Migration of Neonatal Nurses, Neonatal Nursing Education, and Routine Screening for Intimate Partner Violence. COINN has endorsed documents from other organizations that are helping to shape health policy and standards of care at both national and global levels. From 2017 to 2018, COINN has participated in several high-level United Nations meetings, contributed to the Every Woman Every Child and Every Newborn Action plan by committing to training in Helping Babies Breathe™, Essential Newborn Care, and in partnership with Dr. Kris Karlsen of S.T.A.B.L.E. COINN is working with USAID, WHO, and others on a next round of training and policies to be implemented in 2019. COINN received funding from Chiesi Foundation, Parma, Italy, and Dr. Sue Prullage's leadership from COINN to conduct research to determine skills, knowledge, and staffing issues as well as equipment used in all the neonatal units in Rwanda. Rwanda's outcomes are better than that of their surrounding neighboring countries, yet they have many challenges. In October 2018, COINN held its first regional African Conference in partnership with the University of Rwanda, Training, Support and Access Model (TSAM), Global Engagement Institute (GEI), Berlin, Germany, with an office in Rwanda, and others. This meeting attracted over 300 people—primarily nurses from Rwanda, Kenya, Democratic Republic of Congo, Burundi, Zambia, Malawi, and Nigeria as well as the United States and Australia. At this meeting, a side meeting was held to run focus groups to determine barriers, opportunities, and aspirations of nurses in the African countries. Following the focus groups, thought leaders came together from USAID, WHO, GEI, Chiesi, Save The Children, Partners in Health, BirthLink, Project Hope, Rwanda Midwifery Association, Preterm Birth Initiative of University of California San Francisco (funded by the Gates Foundation), COINN, and RANN to begin to develop a roadmap for improving the visibility of nurses and thereby improving neonatal outcomes. This conference/side meeting was most important as it spoke to nurses' vital role in healthcare. This work, along with the Nursing Now Campaign with WHO and ICN, will help with gender equity issues as nursing is still predominantly a female profession (Nursing Now, n.d.; WHO, n.d.-b). COINN also works with the Joint European Neonatal Societies (JENS) to represent nursing's voice at their conferences. In October 2018, COINN board members Agnes Vanden Hoogen and Julia Petty participated in the eighth International Congress of Union of European Neonatal and Perinatal Societies (UENPS). As was started several years ago with the Every Woman Every Child initiative, bottlenecks to care provision need to be identified and relieved to care for the small and sick newborn (Moxon et al., 2015). Some examples of the global perspective and why many issues are the same worldwide are presented in the next sections.

European Foundation for the Care of Newborns and Infants

The EFCNI was founded in 2008 to address the issues surrounding premature infant birth and the infants' families. Since then, this organization has formed alliances with nongovernmental and governmental organizations, including the March of Dimes, European Parliament, and many others, to promote policy changes in the European Union. COINN has endorsed some of their more recent reports. They have issued several landmark reports and white papers. Their Benchmarking Report of 2010 (EFCNI, 2010) highlighted successful ingredients for changing the prematurity rates and outcomes.

Key factors that determine an effective and successful approach to tackling prematurity include the following:

- National neonatal health policy/program;
- Formal dialogue between government, healthcare professionals, and parents;
- Comprehensive data collection on prevalence/morbidity/mortality/cost burden based on standardized definitions and common measurement criteria (e.g., through registries);
- Comprehensive data collection on neonatal intervention outcomes/neonatal service management based on common measurement criteria (EFCNI, 2010, p. 7).

EFCNI issued a white paper in 2012 on caring for newborns and infants. This white paper is a call to action to address the provision of quality and safe maternal infant care (EFCNI, 2012). Thirteen key recommendations were made. While the focus was on Europe, the reality is that these recommendations fit any country.

The 13 key recommendations made in this white paper identify that action is needed at both the European and national level in order to do the following:

1. Recognize the issues of maternal and newborn care and aftercare as a public health priority, particularly the health of preterm infants and infants with illnesses;
2. Acknowledge the potential long-term health consequences of preterm birth and newborns with illnesses that need to be tackled;
3. Address health inequalities in maternal and newborn care within all EU member states;
4. Conduct national audits on maternal, newborn care, and aftercare services and establish multidisciplinary task forces for developing national best practice guidelines;
5. Implement national policies and guidelines for high-quality preconceptional maternal and newborn care and aftercare. These policies and guidelines should include the principles highlighted in this white paper.
6. Provide equal and early access for parents to complete and accurate information, education, and counseling;
7. Harmonize education and training of healthcare providers;
8. Provide social and financial support for parents and families;
9. Develop and implement strategies for public awareness and education;
10. Harmonize cross-border maternal and newborn healthcare;
11. Monitor outcomes and implement audit procedures in maternal, newborn, and aftercare services;
12. Implement Europe-wide standardized datasets for pregnancy and preterm birth outcomes;
13. Invest in comprehensive research to tackle the challenge of preterm birth and its potential long-term consequences (EFCNI, 2012, pp. 5–6).

In the fall of 2018, the *European Standards of Care for Newborn Health* will be released by EFCNI. COINN worked with EFCNI to develop these standards. This is just another example of health professionals and families working together.

RUSSIAN EXAMPLE

Neonatal nurses in Russia have worked hard to raise the status of nursing in their country. They have a very strong Russian Nurses Association that has been a member of the ICN for almost a decade. This group is working to raise the standards of nursing and supports exchanges with other countries. At the same time, Russian neonatal nurses have formed a network to address the specific care and educational needs of neonates and their caregivers. For example, Children's Hospital #1 in Saint Petersburg developed collaboration in the early 1990s. Neonatal teams went back and forth between Russia and Oakland Children's Hospital, Oakland, California. Through this exchange, infection rates as well as neonatal mortality rates dropped significantly (Kenner, Sugrue, Mubichi, Boykova, & Davidge, 2009). Medical leadership in Saint Petersburg supported neonatal nurses going to England to gain bachelor's and master's degrees. The administration supported a neonatal nurse educator at the unit level. Unfortunately, such efforts were not common in Russia, and some places have even eliminated unit educators. On the positive side, Russia has free follow-up care for mothers and babies, including home visits. This country has also supported changing the role of nurses to a more professional level. In the past, it was not uncommon for nurses to sweep and scrub the floors and empty trash in addition to providing care. This unit in Saint Petersburg is the largest NICU in Europe, with 200 beds. It maintains good outcomes, but nurses today face new challenges of providing care with little orientation or specialized training.

INDIAN EXAMPLE

Indian neonatal nurses and neonatologists recognized that there was a growing problem of sicker, smaller babies requiring care. The Neonatology Forum of India, which represents the doctors, encouraged the neonatal nurses to work together with them and seek help from COINN to form a national organization. In 2007, this call to action resulted in the formation of the Indian Association of Neonatal Nurses. The 2007 COINN International Conference of Neonatal Nurses hosted by the Indian Neonatal Nurses Association brought together over 1,000 nurses and doctors from around the globe. Why was this important? At one session during the conference, the president of COINN and a local neonatologist facilitated a discussion of the state of neonatal nursing in India. There, it was revealed that even though it might be considered a Level II or intermediate care unit, the ratio was 75 babies to 1 nurse. The staffing was at critical levels as the nursing shortage was growing. Nurses were frustrated they could not provide the care they wanted so desperately to give. While, of course, this staffing was not the case everywhere in India, the neonatal outcomes were not good. For example in the *Born Too Soon* report (Howson et al., 2012), India is reported to have had just over 27 million births in 2010, with 13 in 1,000 live births being preterm, resulting in over 875,000 neonatal deaths. These figures are just for premature births and not for other neonatal problems. With the sanction of the Ministry of Women's and Children's Health, the IANN was launched in 2007. Since that time, this organization with COINN has advanced neonatal nursing. *Saving Newborn Lives* in conjunction with COINN gave awards to three nurses to attend the international conference hosted by the NNASA and COINN in Durban, South Africa, in 2010. One of the awardees was from the Indian group. Participating in such conferences and having organizations work collaboratively are making a difference. India still faces many challenges as the neonatal mortality rate continues to be high. Nursing must be a part of the solution. The following sections provide exemplars of work going on globally to change neonatal care and education.

SOUTH AFRICAN EXAMPLE

For many years, the challenge of maternal–child health in sub-Saharan Africa has been highlighted. The highest neonatal death rates worldwide are still found in this region. The rate of premature births in South Africa in 2010 was 8 per 1,000 live births, with total births just over 1 million; neonatal deaths due just to prematurity were over 18,000 (Howson et al., 2012). Neonatal nurses had enjoyed a time when their specialty was recognized by the nursing council; however, as the nursing shortage grew, the need for more generalized training grew. Thus, specialized neonatal training was only supported at an institutional or unit level. The neonatal nurses brought the minister of health and *Saving Newborn Lives* to the international conference with COINN. From that meeting, there were media releases to support the need for more education and training, as well as for nurses working with nongovernmental and governmental agencies to improve neonatal outcomes. Policy

changes are slow, but with this organized voice and now thanks to media coverage and more recognition of the vital role nurses play in improving outcomes, progress is being made (Kenner, Boykova, & Eklund, 2011; Kenner et al., 2009). Educational outreach is growing, as are the requests for neonatal nurses to work at the policy table to change neonatal care. Southern Africa, South Africa in particular, must be viewed within the context of a change in healthcare delivery due to the increasing impact of HIV. As hospitals got overcrowded with patients with HIV/AIDS, South Africa developed community-based programs such as home visits and palliative care (Zelnick, 2011). Need for nurses grew at a time when wages and work conditions grew worse (Zelnick, 2011). Nurses, including neonatal nurses, began migrating to other countries, contributing to the brain drain (Zelnick, 2011). This migration, coupled with the growing needs for generalist nurses, has led to tensions for specialized education, especially in the area of maternal–child outcomes. The situation has not really changed in the past few years. But now, with support from nongovernmental organizations, nursing is increasing its presence in the discussion about ways to change the view of nursing. Most of Southern Africa has better neonatal health outcomes than many other countries. More evidence is needed to determine the role nursing education and training has had on these outcomes.

BRAZILIAN EXAMPLE

In June 2012, the Brazilian neonatal nursing community came together in the second annual *Congresso Brasileiro de Enfermagem Neonatal* meeting, held in Fortaleza, Brazil. Almost 1,000 nurses and doctors were in attendance. Amazing work is going on there. A national repository exists to collect data on maternal–child outcomes. Interprofessional teams are beginning to emerge in the educational institutions as well as the practice arena. The nurses are working with policy makers to ensure that the standards of nursing and care are raised. Brazilian nurses are gaining opportunities for more autonomy in practice. They are viewed by many doctors as the key to changing the outcomes for the country. Prematurity rates have decreased over the past decade, and there is more emphasis being placed on breastfeeding, nutrition, and developmental care. Infectious disease is still a problem, as it is globally. They have formed a national research network that encompasses public health initiatives. Brazil is considered one of the BRIC countries—Brazil, Russia, India, and China. This refers to the growing economies in these countries and the important role they will have in changing global markets. For health, this means that more countries will want to invest in BRIC and therefore will need a healthy workforce to draw workers from and to maintain. According to UNICEF, the younger than 5 years of age mortality rate in 1990 was 59 in 1,000 live births, but by 2010 the rate was 19 in 1,000 live births (UNICEF, 2012a). By 2017 the under 5 years of age mortality rate was 14.8 per 1,000 live births (UNICEF, 2019). The neonatal mortality rate in 2010 was 17 per 1,000 live births (UNICEF, 2012a). Definite progress is being made in this country. This progress demonstrates the impact of improved nutrition, promotion of breastfeeding, increased support for reproductive health efforts, a strong public health model that includes examining differences between risk and poor populations and the factors that contribute to the differences, provision of public safe water, increased awareness of prematurity and rationale for decreasing elective cesarean sections, as well as monies to support vaccinations and treatment for infectious diseases including pneumonia and diarrhea (Holtz, 2013). With the outbreak of the Zika, monies have been allocated for prevention and treatment and nurses are included in this work. Brazil continues to work to decrease premature births through public education about the dangers of prematurity including the dangers of nonessential cesarean sections.

JAPANESE EXAMPLE

Japan is a global economic and technologic force. Yet neonatal nurses in Japan have a limited role. Nurses in Japan oftentimes are not permitted to do any invasive procedures such as start intravenous therapy; they cannot easily question a doctor's authority, nor can they always contribute to the assessment (Kenner et al., 2011). Tides are changing as nurses and doctors are being invited to lecture and work in Japan to raise the awareness of Western techniques and care standards (Kenner et al., 2011). Gradually, policies are changing through these exchanges. Collaborative efforts are under way to gather groups already working in Japan to address common issues such as neonatal care standards rather than working individually (Kenner et al., 2011). The Japan Academy of Neonatal Nursing joined COINN in 2016. They have been a long-standing organization but felt the time was right to join forces with COINN to increase educational/networking opportunities for their nurses.

RWANDAN EXAMPLE

Rwanda is a changing country. Neonatal mortality rates were 29 in 1,000 live births (UNICEF, 2012b). The amazing change is in the younger than 5 years of age mortality rate that moved from 163 in 1,000 live births in 1990 to 91 in 1,000 live births in 2010 (UNICEF, 2012b). By 2017, the rate had dropped to 16.4 per 1,000 live births (Knoema, n.d.). How did this change come about? Over the past two decades, governmental and nongovernmental agencies have worked together to change the tides of health in this country. EOSVISIONS, COINN, RANN, GEI, and One Good Deed worked together with the Rwandan Ministry of Health and the Kigali Health Institute to provide neonatal education, specifically Helping Babies Breathe (https://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/helping-babies-survive/Pages/Helping-Babies-Breathe.aspx), from the American Academy of Pediatrics and S.T.A.B.L.E. Program developed by Dr. Kris Karlsen of Park City, Utah (www.stableprogram.com; EOSVISIONS, 2012). This collaboration is new, but represents another step in raising the education of neonatal health providers. The formation of the RANN has facilitated discussions about the barriers and opportunities to provide high-quality care. Partnerships with those organizations working in the country to coordinate efforts is most important to changing outcomes.

These are just some examples of challenges as well as opportunities to impact neonatal nursing care and education. There are other broader issues that are also impacting neonatal nursing.

FUNDING FOR NURSING EDUCATION

A major factor in neonatal nursing care is neonatal nursing education. This education is linked to how a country finances medical and nursing education. Many countries fund medical education under the Department or Ministry of Education. However, nursing education is often funded under the Ministry of Health. Obviously, if a country has poor health outcomes and there is increasing political pressure to improve these outcomes, that country will put more financial resources into the care than into education that is competing for the same dollar (Kenner et al., 2009). Mexico, for example, changed this mode of funding several years ago. Nursing education is now funded under education and not health. This is

one example of a policy initiative that needs to continue to be addressed on a country level. COINN and other organizations are raising the awareness of this issue. COINN and other nurses must be involved in the change. They must tell their stories of what it is like to be on the frontlines.

SUMMARY

Global issues in neonatal nursing care and education are at the forefront of the Millennium Development Goals and the Sustainable Development Goals work. It is critical that nurses continue to see a role in changing standards of care for mothers and babies, raise the educational level of neonatal nurses, and work at policy tables to change public and health policies.

CASE STUDY

A 39-week infant was born in a remote village in Central America. The infant was transported by ambulance to a large metropolitan hospital that has an intensive care unit. The infant was diagnosed with a congenital heart defect that could be repaired with surgery. The only pediatric cardiac surgeon was unavailable as he had been in an accident and recovery was expected to take several weeks. The infant was maintained with oxygen in hopes he could survive until the surgeon was well. Transport of the infant out of the region for medical treatment was not possible. This case is replicated in many parts of the world with small variations on a regular basis.

EVIDENCE-BASED PRACTICE BOX

In 2005, Lawn, Cousens, and Zupan, published *The Lancet "Neonatal Survival Series,"* which stated that over 4 million children younger than 5 years old died annually. By 2010, Lawn et al. (2010) reported this number to have been reduced to 3.6 million. By 2017, UNICEF (2018) noted that 2.5 million die during the neonatal period (UNICEF, 2018).

Several strategies were used to reduce this mortality. For example, Lee et al. (2011) report that, of the 136 million babies born annually worldwide, about 8% require help to breathe, while 814,000 neonatal term infant deaths are due to intrapartum-related events resulting in asphyxia. Therefore, this research team conducted a systematic review of neonatal resuscitation and tactile stimulation and the link to neonatal mortality and morbidity whether in term, preterm, hospital, or home birth situations. GRADE criteria were used to determine mortality rate estimates for the Lives Saved Tool (LiST). A Delphi panel was used for effect size determination when there appears to be low-level evidence to support an intervention that was strongly recommended. The findings were that there were 24 neonatal resuscitation studies involving mortality reports, but none included use of immediate newborn assessment and stimulation as the only interventions. The conclusion following the Delphi panel was that, in healthcare facilities, neonatal resuscitation reduces term intrapartum-related death by as much as 30% but is less effective on preterm infant outcomes. In the community, use of low or no technology resuscitation (basic), immediate newborn assessment, and stimulation also had less dramatic effects than in healthcare institutions with term infants. Further research is needed to examine these practices.

PARENT VOICES

Crystal Duffy

The anger and frustration from a NICU parent is never personal; always remember it is never about you (the NICU nurse). A parent in the NICU is often navigating through the most traumatic and difficult time in their life. Your job should always be to try and make that journey a little easier for them.

Gigi R. Khonyongwa-Fernandez

"Freefalling without a safety net."
This is what NICU parents who have their babies unexpectedly (what premature birth is expected?) in a foreign country can feel like. It is what I felt like. We may be at an even bigger disadvantage in trying to cope with the daily traumas of the NICU because we do not have the natural support system (i.e., safety net) of family and friends around

(*continued*)

(*continued*)

us. We are not just in another state but in another country, and in our case, on another continent. We feel lost, like aliens in an unfamiliar situation in an unfamiliar country and sometimes with an unfamiliar language. Familiar customs and cultural supports that we would typically cling to do not exist. We are terrified and feel unanchored. Nurses need to be in tune to this and be gentle and compassionate by providing some familiarity and consistency to such parents. Try to understand what is important culturally to that NICU family, and either provide it or at least be respectful of it. It is also important to communicate clearly what is going on in a way we understand.

Yamile Jackson, PhD, PE, PMP

I grew up in Bogota, Colombia, in a loving family that believes that nobody should suffer alone. My personal and professional purpose changed the day my son Zachary was born 12 weeks prematurely to save my life. The NICU in Houston, Texas, in 2001 did not have a space for us to stay 24 hours; therefore, night after night, I left Zachary scared and suffering alone while I went home without him.

I poured my newly found maternal instinct, my love for Zachary, my professional experience, and PhD in ergonomics and human factors engineering to make a device to support Zachary and me even when we were not together. I needed to lessen my feelings of impotence and being out of control of this baby that was struggling to survive and was feeling a lot of pain.

When he was 3 weeks old, Zachary survived the deluge of Tropical Storm Allison in Houston when power shut down and his life support equipment stopped working. We kept him alive "by touch" for 9 hours until he was evacuated. My chest and love kept him warm and Larry received a crash course on how to "bag" him to help him breathe. He would switch every half hour with a staff member to give Zachary manual breaths.

Read the Readers Digest article by Peter Michelmore entitled "Blackout" (https://goo.gl/fdJR4R).

In those dark hours, I made a promise to Zachary that his pain and struggle to survive were not going to be in vain, and that I would dedicate my life to share with him my love for traveling, and would support parents to help their babies feel loved, grow, and thrive. My prayer was to be given the opportunity to do it on his behalf and not in his memory.

I was granted my wish. Zachary came home after 5 months in two different NICUs. Since then, I have dedicated my life to engineer solutions that translate evidence into practice and to keep the promise I made to my son.

Babies and mothers around the world share the ability to coregulate. There is a tremendous need to raise awareness and education about the importance of early intervention for proper development of the physical, psychological, sociologic, physiologic, and neurologic systems, and prolonged kangaroo care needs to be implemented in countries around the globe.

My experience in traveling to over 45 countries (20+ with Zachary) and the Internet has allowed me to reach professionals globally to educate about the importance of parents and kangaroo care/skin-to-skin contact for bonding and for the best possible quality of life for a lifetime. All newborns in the world, regardless of gestational age, medical condition, or developmental stage, share the need for being nurtured by loved ones, and kangaroo care can meet this need in every corner of the world. It is an evidence-based practice and works in low- and high-technology settings. At Nurtured by Design, we lead on engineering devices for evidence-based developmental care and safe kangaroo care/skin to skin specifically for hospitals. We call our brand The Zaky, and we founded the International Kangaroo Care Awareness Day on his 10th birthday. We do it all on behalf of Zachary, the healthy teenager that is our CIO (Chief Inspirational Officer).

"A baby is born with a need to be loved – and never outgrows it." —Frank Howard Clark

CHAPTER 44

Competency-Based Education and Continued Competency

Geralyn Sue Prullage

INTRODUCTION

Healthcare and healthcare expenditures have been a focus for the United States and the international community for years. Healthcare expenditures are linked to patient safety and quality of care. Since the 1990s, quality of care has been linked to nursing competencies. The Pew Health Profession Commission (1995) recommended that all regulated healthcare providers demonstrate competencies in knowledge judgment, technical skills, and interpersonal skills throughout their career. The call for competencies in skills and knowledge for healthcare providers necessitated change in the way education was offered and how to evaluate the education. For years after this report, nursing education struggled with how to measure and instruct in nursing competencies. There was an attempt to generalize competencies to all nursing domains without success. Within individual nursing domains, there are differing competencies, such as competencies for an intensive care neonatal nurse versus the neonatal nurse practitioner. Within governing bodies, there are differing competencies. The National Association of Neonatal Nurses (NANN) requires the neonatal intensive care nurse to certify within a four-competency domain, whereas the neonatal nurse practitioner has a seven-competency domain (NANN, 2015).

Internationally, there are differing governing competencies for neonatal nurses. In the United Kingdom (UK), the National Health Service (NHS) provides care for neonates in specialized units. The specialized units consist of a transitional unit, special care, high dependency care, and intensive care (British Association of Perinatal Medicine [BAPM], 2011). The different levels of care required UK educators to look at the needed competencies of nurses working in each unit. They developed a competency document called the Qualified in Specialty (QIS), which addressed the competencies in each unit. The competencies are separated into seven different domains. The Scottish Nurses Association later adopted the QIS competencies (BAPM, 2012). Other countries have developed neonatal competencies, while some have not addressed the issue.

Nursing has historically demonstrated a commitment to assuring competency that relied on initial licensure, testing, continuing education (CE), codes of ethics, and comprehensive certification programs designed to protect public safety (American Nurses Association [ANA], 2015). In 2014, the ANA (2013) reaffirmed the commitment to competencies by stating that, "the registered nurse is individually responsible and accountable for maintaining professional competence" (p. 3). The Institute of Medicine (IOM, 2015) linked nursing certification to improved competencies and overall improvement in patient outcomes. On a larger scale, the National Academy of Medicine, formerly the IOM, recommended core competencies that affect the health of a country. These core competencies were created to be linked to the Sustainable Development Goals (SDG; Premji & Hatfield, 2016). Nursing competencies are linked to the overall care of a nation. In 1999, the former IOM recommended the implementation of periodic re-examination and relicensure of physicians, nurses, and other healthcare providers based on competencies of knowledge of safety practice (Kohn, Corrigan, & Donaldson, 1999).

In response to the IOM call for re-examination and relicensure, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) issued standards requiring documentation of the clinical competency of all nursing staff (The Joint Commission [TJC], 2017). Hospitals were tasked to develop systems for assessing initial and continuing competence for their nursing staff at a time when downsizing was resulting in the loss of both unit-based educators and clinical nurse specialists (CNS). Particularly affected were critical care units, such as the neonatal intensive care unit (NICU), which were already short staffed and had high nursing turnover rates.

As this movement toward documentation of minimal competencies for hospital nurses was developing, educational institutions were looking at terminal program objectives and the ways in which these might translate into minimal competency statements for graduates. By this time, competency-based education (CBE) had gained acceptance in the nursing education community. Because it offered a potential bridge between education and practice, there was hope that CBE would help close the gap between a new nurse graduate's education for practice and actual practice requirements.

This chapter traces the evolution of the competency movement in healthcare, discusses the advantages and disadvantages of CBE, and describes the impact of the competency movement on neonatal nursing practice and education. The future of competency-based neonatal care is discussed.

DEVELOPMENT OF THE COMPETENCY MOVEMENT

Hospital-based or diploma programs that used an apprentice model to integrate classroom learning and clinical performance dominated the American educational system for nurses until the late 1960s and early 1970s (Chapman, 1999). Subsequently, the growing importance of higher education shifted nursing education from the hospital-based training program to the academic setting and transferred responsibility for the competence of the new graduate nurse from the hospital or employer to the university and its educators (Bechtel, Davidhizar, & Bradshaw, 1999). University-based nursing education gained in popularity and the hospital-based programs began to disappear. Furthermore, the IOM recommended that to address the needs of the growing population, the nursing community should become an important player and that it would begin with obtaining a BSN degree. The recommendation from the IOM was that there should be an 80% increase in BSN nurses by 2020 (IOM, 2010).

As the new paradigm for nursing education evolved, so did an enormous shift in the healthcare arena. Patients in hospitals were sicker, older, and more knowledgeable about the care they received. The gap between the knowledge and skills required nursing students to learn in a supervised academic setting' the setting needed to function safely and independently became increasingly evident. Nurse educators began to develop strategies to address the gaps between knowledge and skills. One focus was to address how nursing educators educated nursing students. Students bridge the gap between knowledge and skills best when the nursing educator provides the knowledge in the classroom and demonstrates the skills in the clinical setting (Ajani & Moez, 2011). A call was made for nursing educators to demonstrate competency by blending knowledge and skills into clinical practice. Therefore, nurse educator competencies were developed in 2013 (National League for Nursing [NLN], n.d.).

With the trend from traditional orientation programs to competency-based programs, we saw a shift in how the gap between education and clinical practice was addressed. Orientation and CE became more competency-based instead of self-reported competencies. Orientation of a new nurse is now unit competency-based, replacing the previous expensive and ineffective orientation programs. A new graduate or new hire nurse now knows what is expected of him or her during the orientation process. The process is organized in a way that the newly hired nurse can attain agreed upon competencies and success on the unit. The steps to orientation became organized, particularly aimed at the newly hired nurse demonstrating competencies along the way. These steps include the following:

- Preparation, which includes specific didactic courses and the choosing of a preceptor
- Incorporation of nurses to participate in rounds, reports, and staff meetings
- Goal-directed preceptorship: The new nurse and the preceptor set goals from simple to difficult tasks and documentation of attaining competency each time
- Feedback from the preceptor and nurse together and head nurse biweekly evolving into weekly and monthly meetings as competencies are attained
- Final step is ongoing support once the orientation program is finished—a "buddy" is assigned to be a mentor and go between for the new nurse (Cline, 2013)

In 2010, the IOM produced a document called *The Future of Nursing: Leading Change, Advancing Health*, which changed the landscape for nursing and competencies. Shortly after the IOM document, the Robert Wood Johnson Foundation (RWJF) along with the AARP initiated the "Future of Nursing: Campaign for Action (Campaign)." These two documents catapulted nursing competencies into the limelight, requiring academia and hospital administrators to evaluate how nurses work, receive training, and continuously train (IOM, 2010). Now, there were clearly defined objectives to ensuring competencies in education and the organization. Faculty and healthcare organizations were now to prioritize the appropriate competencies needed for the newly hired nurse. The Commission on Collegiate Nursing Education and NLN Accrediting Commission provided clear-cut clinical performance competencies for nurses that work in all settings and across all life spans (IOM, 2010).

In 2015, IOM released a new report on the progress of nursing. As in 2010, the IOM recommended nursing residency programs and called for these programs to be developed and funded. The nurse residency program requires nurse educators to prepare nurses with the appropriate competencies and for defined competencies to be in place before the nurse enters residency. The defined competencies would be used to track and evaluate the quality, effectiveness, and impact of the program (Altman, Stith Butler, & Shern, 2015).

The next step after defining competencies was how to assess the effectiveness. Clinical competency assessment (CCA) involves several steps and should include several assessment tools:

- What: Is the ability of a nurse to perform the prescribed task based on clinical skill, knowledge, education, and experience?
- How: Ongoing assessments. Organizations are expected to assess, monitor, maintain, and improve nurses' competencies throughout their career. Competency assessments include peer evaluation, direct observation of practice, and simulation.
- Where: An ongoing process in education and training in all clinical settings where nurses are employed.
- Who: Nurse managers are to maintain the records of nurses' competencies. Assessments can be performed by CNSs, advanced practiced nurses, nurse educators and managers, and preceptors who demonstrate proficiency in the clinical task being assessed (Schub & Heering, 2016).

It was then asked how ongoing nurse competencies are documented and proven on an ongoing basis. Nurse managers are to keep a portfolio for each nurse in the unit. Within these portfolios are the required skills checklist, documentation of cultural competency education, and a list of ongoing CE.

Every state has a professional license board that regulates and provides licensing for nurses. Yet, state boards of nursing have different requirements for nurses to prove their CE. CE is considered one way to demonstrate competencies. Of all 50 states, including Washington, DC, 13 do not have a CE requirement and the remaining 37 require from 5 to 45 Continuing Education Unit (CEU) per renewal period (Lippincott Nursing Center, n.d.).

Continuing education not only fulfills certain state requirements it provides an opportunity for nurses to improve competencies related to practice. Peer reviewed evidence based CE can fill in the knowledge gaps related to competencies (Martin, 2019). When nursing knowledge gaps in the form of CE's are addressed patient outcomes improve (Nassari, 2018). When an organization provides the time and CE's nursing satisfaction improves (Perry, Richter and Beauvais (2018). Nursing satisfaction in their job performance and autonomy resulted in increased competence (Perry, Richter and Beauvais, 2018). CE's play an integral role in helping nurses attain and maintain nursing competencies.

COMPETENCE AND COMPETENCY

What is competence? What is competency? Is there a distinction between the two? Is competence measurable? Benner (1982) defined

nursing competency as the ability to perform a task with desirable outcomes under the varied circumstances of the real world. In her work *From Novice to Expert* (1984), Benner positioned competence at the midpoint of a continuum ranging from novice to advanced beginner, to competent, to proficient, and finally to expert. According to Benner (1984), competent practitioners are consciously able to plan their actions but lack speed. It is interesting to note that the stage of being a "competent" practitioner is not the final one. Two stages (proficient and expert) come after the development of competence. The National Council of State Boards of Nursing (NCSBN, 2012, p. 1) stated that "competence" means the ability of the nurse to integrate knowledge, skills, judgment, and personal attributes to practice safely and ethically in a designated role and setting in accordance with the scope of nursing practice.

In its "Position Statement on Professional Role Competence," the ANA (2008) maintains that "an individual who demonstrates 'competence' is performing successfully at an expected level" (p. 3). The ANA further states that "competency is an expected level of performance that integrates knowledge, skills, abilities, and judgment" (p. 3). In 2014, the ANA reaffirmed the previous definition of professional role competency (ANA, 2014). The International Council of Nurses (ICN) describes competence this way: "The practice and competence of an individual nurse within the legal scope of practice is influenced by a variety of factors including education, experience, expertise and interests as well as the context of practice" (International Council of Nurses [ICN], 2013, p. 2).

The terms are interconnected but are not necessarily interchangeable. Levine and Johnson (2012) stated there is no universal definition of competence or a consistent method across domains to measure competence. Each certification body and nursing organization defines its individual competencies. Competency measurement generally consists of a nurse exhibiting an ability to perform a task or how to perform in a defined setting. Typical measurement of competency consists of a skills checklist and the nurse's ability to move well through a simulation at a skills station. Not only is it difficult to document competency, the nursing profession is struggling with how to demonstrate ongoing nursing competencies. Yearly skills laboratories and review of the initial skills checklist to assess for improvement is a poor way to validate a nurse's nursing competency. Levine and Johnson (2012) suggested that competency assessment should take place in four domains:

1. What a nurse "knows" measured by demonstration of known knowledge (example: tests)
2. The nurse's "know-how" based on exhibited competencies (example: skills checklist or in skills laboratory)
3. The nurse "shows how" by demonstrating competency in performance (example: simulation)
4. What the nurse "does" based on action (example: direct observation of practice or scenario simulation)

Based on demonstration of competencies in the four realms, the nurse and organization have a viable way to document present and ongoing competencies.

The terminology moves from demonstrating competence to demonstration of competency-based practice or it is sometimes called competency-based learning. Defining competency-based learning is difficult due to the differing terminology utilized by different educational institutions. Some of the most common synonyms are proficiency-based, mastery-based, outcome-based, performance-based, and standard-based education, instruction, or learning (Great School Partnership, 2015).

Bernikova (2017) examined the education shift from learning to practice orientation outcomes. Within the shift the nurse learns to solve clinical problems based on their cognitive, communicative, organizational and moral experiences. By shifting the dynamics from demonstrating competence to practicing competence within the nurse's practice, it is now definable, measurable, and can be evaluated. Competency is also situational and dynamic, and now the context determines the competencies necessary to perform the job (ANA, 2018). With competency-based practice, the nurse is demonstrating the competence at an expected level that integrates knowledge, skills, ability, and judgment. To continue to function within a competency-based practice, the nurse must engage in lifelong learning, continuously reassess his or her competencies, and be able to identify the gaps in knowledge and skills required to function. With identification of the gaps in knowledge, the nurse is expected to seek integrative learning experiences.

The new graduate nurse or the experienced nurse who is changing practice areas cannot reasonably be expected to be competent at the onset of employment in an acute care environment such as the NICU. It is reasonable to expect, however, that both will acquire initial and ongoing competency if provided with appropriate orientation and opportunities for CE. As the professional organization for neonatal nurses and nurse practitioners (NPs), the NANN, and the National Association of Neonatal Nurse Practitioners (NANNP), a division of NANN, hold responsibility for setting the national standard for initial and continued competence for practitioners in the neonatal population focus. To this end, NANNP published a position statement in 2015, "Standard for Maintaining the Competence of Neonatal Nurse Practitioners," which included recommendations for evaluation and documentation of continued competence for neonatal nurse practitioner (NNP) practice:

- Orientation of the novice NNP should provide several assessment points, utilizing multiple evaluative tools and methods, throughout the period of orientation.
- Evaluation of the experienced NNP should be based on the seven NNP domains and core competencies of NNP practice and should be conducted at least annually.
- Continuing review of NNP competencies and observations of procedures may include either a minimum number of actual procedures or procedural review and simulation (NANNP, 2014).
- A professional portfolio should be developed by both novice and experienced NNPs to provide evidence of individual learning and experience.
- State boards of nursing should request that ongoing competencies be part of the annual evaluation process (NANN, 2015).

The American Association of Nurse Practitioners (AANP, 2013) and the IOM (2010) recommend that for nurse practitioners to be competent, they must commit to and demonstrate continuously their commitment to lifelong learning and professional self-development to ensure quality improvement and safe patient care.

COMPETENCY-BASED EDUCATION (CBE)

What is CBE? CBE has been described in deferring terms such as problem-based learning, mastery-based learning, outcome-based learning, and performance-based learning. The ambiguous terminology creates confusion regarding CBE. In the last 10 years, a movement has been created to clearly define CBE. The U.S. Department of Education (2017) stated that, "Competency-based strategies provide flexibility in the way that credit can be earned or awarded, and provide students with personalized learning opportunities" (p. 1). Competency-based programs are different from traditional education programs, which require a student to meet certain set hours in a classroom. Competency-based programs give

credit for prior learning and look at the learning that the student has done outside of the scope of the actual course regardless of where, when, or how the prior learning was attained. CBE is now about feedback from mastered skills and empowers the student to take responsibility for attaining the skills needed. Feedback is quick and frequent and is given in a structured assessment. Now, feedback is an ongoing learning experience rather than an end result. Educational institutions, individual neonatal units, and certification bodies set the competencies needed to prove mastery of a skill and education (EDUCAUSE, 2014).

Not all educational institutions are utilizing CBE to instruct students. The difficulty is defining the measurable learning objectives when a student moves along the educational process at different paces. The typical way of validation learning was the demonstration of passing a class and obtaining a certain amount of credit hours. Many institutions are struggling to redefine CBE models within already existing student learning management. Institutions of learning must agree on core competencies in order for CBE to be a common method of education (EDUCAUSE, 2014). If CBE is to be a valid way of education, higher education institutions must look at the current educational model and develop a workable framework for their institution. With an increasing emphasis on skills acquisitions and transfer of knowledge, students will need to demonstrate CBE through work experience. Now, higher institutions will need to pay close attention to mentors, coaches, and possible tutors who will be helping the students achieve their competencies. Education will need to move from traditional lectures in classrooms to include internships and project-based activities to validate the competencies (EDUCAUSE, 2014). Based on research, students that have graduated from CBE demonstrate a uniform standard of learning (EDUCAUSE, 2014).

In 2011, over 100 educators came together to define what CBE should include. Based on the recommendation of this panel, quality CBE should include the following:

- Advancement for students that demonstrate mastery of a task
- The competencies they master should be explicit, measurable, and demonstrate transfer of learning that demonstrates student success
- The ongoing assessment should be meaningful and a positive experience for students
- The outcomes should highlight competencies that include application, knowledge acquisition, and development of appropriate skills (CompetencyWorks, 2017).

Nursing competencies may be divided into core and population-focused competencies. Core competencies are the skills and knowledge required for the minimum safe level of nursing performance. Population-focused competencies are the skills and knowledge required for the minimum safe level of nursing care for a specific patient population.

Although some competencies are mandated by accreditation agencies such as TJC, most nursing competencies are derived from standards of practice developed by professional nursing organizations. The National CNS Competency Task Force (2010) has developed and validated core competencies for CNS that are comprehensive, entry-level competencies expected for newly graduated CNS. CNS core competencies include Direct Care, Consultation, Systems Leadership, Collaboration, Coaching, Research, Ethical Decision Making, Moral Agency, and Advocacy. These competencies reflect CNS practice across all specialties, populations, and settings (National CNS Competency Task Force, 2010).

The National Organization of Nurse Practitioner Faculties (NONPF) has developed both core and population-focused nursing competencies for NPs. The most recent version of the "Nurse Practitioner Core Competencies" was published by NONPF in 2017. The competencies have been revised several times and now include the recommendation for educational needs of Doctor of Nursing Practice and NP practice (NONPF, 2017); to build upon previous work that identified knowledge and skills essential to DNP competencies (American Association of Colleges of Nursing [AACN], 2006); and to maintain consistency with the recommendations of the IOM report on "The Future of Nursing" (IOM, 2010). The core competencies include Scientific Foundation, Leadership, Quality, Practice Inquiry, Technology and Information Literacy, Policy, Health Delivery System, Ethics, and Independent Practice (NONPF, 2017). The nine core competencies are expected outcomes for an NP graduate, regardless of population focus, and are "acquired through mentored patient care experiences with emphasis on independent and interprofessional practice; analytic skills for evaluating and providing evidence-based, patient-centered care across settings; and advanced knowledge of the health care delivery system" (NONPF, 2017).

The core competencies can be adapted to fit specific population foci within nursing. NONPF recently established the 2013 Population-Focused Competencies Task Force to adapt the core competencies to each NP population focus that is recognized by the "Consensus Model for APRN Regulation: Licensure, Accreditation, Certification and Education" (APRN Consensus Work Group & the National Council of State Boards of Nursing APRN Advisory Committee, 2008). These NP population foci include Family, Adult-Gerontology, Neonatal, Pediatrics, Women's Health, and Psychiatric Mental Health. The adult-gerontology and primary care NP practices have further competency distinctions (NONPF, 2016). Organizations that are specific to each population focus, such as NANN and NANNP, have a multifaceted role in the development of their own specialized nursing competencies. Such organizations are responsible for developing specific educational standards and clinical guidelines on which professional nursing practice is based. Accordingly, NANN published the "Education Standards and Curriculum Guidelines for Neonatal Nurse Practitioner Programs" in 2014. The Education Standards and Curriculum Guidelines provide a framework on which new NNP programs may be developed and evaluated, as well as a self-study tool for existing NNP programs. Professional nursing organizations are also responsible for monitoring issues that affect the practice of nursing, such as the development of an appropriate healthcare policy, and for supporting research to link nursing interventions to patient outcomes. Finally, they support individual competence by providing educational opportunities for nurses to maintain their skills and knowledge, by influencing changes in state nurse practice acts, and by participating in the credentialing process as appropriate (Matthews, 2012).

Since 2010 and the IOM report about 2020 educational competencies, any organization that certifies advanced practice nurses should have developed educational competencies. The NLN has developed an educational model that encompasses seven core values: caring, diversity, ethics, excellence, holism, integrity, and patient centeredness. The model speaks to competencies from a practical nurse to a doctoral prepared nurse. In 2016, the Commission of Nursing Education Accreditation (CNEA) adopted the NLN educational model to set the standards for nursing education (NLN, 2016). Now the NLN Commission for CNEA collaborate through an accreditation process to promote quality and reliability in nursing education worldwide (NLN, 2016). The accreditation process used the NLN core values of caring, diversity, integrity, and excellence (NLN, 2016). Based on the core values, a set of standards of evaluation has been developed. The standards of evaluation are to be utilized by the faculty and staff that educate

nurses with frequent outcomes evaluation, plans for improvement, and plans of dissemination. Now individual programs have a working core value and standard of evaluation for the individual training programs.

In individual programs and hospital orientation, the core competencies are modeled after the IOM and RWJF. The Quality and Safety Education for Nurses (QSEN) developed core competencies: evidence-based practice, informatics, patient-centered care, quality improvement and safety, teamwork, and collaboration. Burke, Johnson, Sites, and Barnsteiner (2017) performed research on the eight competencies and demonstrated that all eight competencies could be used to assess a nurse's abilities as shown in Table 44.1.

Most professional organizations and national certifying bodies for NPs require a minimum number of hours spent in didactic education, clinical education, or both. Validation of competency versus completion of a defined minimum number of required hours for certification within a population focus continues to be a topic of conversation and controversy among nursing leaders.

Ensuring the competency of new nursing staff requires an organized approach to orientation of the unit and a system of verification and validation of knowledge and skills. Competency-based orientation (CBO) is one form of CBE and is the preferred model for orientation in many institutions because it allows for the variation in nurses' backgrounds. CBO requires a new nurse to continually assess his or her learned knowledge and skills, identifies the need for additional comprehension and expertise, and ultimately cultivates a culture of lifelong learning (ANA, 2018). Ideally, this type of orientation would be an extension of a generic, competency-based curriculum followed by the academic institutions, adapted to fit the clinical or practice setting. CBOs are advantageous for the new hire and the preceptors. The defined competencies give a clear guideline of expectations. The preceptors now can identify more quickly those new hires that are not going to meet the required competencies to work within the unit. The preceptor can guide the next step within the orientation by utilizing the competency verification form and help the orientee address deficit or problematic areas (Swilhart, 2010).

CBO has many advantages. One major advantage is the shortened orientation for experienced nurses (Franquis & Seckman, 2016). In the current economic environment, this can result in significant savings for the unit and the institution. Other advantages include (1) advances in clinical competencies, (2) more confidence, (3) improved work satisfaction, (4) reduction in error rates, and (5) decrease in patient safety events (Franquis & Seckman, 2016). In CBO and nursing residency, the nurse is the driver of his or her orientations with the preceptors serving as expert role models and facilitating the learning of the orientee.

Now that defined nursing education and clinical practice competencies have been developed, what remains to be seen is how the competencies will improve patient safety and quality of care.

IMPLICATIONS FOR NEONATAL NURSING

Because neonatal nursing is a population-focused area of practice, most graduate nurses complete their basic nursing education with little or no clinical experience in the NICU. This places the burden of developing practice competence on the unit and the hospital. As a result of the projected nursing shortage, many NICUs will be employing new graduate nurses at a time when the supply of

TABLE 44.1

EIGHT CORE COMPETENCIES FOR NURSES

Competency Domain	Definition
Continuous quality improvement	Utilizes data and quality improvement methods to identify potential and actual problems and opportunities to provide care that is safe, timely, efficient, effective, and equitable
Evidence-based practice and research	Evaluates and integrates the best current evidence with clinical expertise and patient and family preferences and values for delivery of optimal healthcare and systems effectiveness
Leadership	Effectively collaborates and applies innovative systems thinking to engage in systematic evidence-based problem-solving and decision making to promote effective changes within a complex care delivery system, supporting the vision of the organization
Patient- and family-centered care	Recognizes the patient or the patient's designated person as the source of control and full partner in providing compassionate and coordinated care based on respect for the patients, preferences, values, and needs
Professionalism	Demonstrates a commitment to the nursing profession through lifelong learning adherence to the ANA's Code of Ethics for Nurses, participation in a professional organization, and advancement of community outreach
Safety	Minimizes the risk of harm to patients, families, providers, and self through system effectiveness and individual performance
Teamwork	Effectively engages in the process of cooperation, coordination, and collaboration in an effort to provide safer, high-quality outcomes for patients within inter- and intraprofessional teams, including virtual teams
Technology and informatics	Utilizes appropriate information and technology to communicate, manage knowledge, mitigate error, and support decision making across the continuum

seasoned neonatal nurses is dwindling. The traditional orientation approach of classroom learning followed by a period of joint clinical practice with an assigned preceptor may not be possible. As the competition for new graduate nurses intensifies, many hospitals are developing internship or externship programs.

Internships and externships for the new graduate nurse are a viable option for NICUs. Most newly graduated nurses recognize the paucity of their knowledge and skills for intensive care units and want some type of formalized educational program to become staff nurses in these areas. Depending on the availability of staff development instructors and experienced nurses willing to assume preceptor responsibilities, many internship and externship programs offer a mix of traditional classroom teaching and CBE. To maximize resources, hospitals often combine nurse interns and externs for the classroom work. For example, a large tertiary hospital may offer a maternal–child nursing option, whereas a children's hospital may offer a critical care option. In the former case, the interns and externs may take classes together on maternity and pediatric nursing. In the latter case, the interns may be in class for the critical care core content.

CBE is also well suited to orientation for new graduate nurses and for experienced nurses who are changing their focus area. For the seasoned staff nurse who switches from adult intensive care, the orientation can focus on the neonatal-specific aspects of critical care. The orientation program for this nurse can be individualized to allow credit for knowledge and skills previously learned. An experienced staff nurse who switches from the well-baby nursery to the NICU will need focused education on the critical care aspects of newborns, because he or she already has a knowledge base about concerns common to well and critically ill newborns, such as thermoregulation and hypoglycemia.

Orientation of new graduates to the role of the NNP presents its own set of challenges. As the baccalaureate to DNP educational pathway becomes more common, there will be an increasing number of newly graduated NNPs with very little NICU experience. Even experienced NNPs are responsible for maintaining validation of required competencies. In 2014, the National Association of Neonatal Nurse Practitioners [NANNP] redefined the *Competencies and Orientation Toolkit for Neonatal Nurse Practitioners*. In the second edition, they added identified core competencies and roles, standardized method of validation and measurement of competencies, incorporated neonatal competencies developed by the NONPF, and an updated skills checklist.

The goal of this second edition toolkit is to establish clarity and consistent expectations concerning competencies for NNPs at varying levels, from novice to expert, and to provide a method of evaluating their competence. Ultimately, the intention is to assure the public that the NNP possesses the knowledge, skill, and clinical judgment required for providing safe, effective care (NANNP, 2014). The basic skills needed for NNPs include intubation, umbilical line placement, and chest tube placement. In addition to basic skills needed for NNPs, they may be responsible for performing lumbar punctures, bladder taps, arterial line placement, PICC line placement, intraosseous line placement, circumcision, and participate in an exchange transfusion (NANNP, 2014).

COMPETENCY VALIDATION

With the public and healthcare organizations requiring that a nurse perform safely with the appropriate competency, there has been a greater emphasis on validation of those competencies. Validation of competencies has been redefined and is specific in nature. To validate a nurse's competency, the organization must now demonstrate that the nurse has the knowledge consistent with the science and preparation needed for the specific competency. Not only does knowledge need to be documented, but there must also be documentation that the nurse accurately and consistently performs competently in practice. Tools of validity documentation have undergone vigorous validity and reliability testing. The individual that evaluates a nurse's competency must be specially trained in evaluation and be consistent from nurse to nurse. Documentation of competencies now depends on a well-trained evaluator. No longer is a nurse able to just say that he or she is competent in knowledge and skills. All competencies are now documented on a valid reliable scale and observed by a trained evaluator (Dickerson & Chappell, 2016).

The frequency of validation may vary according to the specific skill. The interval for validation of such skills as neonatal resuscitation is determined by the national standard, as set by the Neonatal Resuscitation Program (Wyckoff et al., 2015). Other skills are usually validated annually or as required by accreditation criteria set forth by TJC. Although there is little written regarding the number of procedures required for an NNP to obtain and maintain competence, the types and number of procedures done by an NNP depend on the practice site and patient population. While variations among practice sites may make achieving and maintaining skill competency a challenge, it is vitally important that NNPs maintain competence in certain procedures. NANNP (2014) recommends the following guidelines for maintaining procedural competence: basic procedural and clinical reasoning skills for neonatal resuscitation, including endotracheal intubation, umbilical catheter placement, and needle thoracotomy, must be mandatory for all NNPs; maintenance of a procedural skills log documenting procedures performed, including success rates and complications, should be reviewed as part of an NNP's annual evaluation; and education and evaluation of competence for any procedure should be standardized to include use of universal precautions, use of the time-out, review and discussion of informed consent issues, procedural review, and assessment and management of the infant's comfort and pain. Minimal competence should be defined as performing a preset number of procedures defined by the employing hospital and accrediating body.

Competency validation can be achieved through a variety of mechanisms, including chart or record review, simulation, 360-degree evaluation, portfolio, procedure or case logs, or patient survey (NANNP, 2014). For many skills, a combination of methods is used. For example, the validation of neonatal resuscitation skills includes objective examinations and simulation performance evaluations. TJC stresses that competency validation should be obtained from past and current employers, peer evaluation, obtaining of specialty certifications, testing of competencies, current performance evaluations, and observed skills by a trained competency tester (TJC, 2016).

CONTINUING COMPETENCE

According to the ANA (2014), assurance of continued competence is the shared responsibility of the profession, individual nurses, professional organizations, credentialing and certification entities, regulatory agencies, employers, and other key stakeholders. Maintaining individual competence is the professional obligation of every neonatal nurse. This obligation is spelled out clearly and reaffirmed by the ANA in its position statement on *Professional Role Competence* (ANA, 2014): "The public has a right to expect registered nurses to demonstrate professional competence throughout their careers. ANA believes the registered nurse is individually responsible and accountable for maintaining professional competence" (p. 1).

Certification is a process that functions on a continuum throughout a nurse's career that is supported by *lifelong* learning

and ongoing professional development. Voluntary certification is an excellent mechanism for staff nurses, CNS, and NPs to document their ongoing competence in neonatal nursing. In addition to measuring knowledge that is unique to a specific population, national certification examinations require documentation of ongoing education to maintain the certified nurse's expertise. Examinations for neonatal critical care nurses and specialists are available through the American Association of Critical-Care Nurses (AACN) Certification Corporation (AACN, 2017). The National Certification Corporation (NCC) offers several examinations for neonatal nurses. These include examinations for both neonatal intensive care nursing and low-risk neonatal nursing care. Subspecialty areas, such as electronic fetal monitoring and neonatal pediatric transport, are also available to certified nurses (NCC, 2019). In recognition of the expanding knowledge base needed to function in an increasingly complex healthcare environment, the NCC replaced their Certification Maintenance Program with Continuing Competency Initiative (NCC, 2019). The focus of the new program is to determine that each certified nurse has maintained knowledge of the core competencies related to the certification specialty role. A specialty assessment evaluation is being utilized to identify targeted individual-specific CE needs to address knowledge gaps and provide a learning plan that the certified nurse can follow to meet certification maintenance requirements (NCC, 2019). NCC notes that this approach "brings greater accountability and transparency to the certification maintenance process while providing employers and the public a valid measure of assurance regarding the ongoing competency of nurses certified by NCC" (NCC, 2019).

INTERNATIONAL NEONATAL NURSING COMPETENCIES

After the accomplishments of the Millennium Development Goals (MDG) in 2015, the World Health Organization (WHO) moved to Sustainable Development Goals (SDG) to ensure continued improvement in the care of the world population. Specific to neonatal care is the SDG 3.2, which states every country should work to decrease the neonatal mortality rate to 12 deaths per 1,000 live births (WHO, n.d.-b). The neonatal period is the most vulnerable time for a child's survival. In 2016, it was estimated that 7,000 newborns died each day (WHO, n.d.-a). If the current trends continue, over 60 countries will miss the SDG 3.2 goal, and these countries will carry 80% of the burden of neonatal deaths (WHO, n.d.-a). Several strategies have been employed to ensure that these countries achieve SDG 3.2 or decrease their neonatal mortality rate. One of the strategies is to look at neonatal nursing and the accompanying competencies. Neonatal nursing education is currently being added to university-level courses in many countries with the highest burden rate. Training in resuscitation is mandated by many countries. There has been a call to look at and develop neonatal nursing competencies in the high-burdened countries.

In 2017, the Council of International Neonatal Nurses performed a survey with 5,000 members. Six key questions were asked: (1) Does your country have any officially accepted and applied neonatal nursing competencies? (2) Who is responsible for writing and publishing neonatal nursing competencies in your country? (3) Do you think neonatal nursing competencies are needed in your country? (4) Would you like to help develop neonatal nursing competencies for your country? (5) How many years have you worked in a neonatal unit? (6) Which continent do you live in? The results of this study are illustrated in Figures 44.1 to 44.6. Although the percentage of the answers came from North America and Africa, it is obvious there was a great deal of interest in creating neonatal competencies for their counties and a willingness to volunteer to work on the document. The call to decrease neonatal mortality is compelling, and neonatal nurses can be at the forefront of this movement. Developing neonatal competencies and the ongoing validation process will be needed.

SUMMARY

Ensuring the competency of neonatal nurses and advanced practice nurses is a major concern of hospitals, regulators, insurance companies, and the public. Changes in the healthcare industry as a result of managed care, mergers of provider institutions such as hospitals, and significant reorganization within the delivery system have placed new demands on the nursing profession to ensure the ongoing competence of its members. Individually and collectively, nurses are challenged by the need to keep current in the midst of a knowledge and technology explosion, by the demand from payers for greater productivity and efficiency in healthcare, and by consumers' growing sophistication regarding the consequences brought about by incompetent providers. Standards of nursing practice and accreditation criteria from professional nursing organizations and agencies such as TJC are used to develop nursing competencies.

CBE provides a mechanism for contemporary nursing to provide a cost-effective, quality approach to nursing education. The competency-based approach is also well suited to individualizing orientation programs to meet the unique needs of nurses who have significantly different backgrounds and levels of experience. CBE shifts the focus of learning from the traditional model of objectives and classroom teaching to a new model based on achievement of specified competencies and outcomes.

Validation of competence is essential to ensure that the nurse continues to maintain the level of expertise necessary to provide safe, effective, quality care. A variety of methods and evaluative tools are currently used to validate nursing knowledge, and skills may include direct observation, patient records, portfolio, demonstrations, skills laboratories, certification, credentialing, simulation exercises, virtual reality testing, targeted CE with outcomes measurement, employer skills validation, and practice evaluation. While there is a variety of methods available, no single tool or method can guarantee competence.

Assurance of continued competence is the shared responsibility of the profession, professional organizations, credentialing and certification entities, regulatory agencies, employers, and other key stakeholders. Ultimately, however, maintaining competence is the professional obligation of each individual nurse. Continued competence is an ongoing process throughout

a nurse's career that must be supported by lifelong learning and ongoing professional development. Each nurse is individually responsible and accountable for maintaining professional competence.

Internationally, nurses who work in neonatal units are interested in developing neonatal competencies and validation. Perhaps the pool of neonatal nurses could be utilized to develop an international competency statement that could be utilized to help hospitals, educational institutions, and political stakeholders develop competencies specific for their countries and institutions. The development of neonatal competencies can pave the way for high-burden countries to achieve SDG 3.2.

EVIDENCE-BASED PRACTICE BOX

Nursing is a complex combination of theory and practice that must be successfully integrated by nursing students in order for them to attain competence. Competence assessment methods must therefore be capable of measuring both knowledge and skills. The portfolio has been identified as a valuable means of assessment, enabling students to demonstrate achievement of competencies by presenting evidence from a variety of sources that display their experience, strengths, abilities, and skills. Hwang, Kuo, and Tu (2017) validated a health education competency tool for nursing students and practicing nurses. The tool consisted of 33 questions in four domains: planning (8 items), pedagogy (15 items), empowerment (6 items), and motivating discourse (4 items). Planning questions consisted of assessment, design, and evaluation. Pedagogy included didactic skills, evidence-based knowledge, and organized teaching content. Motivating discourses included dissonance, appreciate belief system, roll with resistance, grasp client perspective, affirm client efforts, and collaborate to evocate plan. Empowering consisted of support of autonomy and establishing relationship. The tool demonstrated high reliability and validity.

Unit VIII: Neonatal Diagnostic and Care Protocols

I

Diagnostic Processes

Samual Mooneyham

INTRODUCTION

Care of the neonate typically involves numerous diagnostic procedures and tests to identify dysfunction related to birth, prematurity, illness, or congenital malformations. This chapter highlights the commonly used methods for developing a medical or surgical diagnosis in the newborn and infant. The nursing implications for appropriate assessment of preprocedural and postprocedural care are also discussed.

Diagnostic imaging has assumed an increasingly important role in neonatal diagnosis and the assessment, evaluation, and follow-up of neonatal care. Technological advances since the 1970s have resulted in a variety of imaging modalities that demonstrate not only the internal structure but also the function of organ systems in the fetus and neonate. The spectrum of diagnostic imaging methods includes radionuclide imaging, ultrasonography, and MRI, as well as conventional roentgenologic techniques. With such an array of imaging modalities available, complex, problem-oriented decision making is required to determine which techniques should be used and which ones omitted in a particular clinical situation. In addition, diagnostic imaging examinations are expensive, with ultrasonography being the least expensive and MRI the most expensive. As the public, the government, private insurers, and the healthcare system have become increasingly cost conscious, healthcare providers have faced growing pressure to make efficacious and cost-effective decisions about the use of imaging examinations.

The selection of a particular imaging examination should be based on the risk versus benefit analysis, including consideration whether or not a particular test will result in a diagnosis. To minimize risk, consideration must be given to the size, age, and condition of the neonate.

The roles of the nurse, neonatologist, nurse practitioner, and radiologist are critically interrelated in diagnostic imaging. It is essential that the history, clinical presentation, physical examination, and laboratory data be understood so that the imaging modalities selected are the ones properly indicated for the diagnostic evaluation and subsequent therapy of the individual newborn.

Nurses should be aware of the rationale for the selection and sequencing of these diagnostic evaluations, the indications for various imaging modalities, the need for patient preparation, and the biophysical principles involved in producing the image. The nurse ensures that the correct newborn undergoes the procedure, monitors the newborn during and after the procedure, and minimizes changes in the thermal environment. The nurse may also be responsible for preparing information about the infant that is essential to the interpretation of imaging examinations. Pertinent maternal history, intrapartal complications, and gestational age must be considered. The relationship the nurse establishes with the family often provides an opportunity to inform the parents of the benefits and risks of the procedure and allows the parents to express their questions and concerns. Armed with a thorough understanding of these concepts, the nurse is able to coordinate the acquisition of diagnostic information with minimal disruption to patient care. A knowledge of patient preparation, proper positioning, and the potential risks of each procedure forms the basis of the care plans and parent teaching. These plans of care and acknowledgment of risks facilitate the development of unit policies and procedures.

DIAGNOSTIC IMAGING IN INFANTS

Diagnostic imaging in newborns and infants is unique, differing in several ways from the procedures used for older children and adults. Infants and newborns are not just small adults for whom smaller films and less exposure are all that is required. The exposure, radiation protection, and the types of diseases are different.

Conditions Requiring Diagnostic Imaging

Pathologic conditions commonly encountered in adults are often not found in infants, and many abnormal conditions are exclusive to the newborn period. Examples of these pathologic conditions are the congenital abnormalities of the newborn, genetic conditions, intrauterine growth restriction, tumors, and infections such as cytomegalovirus, toxoplasmosis, and syphilis, which can potentially be detected by diagnostic imaging (Martin, Fanaroff, & Walsh, 2015).

Anatomic Proportions

The anatomic proportions of infants are very different from those of adults, and the younger the infant, the more marked the differences. A thorough knowledge of these proportions is essential for correct patient positioning to limit field exposure and for accurate interpretation of diagnostic imaging (Dowd & Tilson, 1999; Hilton & Edwards, 2006). It is important that not only the specific area in question, but the whole of the area in question, appear in the imaging field.

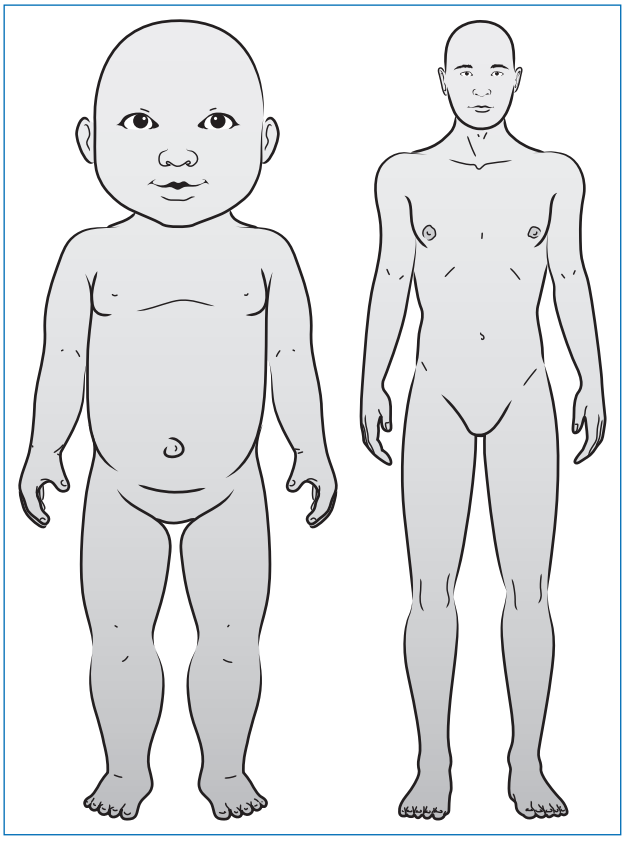

FIGURE I.1 Proportional anatomic differences between a neonate and an adult.

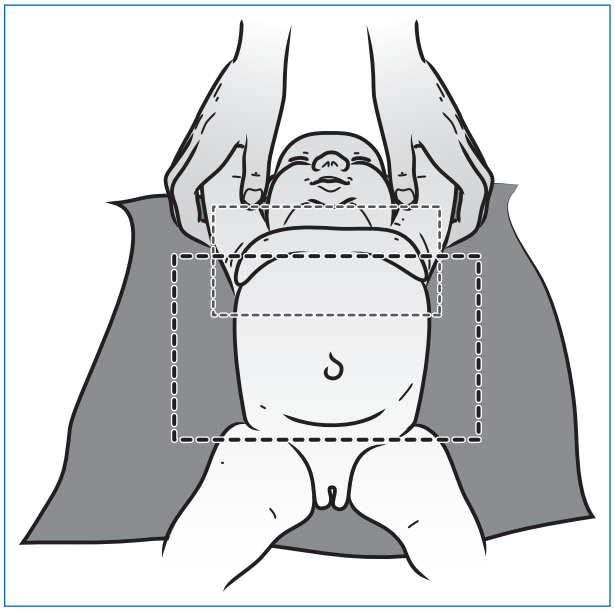

FIGURE I.2 **Neonatal radiographs should be limited to only the area of interest.** Total body radiographs should be avoided. The top box (*light dashed lines*) defines the area of interest for an anteroposterior chest radiograph. The bottom box (*heavy dashed lines*) defines the area of interest for an anteroposterior abdominal film. The gonad shield has been omitted for illustrative purposes.

As shown in Figure I.1, the newborn's head is large in proportion to the body, and the cranial vault is large in proportion to the area of the face. The neck is short, and the diaphragm is high. The kidneys are low, about midway between the diaphragm and symphysis pubis. The abdomen is large because of the relative size of the liver and stomach. The pelvic cavity is very small, and the bladder extends above the symphysis pubis. The chest, pelvis, and limbs are small in proportion to the abdomen (Hilton & Edwards, 2006; Swischuk, 1995, 2003).

In an anteroposterior (AP) projection, the neonate's lungs appear wider than they are long and much higher up in the thoracic cavity than is normally expected (Hilton & Edwards, 2006; Swischuk, 1995, 2003). The diaphragm is located just below the level of the nipples. On a lateral projection, the posterior aspect of the lungs may extend to twice the depth of the anterior part (Swischuk, 1995, 2003).

The newborn's abdomen bulges laterally wider than the pelvis, and the bulge contains abdominal organs displaced by the large liver and stomach. Care must be taken to include this area of the abdomen in the imaging field (Hilton & Edwards, 2006; Swischuk, 1995, 1997). Irradiation should encompass the smallest possible body area consistent with production of the necessary information (Dowd & Tilson, 1999). Often the field is too large, particularly in premature infants and newborns. Arms and legs should not appear on the abdominal film, nor should half the skull and abdomen appear on a chest film (Figure I.2; Hilton & Edwards, 2006; Martin et al., 2015; Swischuk, 1995, 2003).

TYPES OF DIAGNOSTIC IMAGING

Diagnostic imaging methods differ from biochemical and histologic methods in that they detect images a few millimeters in size, while biochemical and histologic methods detect changes at a molecular or cellular level.

The four major diagnostic imaging methods are x-ray (roentgenologic) imaging, radionuclide imaging, ultrasonographic imaging, and MRI (Bushong, 1999, 2000, 2003, 2013; Juhl, Crummy, & Kuhlman, 1998; Treves, 1995). This chapter discusses each of these imaging modalities in relation to the biophysical principles responsible for producing the image, the potential risks of the procedure, and the nursing care of the newborn or infant undergoing such an examination. Table I.1 summarizes the types of diagnostic imaging commonly used for neonates.

X-Ray Imaging (Roentgenology)

The principles of conventional radiography have not changed since the discovery of x-rays in the late 1800s. However, the equipment and techniques have become far more sophisticated; current radiographic methods include tomography, fluoroscopy, CT, and digital radiography.

Roentgenologic Biophysical Principles

X-rays are a form of electromagnetic energy that travel at the speed of light (about 300,000 km [186,000 miles]/second). Other forms of electromagnetic energy include gamma rays, radio waves, microwaves, and visible light. Only x-rays and gamma rays have enough energy to produce an ion pair by separating an orbital electron from its parent atom (Alpen, 1998; Bushong, 1999, 2000, 2003, 2013; Juhl et al., 1998). The amount of radiation present is measured by the detection of such ionization. Radiation exposure is measured either in units of coulombs per kilogram (C/kg) or in roentgens (1 R/258 C/kg). Although the roentgen is no longer an official scientific unit, it is still widely used in radiology. The rad is the unit of measure for the amount of radiation absorbed by the body (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998).

TABLE I.1

DIAGNOSTIC IMAGING METHODS COMMONLY USED FOR NEONATES

Technique	Indications and Advantages	Limitations	Potential Risks	Comments	Cost
Roentgenologic Techniques					
Radiographic imaging	Most frequently used initial diagnostic screening mode	Detects only four different levels of photon absorption (air, fat, water, and mineral); two-dimensional projection of 3D structures	Ionizing radiation; thermal stress of cool film plate	Proper positioning of infant is essential; child must be monitored during procedure	$
Xeroradiographic imaging	Used to evaluate soft tissue structures	Tissue structures defined by relative amounts of air, fat, water, and minerals; seldom used since advent of newer diagnostic imaging methods	Higher level of ionizing radiation than with routine radiographs	Proper positioning of infant is essential; child must be monitored during procedure	$$
Fluoroscopic imaging	Used to evaluate motion or function of cardiovascular, gastrointestinal, and genitourinary systems; may be used to guide therapeutic or diagnostic procedures	Images rely on greater radiation and/or movement of contrast material; improper diagnostic sequencing may delay informational yield; contrast material may have physiologic consequences	Much higher level of ionizing radiation than with routine radiographs; thermal stress of cool radiology environment	Proper positioning of infant is essential; child must be monitored during procedure	$$–$$$$
CT	Used to provide detailed, superior characterization of various soft tissue densities that cannot be detected by conventional radiographs	Motion artifact may cause blurring of scans; radiation dose depends on scan time; contrast material may have physiologic consequences	Ionizing radiation; thermal stress of cool environment	Proper positioning of infant is essential; child must be monitored during procedure	$$$
Ultrasound imaging	Does not use ionizing radiation, but rather uses sound waves to depict anatomic and functional motion of tissue; sound waves can be directed in a beam in a variety of planes; portable; different graphic displays are available	Ultrasound technique is operator dependent; does not provide as much information on organ functions such as urography; reveals less anatomic detail than CT; scan is adversely affected by the presence of bone and air	Thermal stress may occur with application of cool scanning gel to infant's skin; there are no known deleterious effects from clinical use of ultrasound imaging	Proper positioning of infant is essential; child must be monitored during procedure	$

(*continued*)

TABLE I.1

DIAGNOSTIC IMAGING METHODS COMMONLY USED FOR NEONATES (*continued*)

Technique	Indications and Advantages	Limitations	Potential Risks	Comments	Cost
Radionucleotide imaging	Used to trace anatomic proportions and a wide range of physiologic functions in virtually every organ in the body; amount of ionizing radiation emitted by injected agent is significantly less than the amount required for corresponding radiograph	Diagnostic yield depends on uptake of radionucleotide by different organs; radionucleotides are rarely organ specific; limited anatomic resolution	Thermal stress during nucleotide scanning	Proper positioning of the infant is essential; maximum radiation exposure is not always the organ of interest; child must be monitored during procedure	$$
PET and SPECT	Both techniques have greater sensitivity and qualifications of the distribution and density of radioactivity to depict the "metabolic" function of tissue; 3D imaging is possible with computer reconstruction; dose of nucleotide is the same; artifactual lesions can be eliminated; amount of ionizing radiation emitted by injected agents (carbon 11, oxygen 15, nitrogen 13) is significantly less than the amount required for corresponding radiograph	PET scanning requires access to a cyclotron to produce the positrons used in scans	Thermal stress during nucleotide scanning	Proper positioning of infant is essential; child must be monitored during procedure	$$$$$$
MRI	Uses magnetic fields and radio waves to produce images; the region of the body scanned can be controlled electronically, and hardware does not limit scanning sites; scans are free of high-intensity artifacts; newer scanning techniques can quantify many pathologic conditions	Availability and cost; limited use in unstable infants on life support; monitoring equipment must be free from interference with magnetic field	Does not use ionizing radiation to produce images; limited access to infant during procedure	Proper positioning is essential; must be monitored during procedure	$$$$$$

3D, three-dimensional.

When an x-ray beam is directed toward a part of the body, differential absorption of the x-ray photons by different types of body tissue occurs. A beam of x-ray photons is variously attenuated as it passes through the body tissues, producing a shadow image that is recorded on photographic film; the absorbed x-ray photons interact with the tissue, causing ionization in the body (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998). Bone and metal fragments absorb x-ray photons and therefore appear white on the radiographic film, whereas air-containing structures, such as lungs and gas-filled bowel, absorb few x-ray photons and appear black. Soft tissues and blood vessels appear as intermediate shades of gray.

A radiograph gives a two-dimensional projection of three-dimensional structures. An x-ray tube is positioned to direct the x-ray beam through the part of the neonate to be examined so as to record different views or projections on the film. This simple imaging technique can distinguish only among air, fat, and tissues with densities approximately equal to those of water or metals, but it continues to be enormously valuable and is still the diagnostic imaging method most often used in neonatal care.

X-ray photons are generated in the tungsten anode of the tube when it is bombarded by a stream of high-energy electrons emitted from the cathode (Figure I.3; Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998). The energy, or penetrating power, of the resulting x-ray photons is a function of the electron energy, which is controlled by the voltage gradient across the cathode–anode gap. In diagnostic radiology, this gradient usually is 60 to 120 kV (Bushong, 2013; Dowd & Tilson, 1999; Hilton & Edwards, 2006; Juhl et al., 1998). Low kilovoltage x-rays have poor penetrating ability, whereas higher kilovoltage x-rays have deeper penetrating ability. The kilovoltage across the cathode–anode gap, therefore, controls the penetration of the x-ray beam.

The milliamperage (mA) indicates the amount of current applied to the cathode filament (Alpen, 1998; Bushong, 2013). The greater the current, the more electrons are produced for transmission across the cathode–anode gap, and the greater the number of x-ray photons generated by the anode in a finite time. The product of the exposure time and the milliamperage given to the cathode filament controls the amount, or dose, of x-rays and is expressed in milliampere-seconds (mAs; Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998).

Early radiographs required an exposure time of as long as 30 minutes to produce a satisfactory image (Bushong, 2013; Juhl et al., 1998). It is not surprising, then, to find reports of radiation injury in the early days of radiology. Reports of superficial skin and tissue damage, hair loss, and anemia were common among patients and their physicians because of the prolonged exposure times and the low-energy radiation that was available. The development of an interrupterless transformer by H. C. Snook in 1907 and progressive improvements in the cathode ray tube resulted in a marked decline in reports of radiation injury. Since that time, improvements in film sensitivity and fluorescent screens have further reduced exposure times, to the point where the average exposure time for a chest radiograph is approximately one twentieth of a second (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998). The short exposure time diminishes image blurring caused by involuntary and cardiovascular motion and reduces the neonate's exposure to radiation. However, it also is important to limit the cross-sectional area of the x-ray beam to the region of interest to reduce unnecessary irradiation of adjacent organs (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998).

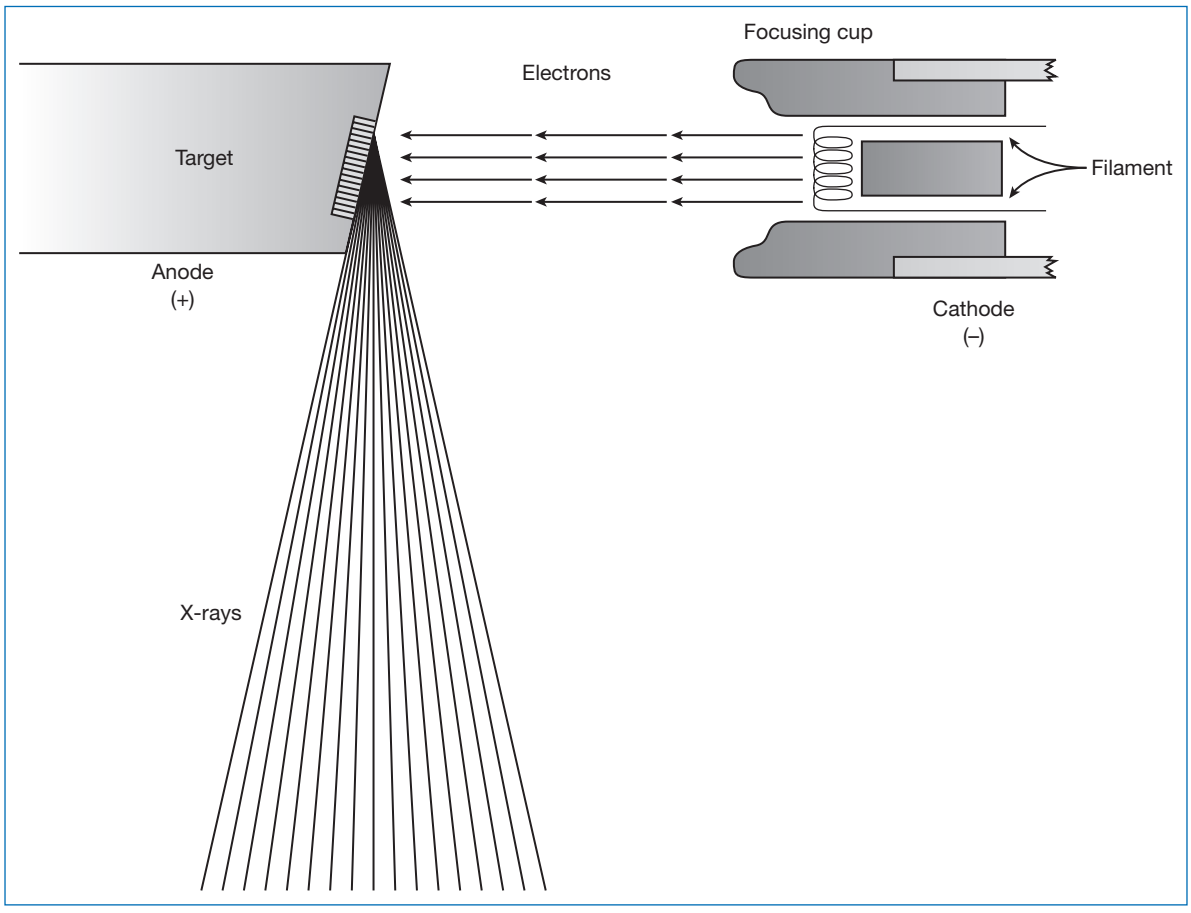

FIGURE I.3 Generation of x-ray photons in a tungsten anode–cathode tube.

Conventional radiographic images have commonly been recorded with large-size photographic film enclosed in an aluminum or plastic lightproof cassette. The film is compressed between fluorescent screens that emit visible light when exposed to x-rays. The fluorescence from the phosphor screens, rather than the direct effect of x-rays on the photographic emulsion, produces most of the image on the film (Alpen, 1998; Bushong, 2013; Juhl et al., 1998). Other diagnostic imaging methods also use ionizing radiation.

Xeroradiography. Xeroradiography is a radiographic imaging technique used to evaluate soft tissue. With this technique, the electrical charge of a photoconductive plate is altered in proportion to the intensity of the transmitted radiation image (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998). The image is recorded on the plate rather than on x-ray film. With soft tissue structures that differ only slightly in density, this method provides much better contrast than conventional radiography. It also provides an "edge effect" at the margins of discontinuous structures and therefore is indicated for the detection of nonmetallic foreign bodies and for evaluation of complex upper-airway abnormalities in the neonate (Hilton & Edwards, 2006; Juhl et al., 1998; Swischuk, 2003). Despite these benefits, the risks associated with this imaging technique must be considered. The radiation exposure involved is six to 12 times greater than that with conventional radiographs (Alpen, 1998; Hilton & Edwards, 2006; Juhl et al., 1998; Swischuk, 1995, 2003).

Fluoroscopic Imaging. Thomas Edison developed the fluoroscope in 1898 (Bushong, 2013). He focused on the use of fluorescent materials in this new imaging modality. During the period of his investigation, Edison analyzed the fluorescent properties of more than 1,800 materials, including zinc cadmium sulfide and calcium tungstate, both of which are still used. Edison halted his research in this area when his assistant and long-time friend, Clarence Dally, suffered severe x-ray burns that required bilateral upper-extremity amputation. Dally's subsequent death in 1904 is considered the first x-ray fatality (Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998).

Fluoroscopic imaging is a radiologic technique used to evaluate the motion of an organ system. After passing through the patient, the fluoroscopic x-rays interact with the input phosphor of the image intensifier tube. The input phosphor converts the incident x-rays into visible light, which causes the photocathode to emit electrons (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998). These electrons are accelerated and focused by electrodes in the image intensifier onto the output phosphor to produce visible light that can be viewed directly through an optical system or by a television system (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999). Fluoroscopic images can be recorded on film or videotape. Videotape recording of fluoroscopy has become essential. It is easier and safer to rerun a videotape several times to evaluate dysfunction than to prolong the radiation exposure from fluoroscopy.

During a fluoroscopic examination, the anatomic structure may be evaluated by obtaining a spot film, which is produced by photographing the output phosphor on 100- or 105-mm film. This type of intensifier optical-coupled spot film camera reduces the radiation dose to the infant by at least 75% compared with a conventional spot film device (Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998; National Council on Radiation Protection and Measurements [NCRP], 1993a, 1993b, 1993c, 2018). Videotapes are used to record motions, and spot films are used to document anatomy. Although fluoroscopy has many advantages, the radiation dose delivered in 1 minute of fluoroscopy is equivalent to that of more than thirty 105-mm spot films or more than eight conventional radiographs (Alpen, 1998; Dowd & Tilson, 1999; NCRP, 1993a, 1993b, 1993c).

Electronic intensification of the faint fluoroscopic image allows fluoroscopy to be performed in subdued lighting. Improved intensifier systems have made invasive catheter studies, such as cardiac angiography, much easier to perform (Bushong, 2013; Dowd & Tilson, 1999).

Fluoroscopically guided cytologic biopsy of the lung, bone, pancreas, and lymph nodes has become possible with percutaneous needle insertion. With the aid of fluoroscopy, arteriovenous malformations can be embolized; arterial stenoses can be dilated with balloon catheters; and plastic stents can be inserted to provide drainage through biliary strictures (Hilton & Edwards, 2006; Swischuk, 1995, 2003). These surgical–radiologic procedures are needed for only a relatively small proportion of neonates; however, all fluoroscopic procedures depend on high-quality image intensification, and all require cooperation among the neonatal, surgical, and radiologic teams to achieve the best results.

Conventional X-Ray Tomography. Tomography is a radiologic method of imaging a "slice" of tissue at a specific level. Coordinated movement of the x-ray tube and the film cassette gives a defined image in the two-dimensional plane of interest, whereas the structures in front of or behind this plane are blurred out (Alpen, 1998; Bushong, 2000; Juhl et al., 1998). Tomography is useful in many circumstances, but its usefulness has been overshadowed by the development of CT.

Computed Tomography. CT was first developed in 1961 by William H. Oldendorf, and by 1973 it had become a recognized diagnostic imaging tool (Bushong, 2000). CT scanning obtains cross-sectional images rather than the shadow images of conventional radiography. Conventional radiography is based on variable attenuation of the x-ray beam as it passes through tissue. Because only the sum total of this attenuation is available for recording on the film, conventional radiography can detect only differences of 10% attenuation (Bushong, 2000, 2013; Juhl et al., 1998). Conventional radiographs, therefore, cannot produce a detailed characterization of various soft tissue densities. The densities that can be visualized on conventional radiographs are air, fat, soft tissue, and bone. CT passes multiple, highly collimated beams through the same cross-sectional slice of tissue at different angles during different intervals of time. In CT scanning, a fan x-ray beam from a source rotating about the infant passes through the body, and the exit transmission of x-ray beam intensity is monitored by a series of detectors (Alpen, 1998; Bushong, 2000). The x-ray beam "cuts a slice" from 3 to 13 mm thick through the infant. The exit transmission at any angle can be used to calculate the average attenuation coefficient along the length of the x-ray beam. By measuring the exit transmission at a large number of angles around the infant, a complex series of mathematic equations can be solved by a computer to calculate and determine the mass attenuation coefficient of small (~0.5 × 0.5 × 10 mm) volume elements, or voxels. The final cross-sectional image is made up of a display of the gray scale value of every voxel, which can be projected on a cathode ray tube and recorded photographically (Alpen, 1998; Bushong, 2000, 2013; Juhl et al., 1998). Bone is the densest, absorbs the largest amount of x-rays, and appears white; air is the least dense and appears black; soft tissues are displayed as intermediate shades of gray. CT scanning has the ability to separate spatial and contrast resolution and is much more sensitive to tissue densities than conventional radiographs. CT can distinguish differences in attenuation coefficients as small as 0.1%; it also detects changes in density in very small areas of tissue and allows identification of various components of soft tissue, such

as subarachnoid space, white matter, gray matter, and ventricles (Alpen, 1998; Bushong, 2000, 2013; Juhl et al., 1998). CT of the body is technically more difficult than cranial examination because of cardiac and respiratory motion; however, a modern body scanner can complete a scan in 2 to 4 seconds, which reduces movement artifact. In the neonate, the rapid heart and respiratory rates limit the usefulness of this technique for thoracic examination.

With CT, the density, or contrast resolution, depends on the radiation dose and scan time (Alpen, 1998; Bushong, 2000, 2013; Juhl et al., 1998). As the radiation dose (i.e., scan time) increases, the number of photons collected in each area increases and the statistical noise decreases, resulting in better contrast resolution. CT demonstrates tissue structure with precise clarity, showing superior anatomic detail compared with conventional radiographic imaging (Alpen, 1998; Bushong, 2013; Juhl et al., 1998). CT permits two-dimensional visualization of entire anatomic sections of tissue, which aids in determining the extent of the disease or malformation. Anatomic and physiologic information can be visualized despite overlying gas and bone. Contrast enhancement can measure blood flow and help define pathologic abnormalities (Bushong, 2000; Swischuk, 1995, 2003). Bolus injection of contrast material allows excellent visualization of vascular structures.

As good as CT is as an imaging modality, it is still not a radiologic microscope; CT does have its drawbacks. It also uses ionizing radiation, and because the computers require a cool room for proper equipment performance, the neonate's environment is altered significantly, a circumstance that must be considered.

Digital Radiography and Digital Vascular Imaging. Digital radiography is the term used to describe techniques that use computers to produce projectional images similar to those of conventional radiography (Bushong, 2013). Although standard CT instruments have been designed to produce two-dimensional images of two-dimensional body slices, they can also be used to project three-dimensional structures into two-dimensional images that are similar to conventional radiographs. These projections do not have the fine detail of conventional radiographs, but because the pictorial data is stored in the computer, the image can be manipulated and subtle features can be enhanced (Bushong, 2013).

Another method of digital radiography converts the image intensifier picture to digital signals that can be stored and manipulated. The most important use of this method is to obtain digital subtraction images of the heart and major arteries from data recorded before and after the injection of angiographic contrast material (Bushong, 2013). This method is much less invasive than catheterization, although the technique is new and the equipment is expensive. It has been used on a very limited basis in the neonate.

Radiographic Contrast Agents

Plain radiography can differentiate only four kinds of body tissue: tissue containing gas (lung and bowel), fatty tissue, tissue containing calcium (bone or pathologic calcifications), and tissues of water density (solid organs, muscle, and blood). To demonstrate blood vessels that are in solid organs or surrounded by muscle or to demonstrate other hollow structures, artificial radiographic contrast agents must be introduced. The contrast medium may be negative or positive and may be injected, swallowed, or administered as an enema (Hilton & Edwards, 2006; Swischuk, 1995, 2003).

Negative contrast media absorb less radiation than adjacent soft tissues and therefore cast a darker radiographic image. Gases such as air, oxygen, and carbon dioxide can be used as negative contrast media. Because negative media provide a limited amount of contrast for conventional radiography, they are seldom used (Martin et al., 2015; Swischuk, 1995, 2003).

Box I.1

RADIOPHARMACEUTICALS USED IN NEONATAL DIAGNOSTIC IMAGING

- Technetium 99m
  - *Sulfur or tin colloid:* used for imaging liver, spleen, bone marrow, ventilation, and gastrointestinal bleeding
  - *Albumin microspheres:* used for imaging lung perfusion
  - *Pyrophosphate, diphosphate:* used for imaging skeletal and myocardial infarcts
  - *Pertechnetate:* used for imaging thyroid, brain, and gastrointestinal tract
  - *Diethylenetriaminepentaacetic acid (DTPA) glucoheptonate:* used for imaging kidney and brain
  - *Hepatoiminodiacetic acid (HIDA):* used for imaging biliary system
- Iodine 131: used for imaging thyroid and fibrinogen and for clot localization
- Xenon 131, krypton 81m: used for imaging lung ventilation
- Thallium 201: used for imaging myocardial perfusion and for testicular localization

Positive contrast media use elements with a high atomic number, which absorb much more radiation than surrounding soft tissues and therefore cast a lighter image. Barium and iodine are the two elements currently used. Barium sulfate, a relatively stable, nontoxic compound, is the major contrast agent used for outlining the walls of the GI tract. Iodine-containing salts that are excreted by the kidneys are used for a wide variety of urographic and angiographic studies. The kidneys also excrete the newer nonionic, iodine-containing media. Because of their lower osmolality, these agents are less painful than iodine-containing salts when injected into arteries, and they are rapidly replacing the older contrast agents (Box I.1; Hilton & Edwards, 2006; Martin et al., 2015; Swischuk, 1995, 2003).

Ionizing Radiation Interactions With Tissue

When an infant undergoes a radiologic procedure, most of the radiation passes through the infant's body and strikes the fluorescent screens encompassing the film. The roentgen (or C/kg) is a measure of how many x-rays were present. For the infant, the more important quantity is the number of x-rays that stop in the body and how much energy they deposit. The radiation dose (rad) is a measure of the energy deposited. X-rays that pass through the infant are attenuated by photoelectric absorption and Compton scattering (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998).

Photoelectric absorption involves the complete interaction and absorption of the incoming x-ray photon by the atom. The photoelectric interaction declines rapidly with increasing energy and increases rapidly with increasing atomic number (Alpen, 1998; Bushong, 2013). This is why lead is such an effective shield and bone is so much more absorptive than soft tissue.

Compton scattering is the phenomenon in which only part of the energy of the incoming x-ray photon is transferred to the atom; this reduces the energy of the original photon and produces a scattered electron (Bushong, 2013).

With ionizing radiation, electrons are removed from their atoms and endowed with energies 14 to 20,000 times greater than those in ordinary biochemical reactions (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998). These electrons can maraud through tissue for some distance and can break any kind of chemical bond in the body (Bushong, 2013; Dowd & Tilson, 1999; NCRP, 1993a, 1993b, 1993c). In biochemical systems the reactions are carefully controlled, often by a special geometric juxtaposition of the reactants. A high-speed electron is akin to a bull in a china shop; it can break anything, anywhere. Once it has ripped an electron out of an atom in a molecule, the molecule itself is placed at such a high-energy level that it can produce all kinds of chemical reactions that would never have been possible without ionizing radiation (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; NCRP, 1993a, 1993b, 1993c).

X-rays and gamma rays are identical in nature except that, in general, x-rays are made in high-voltage machines, whereas gamma rays originate from the nuclei of atoms. Radiations emitted from such naturally unstable atoms as uranium are commonly more energetic per unit than x-ray photons. For example, gamma rays are commonly measured in millions of electron volts (meV) per photon, whereas x-rays are commonly measured in 50 to 100 kiloelectron volts (keV; 50,000–100,000 eV). Gamma rays from unstable nuclei do all the things that x-rays do; that is, they can undergo photoelectric and Compton effects, and they can produce high-energy electrons and positrons (Bushong, 2013; Dowd & Tilson, 1999).

Other radiation decay products also create particulate radiation called alpha and beta rays. Beta rays are not truly rays but high-speed electrons emitted from the nuclei of decay products of uranium (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999). Alpha particles are emitted from the nuclei of uranium. Alpha particles are the "stripped" nuclei of helium and consist of any two protons. Ultimately, the two protons find two electrons in the environment and become helium gas. X-rays and gamma rays, which pass through the body and do not produce effects on tissue, have no biologic effect. However, alpha and beta particles interact at every millimeter along their path through tissue, so if they gain access to tissue, biologic harm is guaranteed (Bushong, 2013; Dowd & Tilson, 1999; NCRP, 1993a, 1993b, 1993c).

Biologic damage from ionizing radiation depends on the amount of energy deposited in a particular tissue. X-rays and gamma rays produce harmful effects only to the extent that they put high-speed electrons in motion. If the same number of electrons is put in motion by gamma rays from plutonium or from deposited radionuclide or by agents from external x-rays, the biologic effects are the same (Bushong, 2013; Dowd & Tilson, 1999; NCRP, 1993a, 1993b, 1993c).

Factors Affecting Radiographic Quality

Interpretation of a neonatal radiograph requires a rapid evaluation to determine whether the radiograph is technically satisfactory. Several factors determine the technical quality of a radiograph, including film exposure, phase of respiration, motion, tube angulation, and infant positioning. If one of these factors is unsatisfactory, the film may be misinterpreted. When nurses have an understanding of these factors, the technical quality of radiographs is improved.

Film Exposure. A reasonable criterion for judging film exposure is satisfactory visualization of the dorsal intervertebral disk spaces through the entire cardiothymic silhouette (Hilton & Edwards, 2006; Martin et al., 2015; Swischuk, 1995, 2003). If the film is underexposed, the dorsal disk spaces are lost, and the lungs and other structures have a homogeneous, "whitewashed" appearance. If the film is overexposed, the pulmonary vascular markings are progressively lost until the lungs have a black, "burned out" appearance (Hilton & Edwards, 2006; Swischuk, 1995, 2003).

Phase of Respiration. The phase of respiration at the time the film is obtained affects the appearance of the radiograph considerably (Figure I.4). On an expiratory film, the heart may appear grossly enlarged, the lung fields may appear opaque (which may simulate diffuse atelectasis), and the diaphragm is located above the seventh rib (Hilton & Edwards, 2006; Swischuk, 1995, 2003). On an inspiratory film, the diaphragm is at the eighth rib, the cardiothymic diameter is normal, and the pulmonary vascularity is prominent. The right hemidiaphragm is slightly higher than the left. If the right hemidiaphragm is at or above the level of the seventh rib, the film was obtained in the expiratory phase or the infant has hypoaerated (Hilton & Edwards, 2006; Swischuk, 1995, 2003).

Motion. If the infant moves just as the radiograph is made, the resulting film is blurred. Motion causes blurring of the hemidiaphragms, the cardiovascular silhouette, and all fine pulmonary detail (Hilton & Edwards, 2006; Swischuk, 1995, 2003). Movement blur on diagnostic images can be prevented by fast imaging and adequate immobilization.

Speed. A short exposure time is essential for obtaining clear images. This can be achieved by limiting the duration of exposure to the energy source and by increasing the use of computed imaging.

Immobilization. The nursing staff is primarily responsible for ensuring adequate immobilization during diagnostic imaging. Inadequate immobilization is an important cause of poor quality on neonatal images. Proper immobilization techniques improve

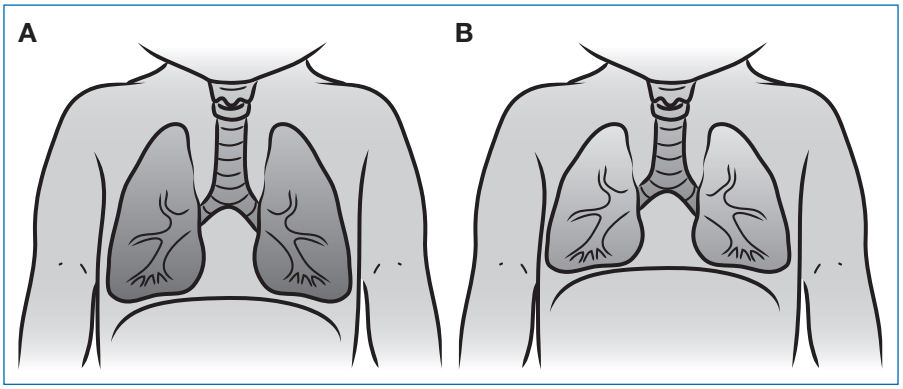

FIGURE I.4 Differences in appearance between inspiration (A) and expiration (B) in a neonatal chest radiograph. On full inspiration, the diaphragm is located at the eighth rib, and the lungs appear larger and darker. During expiration, the diaphragm is at or above the seventh rib, and the lung fields appear smaller and lighter. The heart size may also appear larger on expiratory films.

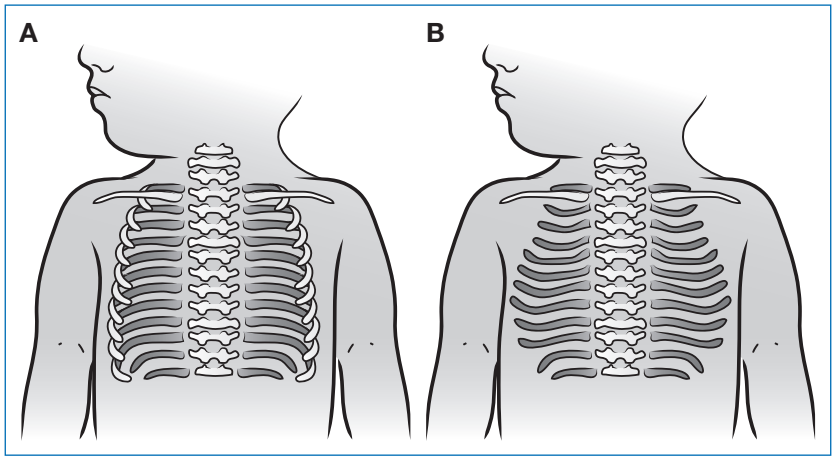

FIGURE I.5 Skeletal position in a normally positioned radiograph (A) and in a film obtained with cephalad positioning of the x-ray tube (B).

image quality, shorten the examination time, and eliminate the need for repeat studies (Hilton & Edwards, 2006; Swischuk, 1995, 2003). Proper immobilization may be less traumatic than manual restraint alone. An immobilization board may be required, or tape, foam rubber blocks and wedges, towels, diapers, or clear plastic acetate sheets may be used.

Physical risks to neonates are associated with immobilization. The type of restraint or an ill-designed immobilization device may cause trauma. Tape or plastic sheets may cause skin and soft tissue damage if not applied and removed carefully. Also, thermal stress may be a factor when a neonate is placed on a noninsulated board or film cassette. The nurse should position and immobilize the infant properly so that the technician can center the tube, position the beam, and make the exposure. If the nurse and the technician work together, superior results are achieved with greater speed and less disruption than if they worked separately.

Infants lie still only when they are very ill. Otherwise, they greatly resent being forcibly restrained, especially in an unusual position. A number of immobilization devices are available, but the best means is a pair of adequately protected adult hands (Hilton & Edwards, 2006; Swischuk, 1995, 2003).

Tube Angulation. Another factor that affects radiographic quality is angulation of the x-ray tube, along with improper field limitation. Often on neonatal films, the infant's chest appears mildly lordotic, with the medial clavicular ends projected on or above the dorsal vertebrae. This results in a rather peculiar chest configuration. The preossified anterior arcs of the upper ribs are positioned superior to the posterior arcs (Figure I.5). The lordotic projection tends to increase the apparent transverse cardiac diameter, making it difficult to determine the size of the heart. Lordotic projections result when the x-ray tube is angled cephalad, when the x-ray beam is centered over the abdomen, or when an irritable infant has arched the back at the time of the film exposure. If the x-ray tube is angled caudad, or the x-ray beam is centered over the head, the anterior rib arcs are angulated sharply downward in relation to the posterior arcs (Hilton & Edwards, 2006; Swischuk, 1995, 2003).

Infant Positioning. Proper infant positioning is important for radiographic quality and interpretation. If the infant is rotated, a false impression of a mediastinal shift may be created (Figure I.6). The direction and degree of rotation can be estimated by comparing the lengths of the posterior arcs of the ribs from the costovertebral junction to the lateral pleural line at a given level. The infant is rotated toward the side with the greatest posterior arc length (Hilton & Edwards, 2006; Swischuk, 1995, 2003).

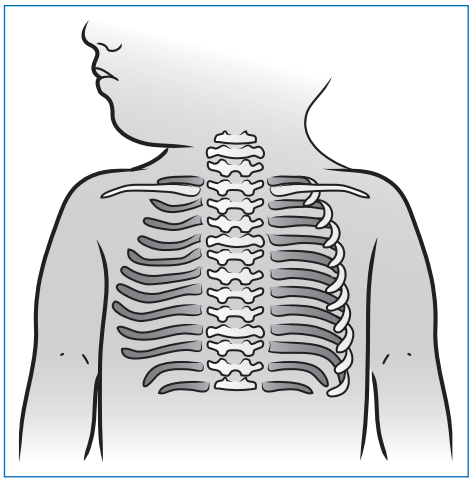

FIGURE I.6 Skeletal configuration in a film obtained with the infant rotated to the right.

Another measurement for determining the degree of rotation is the distance from the medial aspect of the clavicles to the center of the vertebral body at the same level. If the infant is properly positioned, the medial aspects of the clavicles should be equidistant from the center of the vertebral body (Hilton & Edwards, 2006; Swischuk, 1995, 2003). The distance is greater on the side toward which the infant is rotated. On a lateral view, rotation can be readily determined by observing the amount of offset between the anterior tips of the right and left sets of ribs.

Before any chest film is interpreted, these factors must be systematically evaluated. Through experience, this evaluation becomes automatic, and the film can be scanned rapidly.

Radiologic Projections

Radiologic projections are the geometric views of the radiograph, and they vary among institutions and radiologists. They can be customized to the specific infant or clinical condition. For example, the skull may require a simple AP film to make the diagnosis of a fracture, whereas a complete skull series may be necessary for evaluation of congenital malformations. In the neck and upper airway, a lateral film in inspiration with the infant's head extended may be sufficient for the evaluation of stridor, or a xeroradiography of the soft tissue structures of the neck may be required. Because the radiation dose is much greater with a xeroradiography

than with a plain lateral neck film, the indications for this examination should be clear (Swischuk, 2003).

For evaluation of the spine, the AP projection is most commonly used. Oblique views of the spine usually are difficult to obtain in infants because it is difficult to position and immobilize babies. Also, the diagnostic information gained does not outweigh the risk of the greater radiation exposure required to obtain such views. For evaluation of congenital hip dysplasia, an AP view of the entire pelvis and both hips is required. Gonadal exposure should be minimized with proper shielding during radiographic examination of the hips. Assessment of skeletal maturation in the infant requires an AP film of the left hemi skeleton, and a long bone series requires a film of the upper and lower extremities (Hilton & Edwards, 2006; Swischuk, 1995, 2003).

Chest radiographs are the most frequently performed diagnostic imaging procedure in the NICU. In most cases an AP projection from a supine position is satisfactory for evaluating the infant's chest, heart, lung fields, endotracheal tube, line placement, and pneumothorax (air leak complications related to mechanical ventilation). The cross-table view allows verification of the pleural chest tube being placed anteriorly or posteriorly. Lateral decubitus is used to evaluate small pneumothorax and small pleural fluid collection; these can be hard to see on an AP view. The upper right reveals abdominal perforation, which shows free air under the diaphragm (rarely used). Lateral projections of the chest often are poorly positioned, have diminished technical quality, and require greater radiation exposure of the infant. For the experienced radiographer, an AP film in the supine position is sufficient in most cases. In rare cases, a lateral chest film with esophageal barium contrast may be requested for evaluation of the left atrium of the heart (Gomella, Cunningham, & Eyal, 2013; Hilton & Edwards, 2006; Swischuk, 1995, 2003; Verklan & Walden, 2014).

Abdominal x-ray films are also frequently obtained in the NICU. The most commonly used radiographic projections are the AP, cross-table lateral, and left lateral decubitus views. Because the infant's abdomen is relatively cylindric, a lateral view provides more information than it does in an older child or adult. AP views define the gas pattern, intestinal displacement, some masses, ascites, and placement of lines such as umbilical catheters or intestinal tubes, whereas the cross-table lateral view is recommended in the diagnosis of abdominal perforation, and the left lateral decubitus view is for diagnosis of intestinal perforation, and free intra-abdominal air (Gomella et al., 2013; Hilton & Edwards, 2006; Swischuk, 2003).

Exposure Factors in Infancy

Numerous radiographic variables are involved in x-ray exposure. The x-ray machine, films, screens, types of cassette, and processing methods, as well as the radiologist's preference, may vary greatly from one department and institution to another. However, a few general principles can be stated:

1. Exposure time should be kept short to prevent movement blur and to limit the radiation dose.
2. Radiographic technicians should be knowledgeable about factors and variables that affect exposure so that repeat films occasioned by poor technique on the initial radiograph can be avoided.
3. A repeated infant x-ray is the major cause of the largest dose of unnecessary radiation (Hilton & Edwards, 2006; Swischuk, 1995, 2003); every possible precaution should be taken to ensure that the first attempt produces a film of diagnostic quality.
4. Before a repeat is done, the film should be shown to the radiologist or neonatologist who requested it; although the technical quality may not be ideal, the film may provide sufficient information.

Radiation exposure can also be reduced by using other diagnostic imaging modalities, when possible, that do not use ionizing radiation to create an image (e.g., ultrasonography, MRI; Swischuk, 1995, 2003). If radiologic imaging is the best diagnostic approach for the infant's condition, it may be important to "customize" the examinations, to limit the area examined, and to reduce the number of follow-up films. The radiologist and technician should be knowledgeable about the rapid technologic advances in film–screen combinations, filtration, projections, and film processing, which can help produce a film of fine diagnostic quality while minimizing radiation exposure (Alpen, 1998; Swischuk, 1995, 2003).

Ideally, there would be no "routine" radiologic examinations, just problem-oriented procedures. However, there is a logical approach to radiographic examinations. Plain films should be obtained first. Then, if indicated, a dye contrast study (e.g., excretory urography) should be performed, because the contrast material is rapidly eliminated from the body. Last, barium contrast studies should be obtained. Barium contrast studies are performed after the others because (1) barium interferes with any nuclear scintigraphic scans, body-computed tomograms, and ultrasonographic scans and (2) barium is slowly eliminated from the GI tract, which delays further diagnostic evaluation. Additional radiation exposure is possible if the barium must be completely eliminated before the next imaging procedure (Hilton & Edwards, 2006; Swischuk, 1995, 2003).

Adequate patient preparation is another means of reducing radiation exposure (Hilton & Edwards, 2006; Swischuk, 1995, 2003). If GI and genitourinary (GU) imaging are both to be performed, the GU examination should be scheduled first. Although each institution has its own policies, in preparation for a GU examination such as excretory urography, the infant should be kept on nothing by mouth (NPO) status for no longer than 3 hours; this can be accomplished by withholding the early morning feeding and scheduling the examination for 8 a.m. No preparation is necessary for excretory urography in infants with abdominal masses, trauma, or GU emergencies. If the infant has impaired renal function, the radiologist and the neonatologist should discuss the condition thoroughly so that the risks of this procedure are minimized. For an infant who has been feeding, the baby is prepared for a GI contrast study by keeping the child on NPO status for no longer than 3 hours before the examination. Generally, if a contrast study of the entire GI tract has been requested, the lower GI series is performed before the upper GI series (Hilton & Edwards, 2006; Swischuk, 1995, 2003). This allows time for elimination of the barium in the colon and prevents the barium from interfering with the diagnostic quality of the upper GI study. Colon preparation is usually unnecessary in the neonate and should be avoided in infants with an acute abdominal condition and in those suspected of having Hirschsprung disease (Swischuk, 1995, 2003).

Collaborative Care

Radiation Protection. Any radiation is considered harmful to the infant, and all efforts must be made to reduce radiation exposure without forgoing diagnostic information. Radiation exposure can have both genetic and somatic effects (Bushong, 2013; Dowd & Tilson, 1999; NCRP, 1993a, 1993b, 1993c). Reduction of radiation exposure should be the goal for sites that are sensitive genetically (gonads) and somatically (eyes, bone marrow). Although there is no evidence that somatic damage (e.g., carcinogenesis or cataracts) occurs as a result of low-dose diagnostic radiologic procedures, dose reduction should be accomplished for the site examined and for the rest of the body (Dowd & Tilson, 1999). Methods of reducing

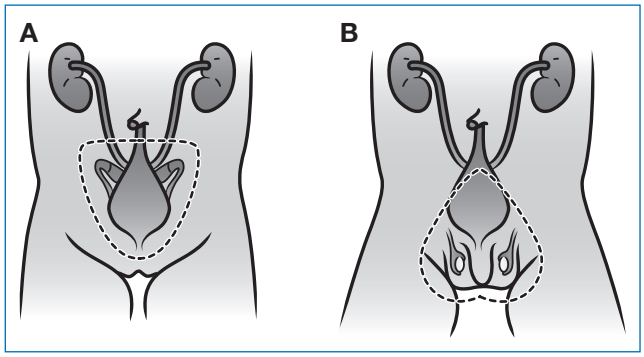

FIGURE I.7 Anatomic placement of gonad shield for female infants (A) and for male infants (B).

radiation exposure include performing examinations only when they are clinically indicated, selecting the appropriate imaging modality, using the lowest radiation dose that achieves an image of diagnostic quality, avoiding repeat examinations, reducing the number of films obtained, using appropriate projections with tight field limitation, ensuring proper positioning and immobilization, and shielding the gonads (Alpen, 1998; Dowd & Tilson, 1999; Hilton & Edwards, 2006; NCRP, 1993a, 1993b, 1993c).

If the gonads are not within the area of interest, gonadal exposure depends on the adequacy of field limitation. The maximum gonadal dose occurs when the gonads are unshielded and exposed to the primary x-ray beam. This dose declines rapidly as the distance from the gonads to the primary beam increases. Gonadal exposure in an AP film that includes the gonads can be reduced by 95% with proper contact shielding (Dowd & Tilson, 1999). The gonads should be shielded whenever they are within 5 cm of the primary x-ray beam.

Contact gonadal shields are easy to make from 0.5-mm thick lead rubber sheets, and they should be sized for gender and age (Figure I.7; Swischuk, 1995, 2003). In males, proper positioning of the shield avoids obscuration of any bony detail of the pelvis if the upper edge of the shield is placed just below the pubis and if the testicles have descended into the scrotum. In females, the position of the ovaries varies with bladder distention. Because of their anatomic location, the ovaries cannot be shielded without obscuring lower abdominal and pelvic structures. The lower margin of the gonad shield should be placed at the level of the pubis, and the upper margin should cover at least the lower margin of the sacroiliac joints (Hilton & Edwards, 2006; Swischuk, 1995, 2003).

Radiation Safety. The three ways to reduce radiation exposure of personnel are: (1) shorten the duration of radiation exposure; (2) increase the distance from the radiation source; and (3) provide radiation shielding between the nurse and the radiation source (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; NCRP, 1993a, 1993b, 1993c). Portable radiologic examinations are the most common form of diagnostic imaging routinely performed in the NICU. During these procedures, there is a tendency for all the nurses to leave the room when an exposure is being produced; consequently, other infants may be left unattended for that short period. Because of this practice, parents have expressed fear about their infants facing environmental radiation hazards.

Using the example of an infant who receives two radiologic examinations per shift, the total dose outside a 30-cm (1 foot) radius of the primary beam is 70 μR. If the staff nurse worked a 250-day work year and held an infant who received two x-ray examinations per shift, the cumulative dose would be 18,000 μR (18 mrad)/year (1,000 μR = 1 mrad). This value is considerably lower than the background radiation in a building, which amounts to 100 to 150 mrad/year (Bushong, 2013; Dowd & Tilson, 1999).

Other radiologic studies done in the NICU have found that within 1.82 m (6 feet) of the target, an unshielded person receives 100 mrad *per hour of exposure*. Because the duration of exposure is approximately 0.1 second, the radiation dose is 0.003 mrad/exposure. This amount of radiation is far below the safety limit of 500 mrad/year. At this rate of radiation exposure, a full-time staff nurse would have to be exposed to more than 6,000 x-rays each day to reach the radiation safety limit per year (NCRP, 1993a, 1993b, 1993c).

It appears that if certain basic radiation precautions are observed, nurses and other NICU personnel need not leave the room during x-ray exposures. However, staff members should stay 30 cm (1 foot) or farther from the infant being radiographed. Care must be taken to ensure that if a horizontal beam film is obtained (e.g., in a cross-table lateral projection), no one is in the direct x-ray beam because the radiation dose in the primary beam is considerably higher than in the scattered portion. When a horizontal beam is used, it should not be directed at any other patient or person. Any employee within 30 cm (1 foot) of the incubator or one who is holding the infant for the exposure should wear a lead apron and gloves.

The x-ray beam must be confined to the area within the cassette edges. An infant causes little scatter, but an adult's hands can easily come within the field of primary radiation and cause scatter. It is important to position and secure the infant properly while keeping the hands out of the x-ray beam. If correct radiographic technique is used, the dose to the nurse's lead-protected hands is approximately 0.01 mSv (millisieverts). The annual dose limit to the hands of nondesignated personnel is 500 mSv.

Table I.2 summarizes the process of systematic interpretation of radiographic images in the neonate.

Radionuclide Imaging

The use of radioisotopes has brought a new dimension to diagnostic imaging, because they can be used to trace a wide range of physiologic functions in virtually every organ in the body, thereby complementing conventional radiography and ultrasonographic imaging. The difference between conventional radiography and radionuclide imaging is that with the former, images are produced by the transmission of radiation, whereas with the latter, images are produced by the emission of radiation (gamma rays) previously introduced into the body and recorded on film or in a computer (Figure I.8; Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Juhl et al., 1998; Treves, 1995).

Radionuclide studies yield both physiologic information and anatomic representations of the distribution of radioactivity, depending on the selective uptake of radionuclide by different organs of the body (Bushong, 2013; Dowd & Tilson, 1999; Treves, 1995). The primary disadvantage of radionuclide imaging is the limited anatomic resolution to diameters greater than 2 cm.

Biophysical Principles. Relatively small amounts of radioactivity are used in radionuclide imaging, and the radiation hazard is significantly smaller than for corresponding conventional radiographic investigations (Bushong, 2013; Dowd & Tilson, 1999; Treves, 1995). The radioactive substance injected is usually distributed throughout the body, and the site of maximum radiation is not always the organ under investigation (Bushong, 2013; Dowd & Tilson, 1999; Treves, 1995). For example, the thyroid gland selectively concentrates radioactive iodine, even if this compound is being used to study another organ. In this case, thyroid iodine uptake can be blocked pharmaceutically. The kidneys excrete the

TABLE I.2

RADIOGRAPHIC INTERPRETATION

Technical Evaluation	Characteristics
Film density and contrast	The intravertebral disk spaces should be visible through the cardiothymic silhouette. Underexposed films appear whitish with progressive loss of spaces; overexposed films have a "burned out" appearance with loss of pulmonary vascular markings.
Phase of respiration	The respiratory phase affects the appearance of the lung fields. During expiration, the cardiothymic silhouette appears larger, and the lung fields appear more opaque; the hemidiaphragms are usually at the level of the seventh rib. During inspiration, the cardiothymic silhouette is normal, pulmonary vascularity is seen, and the lung fields are clear. Adequate inspiration puts the right hemidiaphragm at the level of the posterior eighth rib; the right hemidiaphragm usually is slightly higher than the left during basal breathing.
Motion	Radiology personnel must check for motion at the time the film is taken. Motion is detected by blurring of the hemidiaphragms and cardiothymic silhouette. Motion obscures all fine pulmonary vascular detail, which makes the films unsatisfactory for evaluation of the lung fields.
Tube angulation and patient positioning	AP films of the newborn appear lordotic, with the medial ends of the clavicles projecting on or above the second dorsal vertebra. If the tube has been angled cephalad, the lordosis is exaggerated, with the anterior arcs of the ribs positioned superior to the posterior arcs. The cardiothymic silhouette appears larger because the view is through the transverse diameter of the heart. This occurs if the infant arches during the procedure or if the beam has been centered over the abdomen. Caudad angulation of the beam over the head results in distortion of the chest, with the anterior ribs' arcs angled sharply downward in relation to the posterior arcs.
Rotation of the patient	Assessment of rotation is critical in determining whether mediastinal shift is present. Lateral rotation may lead to the false impression of a mediastinal shift. The trachea shifts toward the side of the rotation, and the contours of the heart are altered. The direction and degree of rotation are estimated by comparing the lengths of the posterior arcs of the ribs on both sides. The side with the longest posterior arc is the side to which the patient is rotated. Rotation also results in unequal lengths of the clavicles when they are measured from the medial aspects to the center of the vertebral body at the same level. The patient is rotated to the side with the longer clavicle.
Heart size and pulmonary vascularity	These features are difficult to determine in the newborn in the first 24 hours of life because of the dynamic cardiovascular alterations that occur during this period. Changes in the transitional circulation are associated with an increase in pulmonary blood flow and in blood return to the left atrium, a decrease in blood return and lower pressure in the right atrium, and changes in systemic and pulmonary arterial pressures. The newborn's heart size is relatively larger in the first 48–72 hours because of those rapid changes. Heart size can be accurately assessed only during basal breathing because the size is significantly altered during phases of the cardiac cycle and during hyperexpansion of the lung. After the first 24 hours, a cardiothoracic ratio above 0.6 is the upper limit of normal. Fetal lung fluid is reabsorbed, and the air spaces are filled with air on inspiration. The resorption of lung fluid enhances the appearance of the pulmonary lymphatics, resulting in an apparent increase in vascularity at birth. Transient tachypnea of the newborn is characterized by perihilar streaky infiltrates with increased pulmonary vascularity and good lung inflation.
Cardiothymic silhouette	The cardiac configuration is difficult to determine in the newborn largely because of the variation in size and shape of the thymus. The aortic knob and main pulmonary artery are obscured by the thymus, which frequently has a wavy border. A tuck may be seen in the left lobe of the thymus at the lateral margin of the right ventricle, a feature called a sail sign. The apex of the heart has a more cephalad position and assumes a more caudal position over time. The elevation of the apex is due to the relative right ventricular hypertrophy of the fetus. After birth, as the left ventricle becomes more prominent, the cardiac apex descends. The thymus involutes rapidly under the stress of delivery and over the next 2 weeks of life may enlarge slightly.
Aeration of the lungs	Satisfactory inspiration positions the hemidiaphragms at the posterior arcs of the eighth rib. Expansion and radiolucency of the right and left sides are equal. If the sides are not comparable, a right and left lateral decubitus film should be obtained to evaluate for fluid levels or air. The lungs may bulge slightly through the ribs. On lateral projection, the hemidiaphragms should be smoothly domed. The AP and transverse diameters of the chest vary with age and disease. In a normal

(*continued*)

TABLE I.2

RADIOGRAPHIC INTERPRETATION (*continued*)

Technical Evaluation	Characteristics
Aeration of the lungs (*cont.*)	newborn, the AP and transverse diameters are equal. Over time, the transverse diameter increases, giving the chest cavity an oblong appearance. Air-trapping diseases produce a more rounded configuration, whereas hypoaeration results in a more flattened AP diameter. With hypoaeration, the right hemidiaphragm is located at the seventh rib, the posterior arcs have a more downward slope, and the transverse diameter of the chest is reduced. Laterally, hypoaeration results in increased doming of the diaphragm. With hyperaeration, the hemidiaphragm is located below the level of the ninth rib, the diaphragm is flattened, and the posterior rib arcs are horizontal. Hyperaeration also results in greater bulging of the lungs through the intercostal spaces and an increased diameter of the upper thorax.
Pulmonary infiltrates	Films should be evaluated for areas of increased pulmonary lucency or density. The characteristics and distribution of densities may lead to a diagnosis. Infiltrates should be described with regard to their distribution (unilateral, bilateral) and nature (alveolar, reticulated, diffuse, nondiffuse, patchy, streaky).
Mediastinal shift	The examiner evaluates for mediastinal shift by determining if the trachea, heart, and mediastinum are in normal position. In general, the shift occurs toward the side with the diminished lung volume or away from the hemithorax with the increased lung volume. Rotation of the patient must first be excluded.
Liver size	The edges of the liver should be clearly defined, and the size of the organ should correlate well with the size determined by palpation, especially when the intestines are filled with air. If insufficient gas is present in the abdomen, the size of the liver cannot be determined. Atelectasis obscures the upper margin of the liver. Radiographically, the size of the liver is not altered by the phase of respiration, as it is during palpation. Liver size may vary with the progression of right-sided heart failure. The position of the liver may be altered by congenital malformations such as situs inversus.
Abdominal gas pattern	Swallowing air produces gas in the stomach. The gas pattern must be interpreted in light of the infant's history. In the newborn, stomach air is present, with progression of air through the small bowel at 3 hours of life and rectal air by 6 hours. With bowel obstruction, gaseous distention progresses until at some point the bowel is blocked; beyond that point there is a paucity of air or a gasless bowel. Lack of haustra in the colon makes it possible to distinguish the small and large bowels on the radiograph. A gasless abdomen may be seen with prolonged gastrointestinal decompression, severe dehydration, acidosis, oversedation, brain injury, diaphragmatic hernia, midgut volvulus, and esophageal atresia. Marked aerophagia may be due to mechanical ventilation, tracheoesophageal fistula, necrotizing enterocolitis, and mesenteric vascular occlusion. Free peritoneal air rises to the highest level and outlines superior structures; therefore, it is best demonstrated on a left lateral decubitus film.
Catheter and tube positions	All catheter and tube positions should be evaluated and reported each time a radiograph is made. The position of these devices may provide clues to the underlying disease, and malpositioning of tubes and catheters may be life threatening. The trachea is positioned to the right in the midmediastinum, anterior and slightly to the right of the esophagus. The carina is located at T4. In the right aortic arch, the trachea is found slightly to the left of the vertebral column. Endotracheal tubes optimally are placed in the midtrachea. If the tip is too low (below T4) or too high (above the thoracic inlet), ventilation is suboptimal. Inadvertent esophageal intubation has occurred when the tip of the tube is below T4 but is still in the midline or when the trachea can be visualized apart from the tube. NG tube placement should be reported. NG tubes may be too short (seen in the distal esophagus) or too long (seen in the duodenum or jejunum), or they may be coiled in the esophagus (tracheoesophageal atresia). The location of vascular catheters must be evaluated. Central catheters should be placed with the tip in the superior part of the inferior cava. Umbilical artery catheters ideally should be located in the high (T6–T9) or low (L3–L5) position, away from major arterial branches. Umbilical venous catheters should be positioned with the tip in the inferior vena cava and not in a hepatic branch.
Bony structures	The skeleton should be evaluated, especially the general configuration of the thoracic cage. Normally, over time, the cephalic portion of the thoracic cage becomes rounded and the transverse diameter increases. Hyperaeration exaggerates cephalic rounding, and the horizontal position of the rib arcs. Hypoaeration reduces the diameter of the upper thorax and increases the inferior slope of the rib arcs (bell-shaped thorax). The radiograph must be evaluated for fractures, dislocations, hypodensities, or other lucencies. Persistent elevation of the scapula and an ipsilateral elevated diaphragm (which occur secondary to phrenic nerve injury) may accompany Erb's palsy. Scans should be done for vertebral, rib, and other bony anomalies. Rib aplasia is associated with hemivertebrae, and complete or partial aplasia of the clavicles may be a manifestation of chromosomal abnormality. The proximal humeri can yield information related to congenital infections such as in rubella, syphilis, and cytomegalovirus infection. The bone density should be evaluated in relation to film penetration.

AP, anteroposterior; NG, nasogastric.

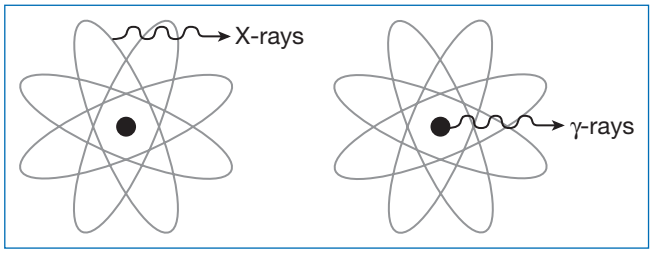

FIGURE I.8 X-rays are produced outside the nucleus of artificially excited atoms; gamma (γ) rays are produced inside the nucleus of radioactive atoms.

radioactive phosphonate agents used for skeletal scanning, and the maximum radiation dose is to the bladder mucosa (Dowd & Tilson, 1999; Treves, 1995). Promoting diuresis can reduce this dose effect. The radiation hazards in radionuclide imaging, therefore, are affected by the physiologic distribution of the agent and its physical half-life, the dose of radionuclide administered, and the pharmacologic half-life in the body (Dowd & Tilson, 1999; Treves, 1995).

Choice of Nucleotide. With nuclear diagnostic imaging, several factors help determine the amount of energy actually deposited in the tissue and may influence the choice of radionuclide. These factors include the following (Dowd & Tilson, 1999; Treves 1995):

- Route of entry
- Fraction of the administered dose that actually reaches the tissue
- Rate of biologic removal of the radionuclide
- Amount of radiation the tissue of interest receives from the portion of the radionuclide deposited in tissues other than the one of interest
- Number of microcuries of radionuclide taken in
- Careful calculation of the average energy of the beta particles emitted, of any ancillary gamma rays emitted, and of any loss of radiation out of the specific tissue
- Metabolic or other factors that might alter the distribution of the radionuclide in various tissues of the human population studied

Estimation of the true dose of energy delivered to a specific tissue by radionuclide exposure, plutonium contamination, or external x-ray exposure, therefore, involves serious technical considerations and requires the efforts of physicists skilled in such measurements.

Nearly all radionuclides used in medicine are artificially produced in nuclear reactors. The most versatile of these compounds is technetium 99m (^{99m}Tc), which has many ideal physical properties, including the following (Dowd & Tilson, 1999; Treves, 1995):

1. It is nontoxic and non-allergenic.
2. It is easily bound to other physiologic compounds.
3. It is relatively inexpensive.
4. It circulates in the blood, and small amounts accumulate in the gastric mucosa, salivary glands, and thyroid tissue.
5. It is excreted primarily in the feces and urine but can also be found in sweat and tears.
6. It does not accumulate in the brain (except in the choroid plexus) unless the blood–brain barrier has been disrupted.
7. It has a short physical half-life (6 hours), long enough for tests to be completed while allowing high initial radio activities to be administered within an acceptable radiation hazard.
8. It emits only gamma photons, which can be detected by the sodium iodide crystals of gamma cameras.

Despite the wide use of technetium, it is not suitable for all investigations, and a number of alternative isotopes are available (Box I.1).

The ideal instrument for detecting the radiation emission of the radionuclide is the gamma camera. With this camera, images are rapidly acquired and dynamic studies are easily performed and quantified. Multiple views from various projections can be obtained. The camera consists of a large crystal of sodium iodide protected by a heavy lead collimator. The shielded crystal is placed over the target organ, and the gamma photons emitted from the body strike it and are converted into light scintillations. The pinhole and converging collimators allow the image to be magnified without loss of resolution. These light scintillations are manipulated electronically to define the distribution and intensity of the radioactivity. The final copy of the image is produced on film or stored on videotape or magnetic disk (Alpen, 1998; Bushong, 2013; Dowd & Tilson, 1999; Treves, 1995).

Because radiopharmaceuticals are rarely organ specific, interference from radioactivity outside the organ of interest is always a factor. Advances in computer processing similar to CT have been developed to eliminate this interfering background data, thereby increasing the accuracy of derived data. Two types of computer-enhanced radionuclide imaging are available: single photon emission computed tomography (SPECT) and PET. Both modalities have significant advantages over conventional planar radionuclide imaging in that (1) the sensitivity and qualification of the distribution and density of radioactivity are much greater; (2) three-dimensional imaging is possible with computer reconstruction; (3) the dose of radionuclide is the same; and (4) artifactual lesions can be eliminated (Bellenger et al., 2000; Bushong, 2001; Lewis et al., 2000; Swischuk, 1995, 2003; Tierney, Varga, Hosey, Grafman, & Braun, 2001; Treves, 1995; Weissleder & Mahmood, 2001).

Single Photon Emission Computed Tomography. With SPECT, a gamma camera is rotated 360° around the infant, and a series of equally spaced, cross-sectional images is obtained and stored in the computer. These images are used to reconstruct a series of cross-sectional slices at right angles to the axis of rotation of the camera. Each cross-sectional slice comprises a series of squares arranged in a matrix. Using a mathematical model, the computer can readily reconstruct these cross-sectional slices in other planes, such as the lateral or coronal plane. The image is then viewed directly from the computer screen or formatted on film. This type of computer-enhanced emission tomography scan uses the standard gamma-emitting radionuclides such as technetium, thallium, gallium, and iodine (Lewis et al., 2000; Treves, 1995).

Positron Emission Tomography. With PET, a different type of radiopharmaceutical, called a positron, is used. Positrons are the same size and shape as electrons but have a positive charge. Typical positrons used in this type of imaging are carbon 11, oxygen 15, and nitrogen 13. Using the metabolic nucleotide from oxygen, carbon, or nitrogen, PET scans create images that depict the "metabolic" function of tissue such as the brain (Bushong, 2013; Dowd & Tilson, 1999; Lin, Laine, & Bergmann, 2001; Treves, 1995; Weissleder & Mahmood, 2001). SPECT is widely available for general use, but PET scanning is available only at large university medical centers with access to a cyclotron, which can produce the short-lived positrons required for this imaging modality. Continued advances in particle physics enhance the development of the technique as a research tool in the study of cerebral blood flow and physiology. The recent substitution of fluorine in the glucose molecule has been very useful in the study of cerebral metabolism in neonates after intracranial hemorrhage (Peterson et al., 2000; Rushe et al., 2001; Swischuk, 2003).

Although this modality is not used frequently in clinical medicine, nurses should understand its potential as a research tool.

Collaborative Care. The care of a neonate undergoing a radionuclide scan requires knowledge about the patient's history and clinical manifestations, the type of nuclear scan requested, and the radiopharmaceutical used. In general, the doses of radiopharmaceuticals are based on the infant's body weight, and the total whole-body irradiation is considerably less than that with a conventional radiograph. The infant poses no radioactivity hazard for the nursing staff or other neonates. Linen, diapers, and body excreta can be disposed of in the usual manner. Nurses should be aware that the radionuclide can concentrate in areas other than the organ of interest so that the proper agents for blocking thyroid iodine uptake can be administered or diuresis can be promoted.

Ultrasonographic Imaging

With neonates, ultrasonography is frequently used in the evaluation and treatment of internal anatomic structures. Unlike conventional radiography, ultrasonography does not involve the emission of ionizing radiation. Instead, sound waves are used to evaluate tissue densities, the movement of tissues, and blood flow (Bushong, 1999, 2013; Martin et al., 2015; Swischuk, 1995, 2003). The images can be recorded on videotape, photographic film, light-sensitive paper, or magnetic disk.

Biophysical Principles. By definition, ultrasound is any sound that has a frequency greater than 20,000 cycles/second (Hz), which exceeds the audible range of human hearing (20–20,000 Hz; Bushong, 2013). Ultrasonography uses high-frequency sound waves (3.5–10 MHz). For echocardiography and Doppler studies, the ultrasound frequencies range in the millions of cycles/second (Bushong, 1999). Ultrasonography has the following advantages as a diagnostic tool (Bushong, 1999, 2013; Martin et al., 2015; Swischuk, 1995, 2003):

1. It emits no ionizing radiation and has no known deleterious somatic or genetic effects; therefore, follow-up examinations may be repeated at will.
2. Ultrasound waves can be directed as a beam.
3. Sound waves obey laws of reflection and refraction.
4. Ultrasound waves are reflected by objects of small size.
5. Ultrasonography can be used in a variety of transverse, longitudinal, sagittal, or oblique planes.
6. Ultrasonography is considerably less costly than either CT or MRI.
7. Ultrasound equipment is easily portable.
8. The examination is relatively painless and well tolerated.
9. Sedation is rarely required.
10. Ultrasonography relies on acoustic impedance of tissue to demonstrate anatomy.
11. Ultrasonography is diagnostically accurate.

The following are the principal disadvantages of ultrasonography (Bushong, 1999, 2013):

1. It is operator dependent.
2. It does not provide as much information on organ function as urography.
3. It has limited value as a screening procedure for "acute abdominal distress"; rather, the examination should focus on a particular area of interest.
4. CT is superior in demonstrating the extent of disease, because ultrasonography demonstrates a smaller area of interest and less anatomic detail.
5. Bone, excessive fat, and gas artifacts adversely affect ultrasonography.

Because of these drawbacks, certain parts of the body, such as the brain, must be imaged through an ultrasound "window," such as the anterior fontanelle. In addition, because sound waves are poorly propagated through a gaseous medium, the transducer must have airless contact with the surface being examined, and parts of the body that contain large amounts of air are difficult to examine.

High-frequency sound passes through the body tissues at a fairly constant speed of approximately 1,500 m/second, or 1.5 mm/μsecond (Bushong, 1999, 2013). Using electronic mechanisms, it is possible to time the passage of an ultrasound impulse to within a fraction of a microsecond so that the distance between an ultrasound transducer and a reflecting interface of tissue can be determined to a fraction of a millimeter. The transducer converts electrical energy into ultrasonographic energy and acts as both the emitter of the initial impulse and the receiver of the reflected impulse.

The velocity of sound wave transmission is the product of the sound frequency and the wavelength. The speed at which sound is transmitted varies, depending on the density and compressibility of the medium (Bushong, 1999, 2013). The velocity of sound transmission is low in a gaseous medium because of the large compressibility and low density of the substance. Sound does not exist in the vacuum of outer space but is readily transmitted through objects of greater density, such as water or metal. This principle can be readily illustrated with the use of a tuning fork. When struck, the tuning fork vibrates and emits sound that can be easily heard. However, when the vibrating tuning fork is placed against the mastoid bone of the cranium, the sound is transmitted to the ear much more readily and is perceived as being louder.

Frequency and wavelength are inversely proportional in ultrasonography (Bushong, 1999, 2013). That is, as the ultrasound frequency increases, the wavelength decreases. The ability to distinguish objects of small size with ultrasonography is directly related to the sound wavelength. High-frequency ultrasonography uses short wavelengths and results in better image resolution than is seen with low-frequency, long-wavelength ultrasonography. This is the case because as the ultrasound frequency increases, the degree of interaction with the conducting medium increases, and absorption of the ultrasound beam is increased. Therefore, at higher ultrasound frequencies, less tissue penetration occurs. For example, ultrasound examinations of the eye typically use frequencies of about 10 MHz, whereas an examination of deep structures of the abdomen uses frequencies of about 2.5 MHz (Bushong, 1999).

The frequency-dependent characteristic of ultrasonography results in its highly directional and collimated nature, which enhances its imaging ability (Bushong, 1999). As the frequency of sound increases, its dispersion from the source is reduced and its transmission becomes more like that of a collimated beam. This becomes apparent when experimenting with a household stereo. The woofers produce a low-frequency bass sound that fills the entire room with sound. A person's perception of these low-frequency sounds does not change, no matter where the person stands in the room. However, the higher frequency sound produced by the tweeters does not disperse as well in the room and can best be heard when the person is positioned directly in front of the speakers. In addition, low-frequency sounds seem at times to penetrate and reverberate in the body, which is not true with higher frequency sounds.

These same principles govern ultrasound transmission through tissue. At higher ultrasound frequencies, the beam becomes more collimated in a forward direction. As the ultrasound frequency is increased, the ability to distinguish small objects increases, but the penetrability of the beam decreases. For these reasons, the highest

frequency transducer is chosen to provide the greatest depth for the tissue or organ images.

Ultrasonography is also useful as a diagnostic imaging method because it is reflected at tissue interfaces. A principle called sonic momentum describes the velocity of sound transmitted through tissue. Sound transmission through different tissues varies with sound velocity, the freedom of motion of the molecules (density), and the sound waves' compressibility. The way sound travels through a tissue is often referred to as the acoustic impedance of that tissue. As a sound wave travels through a homogeneous tissue, it continues in a straight line. When the sound wave reaches an interface between two tissues with different acoustic impedances, it undergoes reflection and refraction (Figure I.9; Bushong, 1999, 2013). The amount of sound reflected depends on the degree of difference between the two tissues; the greater the disparity, the greater the reflection. Diagnostic ultrasound has little interest in the refracted wave but is primarily interested in the intensity of the reflected beam relative to the original sound wave (Bushong, 1999, 2013).

The major patterns of ultrasound reflection are anechoic, echoic, and mixed. An anechoic structure, which is described as sonar lucent, is a structure in which the acoustic medium is homogeneous and the sound waves are unimpeded. An anechoic structure may be fluid filled (bladder), cystic (hydronephrosis), or solid (lymphoma), as long as the tissue is homogeneous. Cystic structures usually have sharp echogenic margins anteriorly and posteriorly. Echoic structures are inhomogeneous and reflect sound waves. These tissues are generally solid and have a variety of densities (typical Wilms' tumor) or may be cystic (hemorrhagic Wilms' tumor). A mixed pattern of reflections has the combined qualities of anechoic and echoic tissues. In addition, ribs and calculi may cause imaging artifacts on an ultrasonographic image. These dense structures prevent further penetration of the ultrasound beam and cause a band-like region of decreased sound transmission beyond that point, called acoustic shadowing (Bushong, 1999).

Applying these principles to clinical practice, it is known that ultrasound is propagated differently in various human tissues and is reflected from each acoustic interface (Bushong, 1999, 2013). A stationary interface results in a reflected ultrasound wave that has the same frequency as the transmitted wave. When the tissue interface is moving (e.g., the movement of red blood cells in a vessel), the reflected ultrasound wave has a shifted frequency directly proportional to the velocity of the reflecting blood cells, in accordance with a principle called the Doppler effect. If the movement of the blood cells is toward the transducer, the frequency of the reflected wave is higher than the transmitted frequency. Conversely, movement of blood away from the transducer results in a lower frequency of the reflected wave (Bushong, 1999, 2013). The difference between the transmitted frequency and the reflected frequency is called the Doppler shift. It is the principle of sound frequency shifts that allows the application of the mathematical relationship between the velocity of the target and the Doppler frequency to calculate flow. This is used most commonly in the echocardiographic evaluation of the heart and in cerebral blood flow determinations (Bushong, 1999, 2013).

Modes of Ultrasonography. Currently, there are five modes of ultrasonic imaging: two static modes (A-mode and B-mode), two dynamic modes (M-mode and real-time), and one Doppler mode. The two static and two dynamic modes use a pulse-echo transducer, which sends ultrasound waves for 0.0001 seconds and then waits for the reflected sound for 0.999 seconds. The first and most intense reflection of a sound wave occurs at the transducer–patient interface. At each succeeding tissue interface, the reflection of the sound wave diminishes in intensity as the tissue is penetrated.

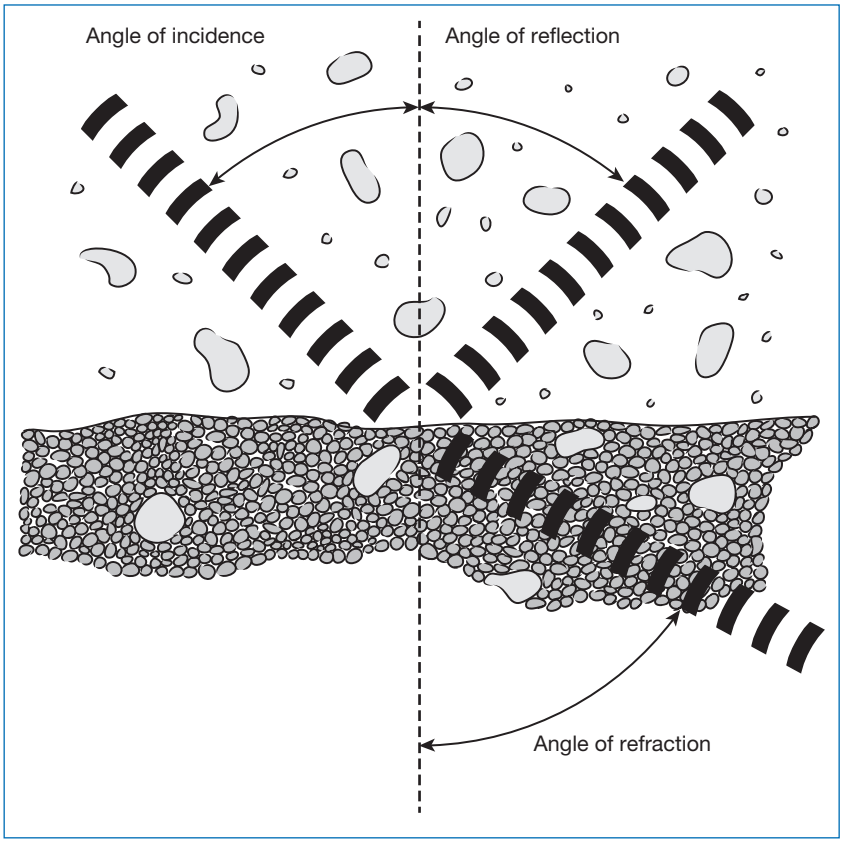

FIGURE I.9 The reflection and refraction of ultrasound.

The time required for the pulse to be reflected to the transducer and its returned intensity indicate the position of the interface; the reflection is indicated as a blip on the video display screen (Bushong, 1999, 2013).

In A-mode, ultrasonic images are displayed on the video screen as a series of vertical blips that represent the returning echoes. The distance between these blips is proportional to the distances between the tissue interfaces, and the height of each blip is proportional to the intensity of the reflected beam. Thus, distal reflections produce lower blips (Bushong, 1999). The main purpose of A-mode imaging is to measure depths of interfaces and to detect their separation accurately. A-mode ultrasonography is primarily used in echoencephalography to determine the cranial midline; it is also used for ultrasonically guided aspiration techniques such as amniocentesis. The advantages of A-mode are that it relies on axial resolution, it is relatively inexpensive, and it is easy to use. The primary disadvantage of this mode is that it requires frequent calibration (Bushong, 1999).

B-mode or brightness-mode ultrasonic imaging displays information as dots, with the brightness of the dot corresponding to the distance of the reflecting interface from the transducer (Figure I.10A and B). Advances in microcomputers and electromechanical coupling have resulted in a compound B-mode image (Bushong, 1999). This is achieved when the spatial position and direction of the ultrasound beam are coupled to the video display screen and the B-mode pulses are individually stored while the transducer is moved about the body. The image that appears on the video display screen, therefore, is the summation of many individual B-mode lines. The spatial resolution of this type of imaging varies considerably and depends on the transducer's characteristics and the electromechanical linkages available commercially. This mode of imaging has become widely used, especially for intracranial and abdominal examinations. The B-mode transducer can be moved linearly to provide a rectangular scan view, or it can be angled to provide a sector scan (Bushong, 1999).

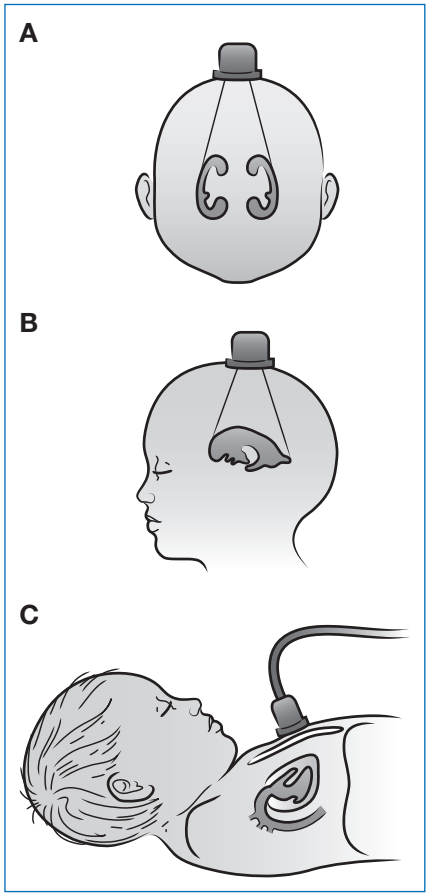

FIGURE I.10 (A) Ultrasound display pattern defining the sagittal sections of ventricular shape and size using brightness (B-mode) imaging. (B) Ultrasound display pattern defining the shape and size of lateral ventricles in the neonate using B-mode imaging. (C) M-mode ultrasound display pattern produces a strip chart for tracing moving tissue interfaces such as appear in the heart.

M-mode, or motion mode, is an imaging process that incorporates pulse-echo ultrasonography to define tissue movement. If an ultrasound transducer is operated in A-mode over the heart, it detects a number of vertical blips from stationary objects, which indicate the motionless interfaces of the tissue. The amplitude of these blips is proportional to the intensity of the echo. The magnitude of the moving objects represents the degree of movement of tissue interface. If this A-mode scan is converted into a B-mode scan, the image is transformed into a number of dots, some of which are fixed and some of which are moving. If this image is driven on the x-axis according to time, as in a chart recording, a tracing of the dots results (Figure I.10C). The stationary dots trace a regular pattern according to the motion of the tissue interface. The y-axis is the depth of the tissue plane. This type of imaging is used primarily to monitor heart function and can be synchronized with the electrocardiograph (Bushong, 1999).

Real-time ultrasonic imaging is another dynamic form of examining tissues. Real time is considered the ultrasonic fluoroscope and has several advantages over B-mode imaging, including the following:

1. Real-time ultrasonography units cost considerably less than B-mode units.
2. Acquisition of real-time images is much less dependent on operator skill.
3. Real-time examinations take less time because the imaging technique is relatively easy.
4. Portable versions of real-time units are readily available.

The transducer used for real-time ultrasonography is longer than the one used for B-mode imaging; therefore, more gel is needed. The real-time transducer is moved over the surface until the anatomic region of interest is found. The dynamic image is recorded on videotape, and the examiner obtains stop-action frames by taking sequential photographs of the display. The disadvantages of real-time ultrasonography are that (1) the ultrasound beam interacts with tissue interfaces from only one direction, whereas B-mode transducers can move while storing the image from many directions, and (2) lateral resolution is superior in B-mode imaging compared with real-time imaging (Bushong, 1999).

The popularity of real-time ultrasonography as an imaging modality has generated three types of real-time transducer devices—mechanical, linear array, and phased array—with displays that have distinct characteristics. The mechanical transducer was the first real-time device developed. This transducer is motorized so that the ultrasound beam is mechanically swept across the field in an oscillating fashion. Each sweep results in one image frame, and as many as 15 frames/second can be obtained. The transducer can be moved linearly for a rectangular view or in an angulated fashion for a sector view (Bushong, 1999). The mechanical transducer was not popular in the early days of real-time ultrasonography because of the limitation of frame rate per second, restricted field of view, and distortion. In recent years, manufacturers have improved this transducer by increasing the frame rate, expanding the viewing field, and reducing the distortion.

The linear array transducer device has a line of 32 transducers aligned in a single case. Because each transducer is only 2 mm

wide, the overall length of the transducer case is 64 mm. In linear array, each transducer is energized in sequence from one to 32. This provides 32 image lines over the pulse of ultrasound, called sequential linear array. If four or five contiguous transducers are energized simultaneously, each pulse of the ultrasound results in four or five scan image lines, called segmental linear array. In a typical system, the transducers are fired in an overlapping pattern so that numbers 1 through 5, then 2 through 6, 3 through 7, and so on, are segmentally, then sequentially energized (Bushong, 1999). This type of transducer device provides for greater image line density and improved image quality over sequential linear array devices. As with the mechanical devices, sequential and segmental linear array devices have poor lateral resolution.

Phased-array real-time ultrasonic imaging is similar to linear array in that it incorporates segmental excitation of the transducer elements. The transducers are segmentally sequenced and have programmable electronic circuitry to incorporate delay lines, so that the excitation and reception of the ultrasound waves by each element can be timed precisely. This delay allows a plane of sound waves from the transducer to be directed, or "phased." The result is a sector scan with a maximum sector angle of 90° (Bushong, 1999). The scan line rate, frame rate, and depth of scan can be selected. The electronic delay lines on the receiver circuitry allow some depth of focusing through synchronization of the returning reflected pulses. The transducer size is smaller than with linear array, and axial resolution is good. As with real-time imaging, lateral resolution is poor but can be improved with acoustic focusing.

Biologic Effects of Ultrasonography. Ultrasonic imaging was introduced into obstetric practice in 1966. Since that time, despite the widespread use of this imaging modality and the use of multiple scans during an individual pregnancy, there have been no reports of manifested injury or late effects in human beings (or fetuses) exposed to diagnostic levels of medical ultrasound (Bushong, 1999). In the laboratory, however, it has been shown that much higher levels of ultrasound can produce measurable tissue effects. The levels of ultrasound energy required to produce these effects are approximately 1,000 times greater than those used in diagnostic medical ultrasonography. In vitro, the mechanism of action of the ultrasonic effects on tissue is presumed to be increased tissue temperature, cavitation, and various viscous stresses on the tissue (Bushong, 1999, 2013).

The thermal effects of ultrasonography occur because of the molecular agitation and relaxation processes caused by the passing sound waves (Bushong, 1999, 2013). Extremely high levels of ultrasound are required to produce even a measurable increase in tissue temperature. The effects of the elevation in tissue temperature occur not only with ultrasonography but also with fever or hyperthermia. At the local tissue level, significant changes in tissue temperature, regardless of the cause, result in structural changes in macromolecules and membranes and alter the rates of biochemical reactions. The thermal effects of diagnostic medical ultrasonography do not result in any increase in tissue temperature.

High levels of experimental ultrasound can also result in alteration in the structure and function of macromolecules and cells without an increase in tissue temperature. These changes can result from cavitation, which occurs when tiny bubbles of gas are formed during the molecular relaxation after sound wave agitation (Bushong, 1999, 2013). As the cavitation increases, more energy is absorbed from the incident ultrasound beam. This is thought to cause a disruption of molecular bonds and the production of free hydrogen and hydroxide radicals resulting from the dissociation of water vapor. Cavitation effects have not been observed with the levels of sound used in diagnostic medical ultrasonography (Bushong, 2013).

Every tissue has a specific density, and the density of tissues on either side of an interface may not be equal. As ultrasound waves interact along this tissue interface, the differences in density result in stress exerted on the tissue boundary. This tissue boundary stress results in small-scale fluid motions called microstreaming (Bushong, 1999). It is theoretically possible that microstreaming can disrupt membranes and cells in the region of the interface. Microstreaming has been observed in vitro only after exposure to extremely high levels of ultrasound.

Experimental evidence has shown that ultrasound in sufficiently high doses can degrade macromolecules and may produce chromosomal aberrations and cause cellular death. To induce these effects in living tissue, however, ultrasound intensities of 10 W/cm^2 exposure over considerable periods of time are necessary. The absolute minimum dose level that has been reported to have an observable effect in experimental specimens is 100 mW/cm^2, and even then only after many hours of continuous ultrasonographic application (Bushong, 1999, 2013). The intensity range of diagnostic ultrasound is 1 to 10 mW/cm^2, and examinations using this modality frequently require only a few minutes of ultrasound exposure. There are no reports of human chromosomal effects or of changes in prenatal or neonatal death rates after exposure to ultrasound, nor is there evidence that ultrasound induces latent malignant disease. Thus, the use of ultrasonic imaging has grown in all areas of medicine, and its uses in neonatal care are increasing rapidly.

Indications for ultrasonography in neonatal intensive care commonly include evaluation of brain parenchyma and ventricular size, myocardial function and structure, cholelithiasis, choledochal cysts, intestinal duplication, renal neoplasms, urinary tract dilation and duplication, pelvic masses, and skeletal anomalies of the spine and hips (Martin et al., 2015).

Collaborative Care. The care of a neonate undergoing a diagnostic ultrasound examination ensures that any disruption of the infant's microenvironment is minimal. The infant's temperature can be maintained more easily if the ultrasound examination can be performed by using the transducer in the incubator. Although this method is technically more cumbersome for the ultrasonographer, cooperation between the ultrasonographer and the nurse facilitates the procedure. The transducer gel should be warmed to the same temperature as the infant's incubator to minimize heat loss. Heat loss caused by wet blankets or skin can be reduced by placing a diaper or some other pad under the imaged area, as well as by removing the gel quickly and drying the skin after the scan.

Having an understanding of the imaging examination to be performed allows the nurse to more accurately position the infant and move electrodes, tape, or other artifacts that limit the surface area to be scanned. The nurse's assistance in performing an ultrasound examination is important for monitoring the infant's tolerance of the procedure and for providing information that may be of diagnostic importance to the ultrasonographer. In addition, the nurse's presence at the bedside allows for immediate visual feedback and interpretation of the extent of the pathologic condition that may be present. This knowledge enables the nurse to better support the infant's parents as they make decisions on further diagnostic testing and treatment after their discussions with the medical staff. Interaction with the ultrasonographer at the bedside may also help the nurse to anticipate the infant's immediate and long-term future healthcare needs.

Magnetic Resonance Imaging

The theoretic basis for MRI is a development of research conducted since the 1940s for studying atomic nuclear structure, which resulted in the awarding of the Nobel Prize for physics in 1952 to

Edward Purcell and Felix Block. In addition to the advances in atomic nuclear research, other developments were necessary, such as superconductivity and advances in computer programming, before this concept could be applied to diagnostic imaging.

As an imaging modality, MRI has several advantages over CT and ultrasound (Bushong, 2003, 2013; Huda, Chamberlain, Rosenbaum, & Garrisi, 2001; Lansberg, O'Brien, Tong, Moseley, & Albers, 2001; Peled & Yeshurun, 2001; Schierlitz et al., 2001):

1. Like ultrasonography, MRI does not use ionizing radiation to produce the image, but rather uses magnetic fields and radio waves.
2. The magnetic resonance image depends on three separate molecular parameters that are sensitive to changes in structure and bioactivity rather than on x-ray photon interaction with tissue electrons as in CT.
3. The region of the body imaged with MRI is not limited by the gantry geometry, as it is with CT, but can be controlled electronically, allowing imaging in transverse planes and in true sagittal, coronal, and oblique planes.
4. Magnetic resonance images are free of the high-intensity artifacts produced in CT scans by sharp, dense bone or metallic surgical clips.

The principal disadvantages of MRI are its high cost and limited availability. Its use for clinically unstable infants on life support is also restricted because the strong magnetic field can interfere with monitoring devices, and access to the infant is limited during the procedure (Lansberg et al., 2001; Peled & Yeshurun, 2001; Schierlitz et al., 2001; Swischuk, 1995, 2003).

Despite the disadvantages of MRI, its clinical applications are rapidly expanding. The image quality is excellent, with the advances in the use of surface coils, and more sensitive head and body coils allow structures such as cranial nerves and small joints to be evaluated more precisely. The increased use of gating, fast scanning, and diffusion-weighted and magnetization transfer imaging have improved MRI evaluation of many tissues and structures and have identified many pathologic conditions that previously could not be quantified (Bushong, 2001; Fogel, Rychik, Chin, Hubbard, & Weinberg, 2001; Huppi et al., 2001; Nolte, Finsterbusch, & Frahm, 2000; Sinson et al., 2001; Swischuk, 1995).

Biophysical Principles. All particles in an atom have either a positive or a negative charge, or a "spin," like a tiny spinning top. The total spin of the protons and neutrons on the nucleus is the sum of the individual spins. Moving charges create magnetic fields; thus, the nucleus of an atom develops north and south magnetic dipoles (Bushong, 2003, 2013; Dowd & Tilson, 1999; Juhl et al., 1998). In most materials such as soft tissue, these little spinning magnetic dipoles are randomly oriented (Figure I.11A). This random orientation causes all the spins and magnetic forces to cancel in the material so that the net magnetic force is zero. However, if the material is placed in a strong magnetic field, the magnetic dipoles align themselves, much like a compass needle aligns itself with the Earth's magnetic field. The alignment of these magnetic dipoles produces a net magnetic force or vector that is oriented parallel to the direction of the imposed magnetic field (Figure I.11B). Not all magnetic dipoles become aligned; some are in constant thermal motion so that nuclei are continually knocked out of alignment (Bushong, 2003, 2013; Juhl et al., 1998).

In MRI, the strong magnetic field is imposed to align the molecular magnetic dipoles, and radio frequency pulses are then applied. The known specific frequency of these radio waves displaces the net magnetic moment by an amount determined by the strength and duration of the pulse. The frequency is directly proportional to the strength of the magnetic field and is known as the resonant

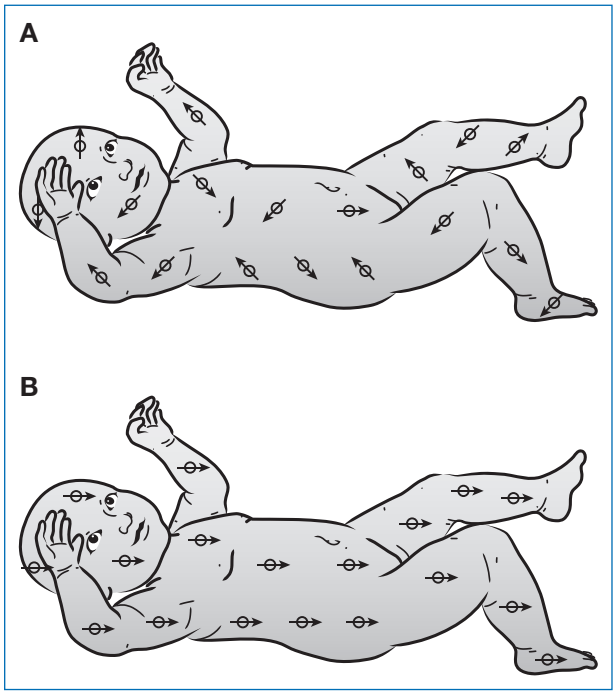

FIGURE I.11 (A) All the magnetic moments are randomly oriented in the body so that the net magnetic charge is zero. (B) Applied radio frequency pulses align the magnetic moments along a predetermined axis. The rate at which the atoms return to their "normal" magnetic moment after the radio frequency is stopped is characteristic for physiologic and pathologic tissues and is responsible for creating the magnetic resonance image.

frequency. After the pulse, the protons emit radio frequencies as they return to their original orientation. Therefore, the frequency of signals emitted by the protons after the application with radio frequency waves reflects their position in the tissue. Although in theory any stable nuclei can be used, hydrogen is the most abundant and has the strongest resonance (Bushong, 2003, 2013; Juhl et al., 1998).

When protons are placed in a magnetic field, proton alignment does not occur instantaneously but rather increases exponentially with a time constant characterized by T_1, or spin–lattice relaxation time, which reflects the interaction of the hydrogen nucleus with its molecular environment (Bushong, 2003, 2013; Juhl et al., 1998). T_1 characterizes the return of the net magnetization from its displaced position to its normal vertical position resulting from spin–lattice interactions. To form an image, the radio frequency pulses must be applied repetitively. After each radio frequency pulse, the net magnetic force of the sample is reduced; therefore, too rapid a radio frequency repetition depletes the magnetization of the tissue, and an image cannot be produced. Thus, radio frequency pulses are sequenced with a certain time interval to allow the magnetic force to be reestablished. The longer the time interval, the greater the magnetic force and the longer the imaging time required (Bushong, 2003, 2013; Juhl et al., 1998).

After exposure to the radio frequency pulse has occurred, the signal emitted from the sample of protons decays exponentially with a time constant referred to as T_2, or spin–spin relaxation time. T_2 reflects the magnetic interactions between protons. It characterizes the exponential loss of signal caused by dephasing or desynchronization of magnetic force, which results from spin–spin interactions (Bushong, 2003, 2013; Dort et al., 2001; Juhl et al., 1998). The interval between the application of a radio frequency pulse and the emitted signal depends on the alignment and synchronization of magnetic dipoles. A strong magnetic force results

in a long interval for the emitted signal after the pulse; this explains the contrast between tissues with different values of T_2 changes. T_1 is not equal to T_2, because each nucleus is not located within identical magnetic fields. Each hydrogen nucleus is subject to different local magnetic fields because of the presence or absence of other hydrogen nuclei (Bushong, 2003, 2013; Dort et al., 2001).

The third variable that affects image resolution with MRI is spin density. Spin density refers to the strength of the signal received from the nuclei before any of the decay processes have taken place (Bushong, 2003, 2013; Dort et al., 2001; Juhl et al., 1998). This strength is proportional to the number of nuclei within the detection volume of the scanner. Spin density is an indication of hydrogen concentration in the tissue.

A magnetic resonance image results from the mixture of these three properties (T_1, T_2, and spin density) unique to each tissue. The values of T_1 and T_2 for various tissues have been defined. A wide range of values exists among various types of tissue, and considerable differences have been documented between pathologic and normal tissue (Dort et al., 2001; Juhl et al., 1998). Each number defined for the relaxation times (T_1 and T_2) for various tissues depends on the primary external magnetic field and thus may vary from scanner to scanner. The visual projection of the magnetic resonance image is similar to that obtained in CT. By controlling the gradient field of radio frequency pulses, a series of projections at uniform angles through the tissue can be collected. The computer can then reconstruct the image and can emphasize the individual T_1, T_2, or spin density parameters to further define detail (Bushong, 2003, 2013; Dort et al., 2001; Juhl et al., 1998).

The spatial resolution of an MRI scan compares favorably with that of CT. If the object scanned is of high tissue contrast, a lesion as small as 1 mm can be defined. As more data is collected on this imaging modality, even greater spatial resolution and enhanced three-dimensional images are being obtained. As stronger magnetic fields are used, the emitted signals become stronger, and greater resolution may be possible using even higher radio frequency pulses (Bushong, 2003, 2013; Dort et al., 2001).

MRI is better able than CT to detect differences between low-contrast structures. The difference in T_1 and T_2 MRI between biologic tissues is frequently 10% or more. For example, on CT scans, the x-ray photon attenuation coefficient between gray and white matter is approximately 0.5%, whereas the differences in T_1, T_2, and spin density between gray and white matter are great, allowing for more accurate definition of these two tissues (Bushong, 2003, 2013; Dort et al., 2001). Thus, MRI has become the diagnostic imaging mode of choice for certain neurologic conditions such as multiple sclerosis, cerebral infarctions, and periventricular leukomalacia. MRI may be useful in the early diagnosis of periventricular leukomalacia, before the characteristic cystic lesions have developed (Huppi et al., 2001; Krishnamoorthy, Soman, Takeoka, & Schaefer, 2000; Peterson et al., 2000; Sie, Barkhof, Lafeber, Valk, & van der Knaap, 2000; Tierney et al., 2001).

Safety of Magnetic Resonance Imaging. MRI scanning uses three kinds of fields associated with the imaging process: (1) a static, moderately strong magnetic field; (2) a switched, weaker magnetic field gradient; and (3) radio frequency waves. The energies associated with the imaging process are approximately 10^{-8} eV/quantum, which are too weak to cause ionization or breakage of chemical bonds (Bushong, 2003, 2013; Dowd & Tilson, 1999). Energies associated with body temperature elevations are 100,000 to 1 million times greater; therefore, these temperature effects are far more disruptive to chemical bonds than the energy associated with MRI (Bushong, 2003, 2013).

In the laboratory, biologic responses in animals, chromosomes, plant seeds, and molecular specimens have shown effects only after extremely high intensities of MRI energy. Long-term studies of human beings exposed to radio frequency waves have not demonstrated any deleterious effects (Bushong, 2003, 2013; Dowd & Tilson, 1999).

The hazards of MRI relate primarily to any ferromagnetic objects (e.g., tools, oxygen cylinders, watches, bank cards, pens, and paper clips) that are accelerated toward the center of the magnetic field. The magnetic propulsion of these objects can result in projectile damage; therefore, any patient with a pacemaker or an extensive metal prosthesis should be excluded from this imaging technique. In addition, MRI has not been fully tested with pregnant women.

Collaborative Care. The care of a neonate who requires an MRI scan includes careful preparation and elimination of any ferromagnetic objects brought near the magnetic field. The infant's condition must be clinically stable because the strong magnetic field affects some monitoring devices, and visualization of the neonate is impossible during the scan. Surface respiratory monitors and possibly an esophageal stethoscope may be used. An MRI scan is degraded by motion; therefore, the infant must be positioned comfortably and safely in the magnetic cylinders. Because the infant must remain motionless for several minutes, an MRI scan is best done after the infant has been fed and is sleeping. If the infant is unable to remain motionless for the duration of the scan, oral chloral hydrate sedation may be recommended.

LABORATORY VALUES

A wide variety of laboratory tests can be used in both the diagnosis and care of the newborn. The values given in this chapter represent the broader normal ranges, but values in a specific chapter may vary slightly, depending on the range the author considers to be within normal limits. Every attempt has been made to provide consistent diagnostic and laboratory values. However, many hospitals have compiled their own lists of acceptable laboratory test values; therefore, specific laboratories should be contacted when evaluating results (Tables I.3–I.16).

CARDIAC PROCEDURES

Electrocardiography

Electrocardiography is a noninvasive diagnostic tool used with neonates. It is most useful in the diagnosis and management of cardiac arrhythmias or in conjunction with other diagnostic measures to evaluate cardiac function, specifically the circulatory demands placed on individual heart chambers. In the neonatal period, however, electrocardiography is less helpful in evaluating cardiac anomalies associated with significant ventricular enlargement (Flanagan, Yeager, & Weindling, 2015).

Echocardiography

Echocardiography, another noninvasive diagnostic procedure, is commonly used in the evaluation of the structure and function of the heart. This information can be important not only in the preoperative assessment of cardiac defects but also in the postoperative evaluation of procedures. High-frequency sound waves send vibrations to the structures in the heart, which reflect energy, which is transmitted into a visual image. Echocardiography may be used prenatally as early as 11 weeks' gestation when used transvaginally or 18 weeks' gestation when used transabdominally (Erenberg, 2011).

Single dimension echocardiography allows the evaluation of anatomic structures, including valves, chambers, and vessels.

TABLE I.3

COMMON ELECTROLYTE AND CHEMISTRY VALUES

Parameter	Normal Value
Serum Electrolytes	
Sodium (Na)	135–145 mEq/L
Potassium (K)	4.5–6.8 mEq/L
Chloride (Cl)	95–110 mEq/L
Carbon dioxide (CO_2)	20–25 mmol/L
Serum Chemistries	
Blood urea nitrogen (BUN)	6–30 mg/dL
Calcium (Ca)	7–10 mg/dL
Creatinine (Cr)	0.2–0.9 mg/dL
Glucose (G)	40–97 mg/dL
Magnesium (Mg)	1.5–2.5 mg/dL
Phosphorus (P)	5.4–10.9 mg/dL

TABLE I.4

NORMAL HEMATOLOGIC VALUES

	Gestational Age (Weeks)		Full-Term Cord Blood	Day 1	Day 3	Day 7	Day 14
Hemoglobin (g/dL)	28	34	16.8	18.4	17.8	17	16.8
Hematocrit (%)	14.5	15	53	58	55	54	52
Red cells (mm^3)	45	47	5.25	5.8	5.6	5.2	5.1
MCV (μm^3)	4	4.4	107	108	99	98	96
MCH (pg)	120	118	34	35	33	32.5	31.5
MCHC (%)	40	38	31.7	32.5	33	33	33
Reticulocytes (%)	31	32	3–7	3–7	1–3	0–1	0–1
Platelets ($\times 10^3/mm^3$)	5–10	3–10	290	192	213	248	252

MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume.

Two-dimensional echocardiography provides more in-depth information about the relationships between the heart and the great vessels (Flanagan et al., 2015).

Doppler echocardiography is used in various forms in the evaluation of characteristics of blood flow through the heart, valves, and great vessels. It can measure not only cardiac output but also flow velocity changes, as demonstrated in stenotic lesions. Regurgitation through insufficiently functioning valves can also be identified. Doppler studies can be used to show regurgitation through insufficiently functioning valves or to identify shunting, as through a patent ductus arteriosus (Bansal, 2015).

Cardiac Catheterization

Historically, cardiac catheterization in the neonate was used for the diagnosis of congenital heart disease. With the advent of more sophisticated echocardiography, especially Doppler echocardiography, cardiac catheterization is used increasingly as a therapeutic modality. The use of radiopaque dye allows for clarification of congenital heart disease and helps to provide data that cannot be obtained from echocardiography.

Immobilization and constant monitoring of the neonate are required during cardiac catheterization. The infant must be

restrained to maintain supine positioning. Electrocardiographic electrodes must also be placed to provide constant monitoring of vital signs. Sedation may be considered to maintain proper positioning during the procedure.

A local anesthetic is administered at the insertion site. A radiopaque catheter is inserted into an arm or leg vessel by percutaneous puncture or cut-down. Under fluoroscopy, the catheter is visualized and passed into the heart. Contrast medium is injected through the catheter to allow visualization of the various cardiac structures. Selected chambers and vessels of the heart can be evaluated for size and function. Intracardiac pressures and oxygen saturations can also be measured during this procedure. The use of balloons during catheterization can facilitate procedures such as septostomy, angioplasty, and valvuloplasty (Erenberg, 2011; Flanagan et al., 2015).

After the necessary information has been obtained, the catheter is carefully removed. If a cut-down was performed, the vessel is ligated and the skin is sutured. Pressure should be applied over a percutaneous puncture site to enhance clot formation. For continued bleeding problems, pressure dressings may be applied to the insertion site; these must be checked frequently for active bleeding. After cardiac catheterization, the vital signs should be measured frequently and compared with precatheterization baseline values. Evaluation of localized bleeding or of signs of hypotension resulting in changes in heart rate and blood pressure is essential. Assessment of the insertion site and affected extremity for bleeding, color, peripheral pulses, temperature, and capillary refill should continue for at least 24 hours after the procedure. In addition, the nurse must monitor for complications of catheterization, including hypovolemia (as a result of bleeding or fluid loss during the procedure), infection, thrombosis, or tissue necrosis.

GENETIC TESTING

Chromosome Analysis

High-Resolution Karyotyping and Banding. Analysis of chromosome composition can assist in the identification of various genetic disorders. A blood specimen is obtained from the infant and used to harvest an actual set of chromosomes. During active cell division, usually during metaphase, the chromosomes are photographed and then arranged in pairs by number. The chromosomes are also separated into regions, bands, and subbands. The end result, a karyotype with banding, is evaluated for the appropriate number of pairs, chromosome size, and structure. Specific genetic disorders can be associated with abnormal numbers of chromosomes (e.g., trisomy 21) or an abnormal chromosome structure, as in cri du chat syndrome, which reflects the loss of part of the short arm of chromosome 5 (Kuller & Cefalo, 1996). Abnormal genes on the chromosomes can also cause genetic disorders, such as Duchenne muscular dystrophy, an X-linked recessive disorder.

High-resolution karyotype is widely used for infants with multiple congenital anomalies. This test consists of analysis of chromosomes from white blood cells. The cells are cultured, stimulated to divide, and cell division is halted with a mitotic inhibitor in the prometaphase stage. In this stage the chromosomes are at their longest length and the observed stained bands can reach 800 to 900. This test can take up to 2 weeks (Gomella et al., 2013).

Fluorescence in Situ Hybridization. Chromosomes can be further analyzed using fluorescence in situ hybridization (FISH) to detect syndromes that are not visible to the naked eye. The FISH process allows fluorescent-coated DNA probes to detect submicroscopic chromosomal deletions. It can be used with interphase and metaphase cells. This test is faster than high-resolution karyotyping (it still could take up to several weeks to complete). This test can provide a quick diagnosis to infants with trisomy 13, 18, 21, or Turner syndrome (Bajaj & Gross, 2015; Gomella et al., 2013; Martin et al., 2015; McLean, 2015).

Bone marrow cells may be analyzed for chromosomes if a more rapid evaluation is required. Skin fibroblast analysis is required when an infant has been transfused, making lymphocyte analysis inaccurate. In cases such as stillbirth, tissue biopsy specimens can be used for chromosome testing because viable lymphocytes are absent (Hamilton & Wynshaw-Boris, 2009).

Sweat Chloride Test

The sweat chloride test is used to evaluate for and confirm the diagnosis of cystic fibrosis. During the procedure the skin is stimulated with pilocarpine and a small electrical current for 5 minutes. The sweat is collected on a 2 × 2-inch gauze pad or filter paper for 30 minutes. Over this 30-minute period, 75 mg of sweat must be produced to ensure an appropriate sweat rate (National Committee for Clinical Laboratory Standards, 1994). A sweat chloride level below 40 mEq/L is normal. Levels between 60 and 165 mEq/L are considered diagnostic for cystic fibrosis (Wilford & Taussig, 1998). Sweat tests can be inaccurate if an inadequate amount of sweat is produced, if the sweat evaporates, or if the patient has edema.

Comparative Genomic Hybridization or Chromosomal Microarray Analysis

The comparative genomic hybridization (CGH) or chromosomal microarray analysis (CMA) detects chromosomal deletions or duplication; this cytogenetic technique is relatively new. CGH/CMA compares reference standard DNA to the patient's DNA through a fluorescent technique. This test compares hundreds of regions across the entire genome to assess for the number of differences. It commonly assesses for microdeletion and microduplication, subtelomeric, and pericentromeric regions (Gomella et al., 2013).

Newborn Screening

Every infant born in a hospital in the United States undergoes newborn screening. Newborn screening is done before leaving the hospital, usually about day 1 or 2. Some states require follow-up at about 2 weeks. All states are required to screen for at least 34 health conditions according to the March of Dimes (MOD, n.d.). In addition to a blood test, infants undergo a hearing test and cardiovascular screening (MOD, n.d.).

GASTROINTESTINAL PROCEDURES

Barium Enema

A barium enema is used in the evaluation of the structure and function of the large intestine. The diagnosis of disorders such as Hirschsprung disease and meconium plug syndrome can easily be supported by the use of this procedure.

For the enema procedure, either air or a contrast solution (e.g., barium sulfate) is instilled and a series of films are taken under fluoroscopy. The infant must be well restrained, starting in the supine position. As the contrast solution is instilled, its flow through the bowel is observed as the infant's position is changed. A series of abdominal x-ray films should be taken once the bowel has been filled with contrast solution. Follow-up films may also be necessary to document evacuation of the contrast solution from

the bowel. Evaluation of the bowel is essential after this procedure to prevent constipation or obstruction. Assessment of bowel elimination is an important nursing concern after barium enema.

Upper Gastrointestinal Series With Small Bowel Follow-Through

As with the barium enema, barium sulfate or some other water-soluble contrast solution is used for the upper GI series with small bowel follow-through. However, the contrast solution is swallowed so that the upper GI tract can be examined. The three main areas examined are (1) the esophagus (for size, patency, reflux, and presence of a fistula or swallowing abnormality), (2) the stomach (for anatomic abnormalities, patency, and motility), and (3) the small intestine (for strictures, patency, and function).

Follow-up x-ray films may be desirable to evaluate both the emptying ability of the stomach and intestinal motility as the contrast material moves through the small bowel. Again, care of the infant includes assessment of temperature and cardiac and respiratory status throughout the procedure. The nurse should be alert for reflux or vomiting, which can be accompanied by aspiration. Evacuation of contrast material from the bowel remains a concern after upper GI series with small bowel follow-through and should be monitored by the nurse. It is also possible for fluid to be pulled out of the vascular compartment and into the bowel, resulting in hypotension. It is imperative that the healthcare team assess the infant for signs of these complications.

Rectal Suction Biopsy

Rectal biopsy is a procedure commonly used to help determine the presence or absence of ganglion cells in the bowel (the latter condition is seen in Hirschsprung disease). Before a rectal biopsy, it is essential to obtain bleeding times, prothrombin time, partial thromboplastin time, and platelet counts, as well as a spun hematocrit, to ensure that the infant is in no danger of excessive bleeding.

The infant is positioned supine with the legs held toward the abdomen. Small specimens of rectal tissue from the mucosal and submucosal levels are excised with a suction blade apparatus inserted through the anus into the bowel. The section of the pathology department that deals with the composition of ganglion cells evaluates the specimens.

Care of the infant after rectal suction biopsy should focus on assessments for bleeding or intestinal perforation. These assessments should include evaluation of vital signs for increased heart rate or decreased blood pressure, fever, persistent guaiac-positive stools, or frank rectal bleeding.

Liver Biopsy

Open or closed liver biopsy may be required for neonates. Open liver biopsy is a surgical procedure that requires general anesthesia, whereas a closed liver biopsy may be done using local anesthesia. As with the rectal biopsy, coagulation studies are essential, including bleeding time, platelet count, and spun hematocrit. Preoperative care may include sedation of the infant, requiring frequent monitoring of vital signs. Throughout the procedure, assessment of vital signs is essential for identifying changes in hemodynamics or respiratory status. After the procedure, assessment of vital signs for signs and symptoms of hemorrhage is essential. Indications of hemorrhage include decreases in the hemoglobin and hematocrit, which makes laboratory monitoring an important element of post biopsy care. The biopsy site must be evaluated for signs of active bleeding, ecchymosis, swelling, or infection.

GENITOURINARY PROCEDURES

Cystoscopy

Cystoscopy permits direct visualization of the urinary structures, including the bladder, urethra, and urethral orifices, allowing diagnosis of abnormalities in the structure of the bladder and urinary tract.

Cystoscopy is performed using general anesthesia. Preparation of the urethral opening with an antiseptic solution is followed by sterile draping. The lubricated cystoscope is inserted through the urethra, and the urinary structures are examined.

As with any patient who has had anesthesia, postprocedural care includes vital sign assessment. However, particular attention should be paid to assessing for adequate urinary output, the presence of hematuria, and signs of infection (Pagana & Pagana, 2013).

Excretory Urography and Intravenous Pyelography

Excretory urography and intravenous pyelography complement cystoscopic evaluation because they allow the examiner not only to evaluate structures but also to focus on the function of those structures. Small amounts of contrast media are injected by the intravenous route, and as the contrast material is excreted through the urinary system, a sequence of x-ray films is taken. The configuration of organs and the rate of excretion of the contrast media are reflected in these films.

Excretory urography and intravenous pyelography are relatively safe for use in neonates and should cause no postprocedural complications.

Voiding Cystourethrogram

The purpose of a voiding cystourethrogram is to visualize the lower urinary tract after instillation of contrast media through urethral catheterization. The infant's bladder is emptied after catheterization and then filled with the contrast media. Serial films under fluoroscopy in a variety of positions are taken during voiding. After voiding, additional films are obtained. Pathologic results of a voiding cystourethrogram demonstrate residual urine in the bladder, such as with a neurogenic bladder, posterior valve obstructions, or vesicoureteral reflux.

As with cystoscopy, the infant should be evaluated for hematuria; the baby should also be checked for signs of infection (fever, cloudy or sedimented urine, foul-smelling urine) in the event of contaminated catheterization.

Electroencephalography

An electroencephalographic examination records the electrical activity of the brain. Numerous electrodes are placed at precise locations on the infant's head to record electrical impulses from various parts of the brain. This procedure can be important for diagnosing lesions or tumors, for identifying nonfunctional areas of the brain, or for pinpointing the focus of seizure activity.

The infant may require sedation during this procedure to prevent crying or movement. As much equipment as is safely possible should be removed to reduce electrical interference. Also, calming procedures, such as reducing light stimulation or warming the environment, may help quiet the infant during electroencephalography. The infant should be closely observed throughout the procedure for any signs of seizure activity.

RESPIRATORY PROCEDURES

Pulse Oximetry

Pulse oximetry is a widely used, noninvasive method of monitoring arterial blood oxygenation saturations (Sao_2). The Sao_2 is the ratio of oxygenated hemoglobin to total hemoglobin. A single probe, attached to an infant's extremity or digit, uses light emitted at different wavelengths, which is absorbed differently by saturated and unsaturated hemoglobin. The change in the light during arterial pulses is used to calculate the oxygen saturation. Pulse oximetry saturations reflect a more accurate measure of actual hemoglobin saturation. Saturations obtained by blood gas sample are calculated using a hemoglobin of 15% (Goetzman & Wennberg, 1999).

Proper placement of the probe should be assessed regularly because movement, environmental light, edema, and diminished perfusion can reduce the accuracy of readings. The probe should be rotated every few hours to prevent skin breakdown at the site.

End-Tidal Carbon Dioxide Monitoring

End-tidal carbon dioxide (CO_2) monitoring is used routinely in pediatrics and in adult ICUs. Its use in neonates, especially the smaller baby, is not yet practical as a continuing therapy because the adapters are heavy and create excess dead space in the ventilator system. End-tidal CO_2 monitoring is most useful during intubation procedures for determining if endotracheal intubation rather than esophageal intubation has occurred (Goetzman & Wennberg, 1999; Yorgin & Rhee, 1998).

Bronchoscopy

Bronchoscopy of the newborn is performed to visualize the upper and lower airways and to collect diagnostic specimens. The procedure can be done in the NICU using a flexible bronchoscope, or it can be performed under general anesthesia in the operating room using either a flexible or rigid bronchoscope. The flexible bronchoscope is preferable for examining the lower airways of an intubated patient or for examining a patient with mandibular hypoplasia. A rigid bronchoscope is more advantageous in situations requiring removal of foreign bodies and for evaluation of patients with H-type tracheoesophageal fistula, laryngotracheoesophageal clefts, and bilateral abductor paralysis of the vocal cords (Wood, 1998). Examination of structures by direct visualization provides the opportunity to identify congenital anomalies, obstructions, masses, or mucous plugs and to evaluate stridor or respiratory dysfunction.

Bronchoscopy done at the bedside requires the nurse to assist with positioning, sedation, and monitoring of vital signs. Whether the infant undergoes flexible or rigid bronchoscopy, respiratory and cardiovascular monitoring should be continued in the immediate postprocedural period. Possible complications related to these procedures include bronchospasm, laryngeal spasms, laryngeal edema, or pneumothorax or bradycardia resulting in hypoxia.

SUMMARY

Marked technical advances over the past two decades have produced a variety of imaging methods for the diagnosis, treatment, and evaluation of neonates. Sizable expenditures have been directed toward improving image presentation and quality on the assumption that a trained clinical eye can make diagnostic use of the data provided. Investigations are useful only insofar as they reduce the diagnostic uncertainty. The final product of any radiologic imaging procedure is not a set of photographic pictures, but a diagnostic opinion that should be beneficial to the infant's management. Before initiating any imaging method, physicians should consider whether further information is really needed, and they should select the imaging technique that will give the required information with sufficient reliability and with minimal risk to the patient. The value of any diagnostic imaging examination must be balanced against the potential hazards. In addition to care of the newborn during and after a procedure, nursing care of newborns and infants undergoing diagnostic procedures requires a knowledge of the expected outcomes and methods so that the best result possible is obtained. Nurses must also be knowledgeable about normal values for the laboratory tests commonly used in the care of newborns and infants.

Guidelines for Supporting Skin-to-Skin Contact in the NICU

Raylene M. Phillips

11

INTRODUCTION

Continuous skin-to-skin contact (SSC) with the mother is the normal environment and developmental expectation for all newborns (Bergman, 2014). The first few days after birth are a critical period for many physiologic and neurologic processes that occur during the complex and multifaceted adaptation to post-uterine life for both the baby and the mother. Some of these neurological processes occur only during the first day after birth, and if they are not allowed to occur, the window of opportunity is missed (Bartocci et al., 2000). Continuous SSC with the mother is how physiologic and hormonal regulation is designed to occur for the newborn and very young infant, as documented in both animal and human studies (Chi Luong, Long Nguyen, Huynh Thi, Carrara, & Bergman, 2016; Gallagher, 1992; Hofer, 1994).

Most term and preterm babies are more stable in SSC with the mother after birth than in any other location (Bergman, Linley, & Fawcus, 2004; Chi Luong et al., 2016). The mother's body is designed to be the regulator of the baby's physiologic stability and has been shown to do so even for babies born prematurely (Bergman et al., 2004; Chi Luong et al., 2016; Feldman, Rosenthal, & Eidelman, 2014; Hofer, 1994; Parmar et al., 2009). Separation, or the absence of contact with the mother's or a primary caregiver's body, induces stress, dysregulation, and even neurologic changes in infant mammals (Arabadzisz et al., 2010; Loman & Gunnar, 2010; Michelsson, Christensson, Rothganger, & Winberg, 1996; Morgan, 2013; Reite, Seiler, & Short, 1978; Sabatini et al., 2007; Shonkoff et al., 2012). This stress is accompanied by high levels of cortisol, which, if prolonged, leads to toxic stress, defined by Shonkoff as "stress in the absence of the buffering protection of adult support" (Shonkoff, 2010, p. 360). Due to the stress and dysregulation that results whenever babies are apart from the mother or another primary caregiver, Dr. Nils Bergman strongly advocates for a policy of zero separation except in the case of life-threatening emergencies, surgical procedures, or severe medical instability (Bergman, 2014, 2015). The need for SSC to support physiologic stability and neuroprotection is inversely proportional to gestational age. Babies born prematurely require SSC to maintain stability and continue gestational maturation. The process of mother–infant bonding and attachment is intricately linked to SSC (Hofer, 2006). If the mother is unavailable, the father or another primary caregiver can prevent toxic stress and provide many of the benefits of SSC. Although continuous SSC is necessary for optimal normal development, even intermittent SSC provides well-documented short- and long-term benefits for babies and parents (Conde-Agudelo & Diaz-Rossello, 2014; Kirsten, Bergman, & Hann, 2001; Mooncey, Giannakoulopoulos, Glover, Acolet, & Modi, 1997; Welch et al., 2014).

Monitoring, nursing, and medical care, as well as many procedures, can be done during SSC. Babies can receive the same excellent medical and nursing care on the mother's body rather than in an incubator, on a bed, or on another surface (Bergman, 2015; Nyqvist et al., 2010). It is well documented that SSC reduces signs of pain during painful procedures (Gray, Miller, Philipp, & Blass, 2002; Johnston et al., 2003). Skin-to-skin contact can be done safely during transport from place to place within the hospital and even from hospital to hospital, and the baby will be more physiologically stable while in SSC (Sontheimer, Fischer, & Buch, 2004). If the mother is not available, the father or another primary caregiver can provide SSC during transport.

If the baby shows signs of instability during SSC, an assessment should be done during SSC and adjustments made as needed. Staff must be able to recognize preterm behavioral signs of stress and dysregulation and know how to respond appropriately. Parents should also be taught how to recognize their baby's signs of stress and how to respond (Als, 1984). SSC should only be discontinued if instability does not resolve after appropriate adjustments are made.

Parents should have round-the-clock access to their baby without limitations or restrictions. Parents need facilities to support their presence for continuous or prolonged SSC and for participation in their baby's care, including a place to sleep, access to food and drink, and whatever is needed for activities of daily living while their baby is in the NICU (Craig et al., 2015; Hall, Phillips, & Hynan, 2016; Nyqvist & Engvall, 2009; Sanders & Hall, 2018).

SSC supports early and exclusive breastfeeding (Bramson et al., 2010; Mikiel-Kostyra, Mazur, & Boltruszko, 2002; Nyqvist, 2008; Uvnas-Moberg, 2003). Mothers need support to initiate milk expression in the first hour and ongoing support to maintain an adequate milk supply. Even very premature babies are able to suckle when in continuous SSC with mother and may begin suckling as early as after a 29-week gestation period. As they mature, suckling becomes breastfeeding. SSC supports early discharge due to

increased stability and earlier full feedings (Nyqvist et al., 2010). Appropriate follow-up is essential (Penalva & Schwartzman, 2006).

It is vitally important that NICU staff from all disciplines actively and consistently promote SSC and encourage parental involvement in their baby's care. NICU staff must be given the education and training to effectively help parents understand how important they are to their baby's short- and long-term well-being (Chia, Sellick, & Gan, 2006; Ludington-Hoe, Morgan, & Abouelfettoh, 2008; Wallin, Rudberg, & Gunningberg, 2005). Parents should be offered adequate support for physical, psychological, and mental well-being and should have access to psychosocial support from a psychologist or other mental health professionals if needed or desired (Craig et al., 2015; Hall et al., 2016; Nyqvist et al., 2010; Nyqvist & Engvall, 2009; Sanders & Hall, 2018).

PREREQUISITES

There are no gestational limits to SSC. The only prerequisite is that the baby's skin be intact enough for handling without damage. If the baby is not receiving continuous SSC, parents should be available for a minimum of 60 minutes of SSC to support the neurologic process occurring during an entire 60-minute sleep cycle (Ludington-Hoe et al., 2008). Prolonged sessions of SSC should be encouraged. If only intermittent SSC is occurring, parents may want to practice the transfer from the bed to the parent's chest with a doll before the first SSC session. Staff should be trained and comfortable with transferring small babies from the incubator to the parent's chest. For optimal safety, if the baby is not intubated and has no arterial line, at least one extra staff is needed to help with the baby's lines and tubes. If the baby is intubated and has an arterial line, ideally two extra staff are needed to help support the initiation of SSC.

CONTRAINDICATION

Contraindications to SSC are few. Babies with extremely immature, gelatinous skin should have minimal handling until the skin matures but will benefit from the parent's presence, smell, and voice. Babies with unhealed chest or abdominal surgical wounds will also benefit from the parent's presence, smell, and voice, as well as containment with the parent's hands. If a baby has an arterial line that is not well secured, SSC should be deferred until the line can be safely secured. When babies have significant physiologic instability and cannot tolerate the movement necessary for transfer from the bed to the parent's chest, they will benefit from the parent's presence, smell, and voice, and will often have a positive response to gentle, whole-hand, containing touch. Since there is an energy cost when transferring a very preterm infant from the bed to the parent's chest, if parents are available for less than 60 minutes, they should be encouraged to support their baby with their presence, smell, voice, and gentle containing touch.

INITIATION

Whenever possible, the newly born baby should be placed immediately on the mother's abdomen or chest where assessment, stabilization, and monitoring can be performed. Plastic wrap and/or a warmed blanket should be used to enhance warmth. Continuous positive airway pressure (CPAP) can be started, and monitoring leads placed while the baby is in SSC with the mother. If more extensive resuscitation must be done on a warming table, the baby should be returned to SSC with the mother as soon as possible. If the mother is unstable, the baby can be stabilized in SSC with the father or another primary caregiver. It is important to remember that the mother's body is designed to regulate newborn infants and being in SSC, ideally with the mother, is how newborns will stabilize in the most optimal manner. If SSC has not occurred in the delivery room, it should be done as soon as possible in the NICU if no contraindications are present.

During transfer from the delivery room to another location in the hospital, the baby should remain in SSC with the mother, father, or another primary caregiver using a gurney or wheelchair. Babies on mechanical ventilation can be transferred in SSC, as they will be more stable if they are in SSC with the mother, father, or another primary caregiver. The stress of separation from SSC is immediate and profound, resulting in decreased physiologic stability and increased cortisol levels. If the baby must be transferred to another hospital, the baby will be most stable during transport if in SSC with the mother, father, or another primary caregiver. All electronic monitoring can and should be done during transport in SSC.

POSITIONING

The baby should be wearing only a diaper and a hat and placed in a prone position on the parent's bare chest. The baby's head should be turned to the side by about 45° with the chin slightly extended. The baby's limbs should be flexed and placed in SSC on the parent's chest with the baby's hands near his/her face. A warmed wrap or blanket should be secured around the baby and the parent to keep the baby in place for comfort and safety, even when the parent is sleeping. The wrap or blanket should be tucked under the baby's feet to provide a foot boundary that will simulate the walls of the uterus. Neither the mother nor the baby should ever be left unmonitored but rather should be monitored continuously and observed regularly for comfort, stability, and safety.

EQUIPMENT

An adult bed in the NICU is ideal for continuous or prolonged SSC. When a bed is not available or feasible, a comfortable reclining chair should be available. Rocking chairs are not suitable for prolonged SSC. They are usually not as comfortable as a reclining chair and can be unsafe when used with an intubated baby, as the rocking motion can lead to inadvertent extubation. If the NICU does not have private rooms, a privacy screen should be used during the transfer of the baby to the parent's exposed chest. A warm wrap designed for SSC or a blanket should be used to secure the baby to the parent's chest, so that the baby will be safe, even when the parent is sleeping. Clips can be used to secure lines and tubes. A mirror is useful for the parent to be able to view the baby's face.

DURATION

Continuous SSC is the developmental expectation of all newborns and where they are usually the most stable. SSC should continue unless the baby becomes unstable and all measures to stabilize the baby while in SSC have been unsuccessful. The most common reason for transient instability is positioning, so the baby's position should be checked and adjusted if needed. The baby's airway, ventilation tubing, and IV sites should also be evaluated as well as the need for oral or nasal suctioning. If the baby remains unstable with apnea, bradycardia, desaturations, or hypotension in spite of these adjustments, the baby should be returned to the bed for further

evaluation and treatment and returned to SSC again as soon as possible when the instability has resolved.

To provide continuous or prolonged SSC, parents must be supported physically, mentally, and emotionally. Parents will need to trade off and can share SSC with a limited number of primary care providers designated by the parents. An adult hospital bed placed next to the baby's monitoring or ventilator equipment is ideal. A comfortable reclining chair with good back support is required if a bed is not available. If no reclining chairs are available, at a minimum, good back support and a footstool should be provided.

STAFF EDUCATION

Staff education and training about SSC are essential for NICU staff from every discipline that will be interacting with babies and/or parents. Staff education should be provided in a variety of learning formats such as classroom, online, written, and simulation. The multiple, well-documented benefits of SSC for babies and parents such as warmth, physiologic stability, neurodevelopment, breastfeeding, bonding/attachment, and love should all be included. NICU staff from all disciplines should recognize the importance of their own attitudes about SSC and the vital role they play in actively encouraging parents to provide SSC for their preterm or sick baby. They should also understand the importance of good hand hygiene for themselves and the need to teach parents how to perform effective hand cleaning. Staff should also be proactive in ensuring a quietly healing environment that includes an absence of loud noises, bright lights, or noxious scents (including tobacco and strong fragrance).

All NICU staff who might assist in transferring a baby from the incubator to the parent's chest should have hands-on practice/simulations doing both standing and sitting transfers utilizing a doll with tubes and lines. Theoretical knowledge is not enough, and it is important that these techniques be practiced in order to ensure safety during the actual process. Staff should know practical ways to position the baby to support comfort and stability, including placing babies' hands near their face, providing foot support, using a firm but gentle touch with the whole hand (rather than fingertips), and encouraging parents to softly talk or sing to their babies.

Staff should be able to recognize preterm infant physiologic and behavioral signs of discomfort, stress, and dysregulation and should not rely solely on the monitor to assess instability. In this way, small adjustments can be made to help prevent escalation of a problem. Physiological signs of stress or dysregulation include sudden changes in heart rate, respiratory rate, or color, and behavioral signs of stress or dysregulation include hiccups, yawning, limb or finger extension, arching, hypotonia, or eye eversion. It is the staff's responsibility to share this information with parents, so they can be partners in supporting their baby's comfort and stability.

PARENT EDUCATION

Parents also need education related to SSC in a variety of learning formats about the many benefits of SSC for both the baby and the parent, as well as the importance of continuous or early, frequent, and prolonged SSC. Parents need to understand just how important they are for baby's physical stability as well as emotional and neurologic development. They need education on how to effectively clean their hands and how important this is to their immune-compromised baby. They can be partners in maintaining a quietly healing environment free of loud noises, bright lights, and noxious scents. They should be taught ways to support their baby's comfort and stability with positioning support and firm, whole-hand touch as well as softy talking or singing to their baby. By learning to recognize their baby's signs of stress or dysregulation and applying what they learn about supporting the baby's stability, they will be actively parenting their baby and will be seen by staff and themselves as active partners in their baby's care. If continuous SSC is not being done from birth, parents should have an opportunity to practice standing or sitting transfers with a doll if desired.

TRANSFERS

If the baby is not in continuous SSC, a transfer from the incubator to the parent's chest will be necessary. Transfers of very preterm babies require a team approach and should not be done without assistance from another staff. This is especially important if the baby is intubated or has an arterial line. A standing transfer is preferred if the parent is able to safely stand, as this technique maximizes the baby's contact with the parent and, therefore, maximizes the baby's stability. Whether doing a standing or sitting transfer, it is important that all movements during transfer be done very slowly and gently as this will greatly contribute to the baby's stability. If the baby is safely secured to the parent's chest, there is no reason the parent cannot fall asleep during SSC, but both parent and baby should be monitored continuously while in SSC and be observed regularly for comfort, stability, and safety.

SUMMARY

Skin-to-skin contact with mother (or primary caregiver) has been studied extensively in both animal and human models. The benefits are undeniable and implementation is relatively simple and cost effective. SSC is every new baby's birthright and, baring extreme circumstances, it is our privilege and responsibility to be sure they receive it.

III

Developmental Care for the Sick and Preterm Infant

Caitlin Bradley and Christina Mahoney

INTRODUCTION

Temporary and permanent structural and functional limitations occur with prematurity and illness in the newborn period and are associated with morbidities such as positional deformities, cerebral palsy, cognitive issues, behavioral issues, inattention/hyperactivity, anxiety, social issues, emotional difficulties, and epilepsy (Glass et al., 2015). These morbidities increase in frequency and severity depending on diagnoses, gestational age at birth, and care management. Research demonstrates that developmental care is an effective method to support the premature and sick infant during a time of vital neurosensory development, leading to short- and long-term benefits, and perhaps diminishing morbidity (Altimier & Phillips, 2013, 2016; Cardin et al., 2015).

Since its inception in the 1970s, developmental care for the premature and sick infant has undergone significant evolution. The comprehensive benefits of developmental care are neuroprotective. Evidence demonstrates that neuronal cell death can be avoided, and the fragile brain can even heal with neuroprotective developmental care (Altimier & Phillips, 2013). The seven neuroprotective core measures used to frame this protocol are: (1) the healing environment, (2) partnering with families, (3) positioning and handling, (4) safeguarding sleep, and (5) minimizing stress and pain (6) protecting skin, and (7) optimizing nutrition (Altimier & Phillips, 2013). (For more information see Chapter 32, The Neonatal Intensive Care Unit [NICU] Environment).

NEUROPROTECTIVE CORE MEASURES

The Healing Environment

Altimier and Phillips (2013) define the healing environment as inclusive of the infants' total environment including the physical space they occupy, their safety, and sensory experiences. Ideally, the intrauterine environment integrates all these components, exposing the developing fetus to appropriate amounts of stimulus. The neurosensory system develops during the final 16 to 20 weeks of gestation; therefore, the development of the neurosensory system among premature infants is shaped by the NICU's ever-changing environmental and sensory stimuli. Instability in the NICU environment can be detrimental to the infant's developing neurosensory system (Graven & Browne, 2008). However, there are neuroprotective interventions that can be implemented by the multidisciplinary team and the infant's families that can mitigate the negative environmental and sensory stimuli and improve outcomes.

Physical space and ambient temperature are critical components to the general NICU environment. Traditional open-bay units cannot be tailored to an infant's individual needs, lack privacy, and prevent feelings of discharge readiness by family members (Meredith, Jnah, & Newberry, 2017; Winner-Stoltz et al., 2018). Inability to control temperature in the open-bay NICU design can result in hypo- or hyperthermia, increasing the infant's metabolic demand and impeding weight gain and healing. A neutral thermal environment (NTE) is one that leads to neither heat loss nor gain. Therefore, the environment should not increase the metabolic demand of the premature and sick infant. Monitoring temperature and maintaining ambient temperature is critical. Double-walled incubators are preferred to radiant warmers, as they perform several neuroprotective functions including reduction of convective heat loss, evaporative heat loss, and noise. Regardless of the exogenous heat source, temperature probes must be used to continuously monitor the infant's temperature. This serves several purposes: (1) the exogenous heat source can adapt to the infant's temperature, which prevents heat loss or gain, (2) reduction of hands-on, manual temperature checks, allowing clustered care, and (3) sleep disruptions to monitor temperature are minimized (Altimier, 2012).

NEUTRAL THERMAL ENVIRONMENT

Environmental temperature: 72°F to 78°F (22°C–26°C)
Infant temperature: 97.7°F to 99.5°F (36.5°C–37.5°C)

Source: From Altimier, L. B. (2012). Thermoregulation: What's new? What's not? *Newborn and Infant Nursing Reviews*, *12*(1), 51–63. doi:10.1053/j.nainr.2012.01.003

Inappropriate neurosensory stimuli can also alter development. The source of stimuli can be light, noise (sound), smell, taste, and/or touch. Excessive light in open-bay unit designs can lead to poor weight gain, eye damage, and sleep disruption and must be avoided (Meredith et al., 2017). In general, lighting should be limited to the guidelines found in Table III.1. When excess lighting is required for examinations and procedures, the infant's eyes must be shielded. This shielding can be accomplished using phototherapy goggles, a hat, or a soft washcloth. Further, dimming lights at night and providing brighter lighting during the day, as tolerated, is also recommended (Meredith et al., 2017; M. S. Rea & Figueiro, 2016).

The effect of noise on the developing brain has a dose–response relationship, with risks including interrupted sleep, stress, increased intracranial pressure, hearing loss, sleep disruption, and abnormal long-term behavior (Casavant, Bernier, Andrews, & Bourgoin, 2017; Edwards & Austin, 2016; Meredith et al., 2017). Approximately 25% of hearing loss identified during childhood is due to injury incurred during the intrapartum or perinatal period (Centers for Disease Control and Prevention, 2014). For NICU patients, a range of factors and exposures, including ischemia, infection, ototoxic medications, and others, represent risk factors for hearing loss (Stewart, Bentley, & Knorr, 2017). Modifiable risk factors include daily exposure to alarms, conversations, cellular telephones, and overhead announcements. The American Academy of Pediatrics (AAP) and the *Recommended Standards for Newborn ICU Design* recommend that mean noise levels in the NICU should not exceed 45 decibels; this level of noise is like the ambient noise in a quiet home or the level of noise experienced in light traffic (White, Smith, & Shepley, 2013).

Noxious smells and tastes represent another risk in neurosensory development for NICU patients. Examples of noxious smells include tobacco and strong perfumes. Commonly used NICU products that produce noxious smells and tastes include alcohol wipes and alcohol-based hand sanitizers (Altimier & White, 2019). Consequences of noxious smells and tastes include apnea, bradycardia, and tachypnea. Every effort should be made to minimize these life-threatening, exposure-elicited stress responses (Browne, 2008).

While there are many risks for the developing infant, evidence suggests that neuroprotective measures can improve care and reduce morbidity. Perhaps the intervention with the most potential for global improvement in neuroprotective care is modernizing the physical space. New NICU design and construction is focused on single-family rooms. Single-family rooms have many benefits for infants, their families, and the multidisciplinary team. Ambient temperature, light, and sound can be tailored for the infant's individual needs, to decrease stress and minimize sequela of negative stimuli (Meredith et al., 2017; Winner-Stoltz et al., 2018). Single-family rooms are reported to offer increased control of the environment without impeding the delivery of care (White, 2018). Single-family rooms provide private space for pumping breastmilk and quicker establishment of breastfeeding (Winner-Stoltz et al., 2018). Additionally, single-family rooms allow earlier independent functioning for the family and facilitate discharge readiness (Meredith et al., 2017; Watson, DeLand, Gibbons, York, & Robson, 2014).

Single-family room design is not only therapeutic for infants and families but is also an efficient workspace for the multidisciplinary team. Multidisciplinary teams express satisfaction with single-family rooms due to fewer interruptions in the delivery of care, which reduces errors (Winner-Stoltz et al., 2018).

TABLE III.1

LIGHTING STANDARDS RECOMMENDATIONS

Ambient lighting in the immediate care area	10–600 lux (e.g., dark to regular indoor lighting) Must have the ability to manually adapt lighting
Procedure lighting	2,000 lux (e.g., bright indoor lighting) Infant's eyes must be shielded
Ambient lighting in non-care areas	300 lux (e.g., dim indoor lighting)
Cyclic lighting	Windows with daylight access, and the ability to limit this light

Source: Rea, M. S., & Figueiro, M. G. (2016). The NICU lighted environment. *Newborn and Infant Nursing Reviews, 16*, 195–202. doi:10.1053/j.nainr.2016.09.009

Partnering With Families

The hospitalization of a newborn is often unexpected and a significant stressor to the family. Promoting an environment that fosters involvement, bonding, and education positively impacts both the infants and families (Craig et al., 2015). Family participation is the foundation to providing quality developmental care. Utilization of the family integrated care model supports family involvement in all aspects of their child's care through education, hands-on developmental care, and collaboration with the multidisciplinary team (O'Brien et al., 2013; Shoo & O'Brien, 2014). Programs should be in place to provide continuing education to staff on family-centered care practices and how to best support parents through education.

Education for parents begins on the first day of the NICU admission. Teaching families about their child's illness and care interventions empowers parents to make informed decisions for their child and conveys to them just how integral they are within the team (Maree & Downes, 2016). Staff should welcome families as the primary caregivers, answer questions, listen to concerns, and educate parents on the care of their infant (Altimier, Kenner, & Damus, 2015). Parents who feel included in their child's care will be more informed and become better advocates. Some NICUs have adopted parental involvement during team rounds, incorporating parents as a vital member of the team. Parents have reported positive benefits of being directly included in discussions and feel more knowledgeable about their child's care. Participation during rounds can lead to an increased understanding of their child's condition and can facilitate relationships with the healthcare team (Gustafson, LaBrecque, Graham, Tella, & Curley, 2016).

All members of the multidisciplinary team must aim to partner with families and provide a welcoming environment, with open visitation, and encourage interaction with their infants. It is important to develop a relationship of trust and support between healthcare staff and families. Strengthening these relationships has shown to reduce parental anxiety and can provide increased trust and confidence in the medical team (K. E. Rea, Rao, Hill, Saylor, & Cousino, 2018).

Facilitating skin-to-skin care (or kangaroo care) between the infant and family member is another way of integrating them into the care of their infant. Skin-to-skin care meets the environmental, proprioceptive (spatial awareness), and thermoregulatory needs of the premature and sick infant. It provides an ideal neutral thermal environment (NTE) and optimizes smell, taste, touch, and proprioception (Altimier & Phillips, 2016, 2018). Infants, wearing only a diaper, are placed on the bare chest of their family member. To minimize heat loss through skin that is not in contact with their

family member, gently warmed blankets are used to cover the infant's back and a hat is placed on his or her head.

When skin-to-skin care is not available or appropriate, and exogenous heat is required, family members can be encouraged to participate in care through other methods. Assist family members in the use of positional supports, a wearable blanket, or swaddling the infant. Providing the smell of family members can also be accomplished with the use of fabric items that have been held by family members.

Positioning and Handling

The gestational age and the severity of illness can necessitate medical interventions, procedures, frequent handling, and use of medical equipment that restricts proper positioning (Danner-Bowman & Cardin, 2015). Improper handling of premature and sick infants causes autonomic instability, as manifested by mottling, hiccupping, apnea, bradycardia, and oxygen desaturation. Improper or excessive handling may lead to poor weight gain secondary to excessive metabolic demands.

Preterm and sick infants must be handled using slow motion, while simultaneously maintaining the infant in a flexed/contained position. Staff should encourage hands-on care through skin-to-skin contact and proper positioning with guidance on infant behavioral cues and signs of stress. Research demonstrates that educating parents to identify stress signs reduces stress in their infants and is neuroprotective (Craig et al., 2015). Clustered-care or using the infant's wakeful cues to guide timing of handling is also important to minimize sleep interruptions.

Preventing problems associated with improper positioning of infants is often difficult and hindered by the patient's condition. Similar to handling issues, improper positioning can lead to both short-term and long-term consequences. Short-term consequences from improper positioning of infants include discomfort, poor sleep, limb and joint deformities, autonomic instability, poor weight gain, and positional head deformities (Hunter, Lee, & Altimier, 2015; Jeanson, 2013). The most prevalent head shape deformities among NICU patients are scaphocephaly, plagiocephaly, and brachycephaly. Examples of long-term implications of positional deformities include poor parent–infant attachment, bullying, and neurobehavioral problems. These short- and long-term consequences are also detrimental to the neurodevelopment of infants, placing them at risk for delayed milestones (Danner-Bowman & Cardin, 2015).

Preterm and critically ill infants may remain inpatient for prolonged periods; thus, positioning interventions require the attention of all caregivers. Interventions to prevent position-associated problems include frequent position changes and approaching the infant from all sides. Assisting infants to remain in a flexed, midline, and contained position can be achieved with the aid of positioning devices. Supportive positioning can promote comfort, respiratory function, and aid in musculoskeletal integrity (Danner-Bowman & Cardin, 2015). One method to support positioning is swaddling, which improves muscle tone and sleep quality, and decreases physiologic stress (Kitase et al., 2017).

With respect to head shape deformities, the correction depends upon the severity of deformity. Similar to prevention methods for other positioning problems, mild head shape deformities can be corrected through changes in position and approaching the infant from all sides. For more significant deformities, therapeutic positioners that provide support to the infant's developing head can aid correction without negatively impacting the infant's physiologic condition (Knorr, Gauvreau, Porter, Serino, & DeGrazia, 2016). When cranial support apparatuses are used in conjunction with other positioning aids, such as swaddling and boundaries, containment and proper body alignment can also be achieved.

Positioning and handling guidelines to support the development of premature and hospitalized infants should be adopted by all caregivers. Providing infants with skillful, supportive positioning and aiming to minimize handling throughout their hospital admission can promote sleep, self-regulation, growth, and weight gain, which will optimize brain development (Altimier & Phillips, 2013). Positioning tools can be used to encourage staff consistency in positioning babies in the NICU (Jeanson, 2013; Spilker, Hill, & Rosenblum, 2016).

Encouraging interaction between the infant and family member while the infant is prone and awake is also shown to be beneficial (Danner-Bowman & Cardin, 2015). The multidisciplinary team should provide families instruction and demonstration in proper handling and positioning of the infants. Through education, families can transfer what is learned in the hospital setting to their homes and optimize both physical and neurodevelopmental outcomes of their child (Danner-Bowman & Cardin, 2015). The AAP (2016) *Back to Sleep* guidelines should be implemented when developmentally appropriate and prior to hospital discharge (see the section on Safeguarding Sleep later in this chapter).

Therapeutic Positioning and Safe Sleep

Therapeutic positioning provides support to the hospitalized infant by facilitating physiologic stability, growth, and musculoskeletal and brain development (Altimier & Phillips, 2016). Devices used to provide therapeutic positioning promote proper body alignment and containment, without restricting spontaneous movement (Altimier & Phillips, 2013). The appropriate timing for the transition from NICU therapeutic positioning to safe sleep for Sudden Infant Death Syndrome (SIDS) prevention must be considered prior to discharge to home. Transitioning from therapeutic NICU positioning to safe sleep practice is a multidisciplinary decision that includes the family.

The criteria that an infant is medically stable and reaching appropriateness for safe sleep readiness include greater than 34 weeks corrected gestational age, off positive pressure ventilation, and able to regulate temperature in an open crib (Table III.2). Table III.3 includes safe sleep practice recommendations including supine, flat head of the bed, and more. Educating families about safe sleep is incredibly important; NICU patients are specifically at high risk for SIDS. Education coupled with healthcare providers serving as role models for safe sleep practices can improve parental compliance, which is also an issue for families whose infants had been in the NICU (Moon, Darnall, Feldman-Winter, Goodstein, & Hauck, 2016).

Parents should receive updated AAP safe sleep guidelines (see Table III.3; Moon et al., 2016) and practice/demonstrate safe sleep positioning a minimum of 5 to 7 days prior to discharge (Altimier et al., 2015). Beyond safe sleep positioning, secondhand smoke must be avoided, as it increases the risk for SIDS, independent of safe sleep positioning. Additionally, maternal alcohol and drug abuse also increases the risk of SIDS. Families should be screened and counseled to avoid tobacco, alcohol, and drugs. Breastfeeding should be encouraged because it is known to reduce the risk of SIDS regardless of gestational age.

TABLE III.2

INITIATION OF SAFE SLEEP

34 weeks corrected gestational age
No longer requiring positive pressure ventilation
Open crib

TABLE III.3

SAFE SLEEP PRACTICE RECOMMENDATIONS

Supine positioning for sleep
Sleep surface must be firm, flat mattress with a fitted sheet, and no other bedding or soft objects
Breastfeeding should be encouraged
Sleep location should be close to the parents, but a separate surface
No cobedding
Consider use of a pacifier during sleep times
Avoid overheating
Immunize according to the AAP and CDC guidelines
Encourage awake, observed tummy time
Discontinue swaddling while sleeping when the infant can roll
Maternal smoking and alcohol must be avoided

TABLE III.4

STRESS SIGNS AUTONOMIC, MOTOR, AND STATE SYSTEM

Autonomic System	
Respiratory	Tachypnea, irregular breathing pattern, apnea, bradypnea, sighing, gasping
Color	Pale, mottling, plethoric, cyanosis
Visceral	Multiple coughs, sneezes, or yawns, hiccupping, gagging, grunting, straining, and vomiting
Related motor	Tremors, startles, twitching
Motor System	
Tone	Hypertonia, hypotonia, hyperflexion
Posture	Unable to maintain flexion, alignment
Level of activity	Frequently moving, or no movement
State System	
Sleep	Restless, low cries, responsive to environment
Awake	Unfocused, gaze aversion, hyperalert with wide eyes, crying, eyes closed to avoid gaze, poor sleep times, difficult to console

Minimizing Stress and Pain

Symptoms of stress and pain among NICU patients have long been established (see Table III.4). Pain assessments in neonates are challenging as neonates display a wide range of responses; stress and pain symptoms change as gestational age increases (Montirosso & Provenzi, 2015). Minimization of stress and pain plays a significant role in neuroprotection. While the signs in Table III.4 have long been recognized, they can be difficult to discern considering other clinical scenarios including prematurity, sepsis, respiratory distress, apnea of prematurity, feeding intolerance, and others.

Chronic stress and pain are deleterious to optimal neurodevelopment, and even have a negative impact on the stress response later in life (Montirosso & Provenzi, 2015). For preterm and sick infants, stress originates from several sources: separation from the family, painful procedures, noise, tactile stimulation, and more (Alvarez-Garcia, Fornieles-Deu, Costas-Moragas, & Botet-Mussons, 2014). From a physiologic perspective, there are short- and long-term effects of stress and pain (Anand, 2000). Short-term effects of stress and pain include cortisol release and binding onto glucocorticoid receptors (Montirosso & Provenzi, 2015). When stress and pain are chronically experienced, glucocorticoid receptors become saturated, leading to loss of dendritic arborization, negative synaptogenesis, and ultimately decreased cerebral volume. These physiologic findings lead to increasingly poor neurodevelopmental outcomes including motor and cognitive deficiencies. Prevention of stress is accomplished using the neuroprotective interventions previously discussed, including nonnutritive sucking, clustered care, midline positioning, and skin-to-skin care as examples. These techniques should be used prophylactically when performing any procedures on NICU patients, including routine care. Stress can be eliminated or reduced with preventive strategies. When caregivers recognize stress signs, rectifying the infant's experience can limit or prevent negative neurodevelopmental consequences.

Pain management is achieved with a multitude of interventions, depending on the source and severity of pain. Breastfeeding, nonnutritive sucking, skin-to-skin care, facilitated tucking, swaddling, and administration of sucrose are effective for mild to moderate pain. Medications, such as morphine or fentanyl, can also be used for more severe pain, in addition to other nonpharmacologic methods such as swaddling and nonnutritive sucking. Recognizing and treating pain in NICU patients is critical to avoid excess metabolic demands and promote physiologic stability.

Safeguarding Sleep

Sleep is vital to brain development. Proper sleep cycles are necessary for temperature regulation, energy storing, learning, and memory formation (Lacina et al., 2015). Sleep interruptions lead

to increased learning disabilities and behavioral issues, and decreased brain volume (Altimier & Phillips, 2016).

The NICU environment can create interference to sleep cycles by exposure to excessive lighting, elevated noise levels, and frequent handling for cares or procedures (Lacina et al., 2015). Minimizing sleep interruptions is achieved by adjustments to the NICU environment and, when able, by limiting caregiver interruptions. Sleep can be improved using several methods. Interventions such as use of single-family rooms, appropriate lighting and noise, clustered-care, and using individual infant cues are important strategies to minimize sleep interruptions. Interventions to minimize sleep interruptions should also include education for the family.

Along with the staff, the family members can be taught to use positioning aids such as swaddling or conformational positioners, fluidized neonatal pillows, or containment techniques and boundaries. In a study evaluating the sleep of infants using a conformational positioner in comparison to standard positioning, the use of a positioning pillow significantly improved sleep quality (Lacina et al., 2015). The infant's individual awake and sleep periods also improves sleep quality. To further enhance this intervention, adapting the caregiver's approach based on the infant's stress signs decreases sleep disturbances (Altimier et al., 2015). When infants require incubators for thermoregulation, incubator covers improve sleep quality and should be used in conjunction with lighting guidelines found in Table III.1. Also, skin-to-skin contact, proper positioning, and handling all benefit sleep and are neuroprotective.

Protecting skin

Skin has many important functions: thermoregulation, balance of fluid and electrolytes, immune protection, and sense of touch. Premature skin structure is immature when compared to full-term infants in several ways that predispose them to greater risk for infection and poor thermoregulation. The premature infant's skin is underdeveloped and has higher body surface area to weight. Supportive care during skin development is crucial to alleviate poor thermoregulation and risk of infection (Visscher, Adam, Brink, & Odio, 2015; Visscher & Narendran, 2014).

The acid mantle is a critical part of the skin's defense from pathogens. However, maturation and proper function of the acid mantle is delayed up to 8 weeks among premature infants (Visscher et al., 2009). While the skin of full-term infants can take up to 1 week to mature, the skin of premature infants can take up to 3 weeks (Altimier & Phillips, 2013). During this time, they are vulnerable to infection via their skin. While there is no way to hasten this process, caregivers can avoid further disruption. For example, bathing should not be done if the infant has gelatinous skin. After the skin matures enough for bathing, it should be done only one to two times per week, and only with water (Allwood, 2011).

Thermoregulation is another critical function of the skin. Due to the lack of maturity and large body surface area to weight, transepidermal water loss (TEWL), heat maintenance, weight loss, and hypothermia are risks to the premature infant. To provide a neutral thermal environment and reduce TEWL, a polyurethane wrap is used in the delivery room for very preterm infants (Allwood, 2011; Altimier, 2012). In the NICU, double-walled incubators provide heat and have the capacity to provide humidity. While the use of emollient creams was routine in the past, the evidence for the effectiveness of this practice is lacking. Further, they have been linked to nosocomial bacterial and fungal infections; therefore, their routine use is discouraged (Allwood, 2011; Saiman, 2006).

Optimizing Nutrition

Growth is critical for infants. For infants in the NICU, enteral nutrition may not be appropriate depending on clinical condition. For these infants, parenteral nutrition is necessary. Central lines are used to deliver parenteral nutrition; however, there is a risk of central line associated bloodstream infections (CLABSIs). The earliest attainment of full enteral feedings, and earliest removal of central lines, reduces the risk for infection. The benefits of breastfeeding for infants have long been documented and include ease of digestibility, earlier attainment of full enteral feedings, and reduced risk for infection (short-term and long-term; Hawes & Lee, 2018). While the type of enteral feeding is important in achievement of full feedings and weight gain, the use of feeding guidelines can also improve earlier attainment of full feedings without increased risk for necrotizing enterocolitis (Culpepper, Hendrickson, Marshall, Benes, & Grover, 2017).

SUMMARY

Common threads of the seven neuroprotective core measures presented in this chapter simultaneously aid caregivers as they endeavor to support the neurodevelopment of premature and sick infants. As an example, skin-to-skin care offers many benefits including supporting the healing environment (temperature, touch, and proprioception); smell and taste; partnering with families, positioning, and handling; safeguarding sleep; and minimizing stress and pain (Altimier & Phillips, 2016). Skin-to-skin care also supports breastfeeding, which improves nutrition for the premature and sick infant.

Neuroprotective care has been critically important in achieving improved outcomes for fragile infants. Promoting neuroprotection for premature and sick infants requires skillful care and a multidisciplinary team approach. The multidisciplinary care team is inclusive of family members, which provides the most long-term benefits. Individualized care guided by infant's cues is critical. The future of neuroprotective developmental care includes researching developmental and family outcomes.

Neonatal Transport

Dorothy M. Mullaney

IV

INTRODUCTION

It has been estimated that there are over 65,000 transports of critically ill neonates in the United States each year (Karlsen, Trautman, Price-Douglas, & Smith, 2011). Neonatal transports have been described as a high-risk service due to the types of patients transported, the different environments the transport team must function in at each referring facility, the transport equipment itself, the mode of transportation, and the level of responsibility the transport team must assume as representatives of the receiving facility (Bouchut, Van Lancker, Chritin, & Gueugniaud, 2011; Cornette, 2004a; Dulkerian, Douglas, & Taylor, 2011; Fenton, Leslie, & Skeoch, 2004; Insoft & Schwartz, 2015; Kilpatrick, Papile, & Macones, 2017; Leppälä, 2010). For the most part, neonatal transports represent a low-volume, high-acuity aspect of neonatal intensive care (Duby et al., 2018).

While in the process of providing expert care and stabilization to the neonate, members of the transport team are also expected to provide education to the team at the referring facility and communicate with the family in a manner that will form the basis of parent and family involvement in the care of their infant (Duritza, 2009; Hawthorne & Killen, 2006; Hogan & Logan, 2004; Macnab, Richards, & Green, 1999; Mullaney, Edwards, & DeGrazia, 2014; Steeper, 2002).

REGIONALIZATION OF NEONATAL CARE

The 1976 March of Dimes publication *Toward Improving the Outcome of Pregnancy, Recommendations for the Regional Development of Maternal and Neonatal Health Services* described the development of a regionalized perinatal healthcare system (Little, Horbar, Wachtel, Gluck, & Muri, 2010). The underlying concept is to ensure effective and efficient patient flow with safe and quality care throughout the regional system (Kilpatrick et al., 2017; Robles et al., 2017; Rochefort & Lamothe, 2011; Staebler, 2011; Warner, Altimier, & Imhoff, 2002). These systems are generally defined geographically and within each geographic region are facilities that provide varying levels of neonatal care, designated as Level I, Level II, Level III, or Level IV. The AAP Committee on Fetus and Newborn (Barfield et al., 2012) and AAP and ACOG (Kilpatrick et al., 2017) have defined these four levels of care as described in Box IV.1. Facilities that provide Level III and IV care are also referred to as tertiary facilities or centers (Chang, Berry, Jones, & Sivasangari, 2015). Any facility that cares for neonates, no matter what their designated level is, is expected to be capable of providing neonatal resuscitation and stabilizing an ill neonate until a transport team arrives to assume care (Barfiled et al., 2012). For the most part, tertiary facilities assume the responsibility of providing interfacility neonatal transports and outreach education for the regional program.

STABILIZATION BY THE REFERRING FACILITY

It is preferable that identified high-risk neonates be born at a tertiary center, if that level of care is anticipated. However, the birth of an ill neonate requiring transport will be unexpected in most cases and the local team must be able to quickly recognize this need and provide the appropriate initial care (Fenton et al., 2004). The first step in the transport process is recognizing the neonate who requires care at a higher level facility. This is especially true for very low birth weight (VLBW) infants who have a much higher risk of morbidity and mortality if born at a referring hospital (Barfield et al., 2012; Chang et al., 2015; Kilpatrick et al., 2017; McNamara, Mak, & Whyte, 2005; Robles et al., 2017). A goal of *Healthy People 2020* (Healthy People 2030, 2019) is to reduce the percentage of births of VLBW infants outside of a Level III or IV facility to less than 17%.

There are programs available, such as PCEP® (Sinkin & Chisholm, 2016), S.T.A.B.L.E.® (Karlsen, 2017), and ACoRN® (www.acornprogram.net) that can be used as educational resources to train staff to care for unexpectedly ill neonates. Most regional programs will support one or two of these programs and the Level III or IV unit should actively participate in training staff at the referring facilities to recognize and begin to stabilize the unexpectedly ill neonate.

Once a neonate had been identified as needing transport, the nurse practitioner, physician assistant, or attending physician should contact the tertiary center to begin the transport process. While waiting for the transport team to arrive, the referring team should continue with the stabilization process they have already begun, paying particular attention to thermoregulation, glucose homeostasis, maintaining oxygenation and ventilation, establishing

Box IV.1

LEVELS OF NEONATAL CARE

Level I—Newborn Nursery

- Provide care to newborns >35 weeks' gestation that are physiologically stable

Level II—Special Care Nursery

- Provide care to stable or moderately ill born at >32 weeks' gestation and weigh ≥1,500 g with physiologic immaturity
- Provide convalescent care to neonates that have been in a tertiary unit
- Provide continuous positive airway pressure
- Provide mechanical ventilation for up to 24 hours

Level III—Neonatal Intensive Care

- Provide care for extremely high-risk and critically ill newborns
- Provide comprehensive care for neonates <32 weeks' gestation and/or weigh <1,500 g
- Provide conventional mechanical ventilation
- Provide high-frequency ventilation and inhaled nitric oxide
- On-site accessibility to pediatric subspecialists

Level IV—Regionalized Neonatal Intensive Care

- Provide Level III NICU care
- Provide ECMO therapy
- Repair complex cardiac abnormalities requiring cardiopulmonary bypass

ECMO, extracorporeal membrane oxygenation; NICU, neonatal intensive care unit.

Policy statement: Levels of neonatal care. *Pediatrics, 130*(3), 587–597. doi:10.1542/peds.2012-1999; Kilpatrick, S. J., Papile, L.-A., & Macones, G. A. (Eds.). (2017). *Guidelines for perinatal care* (8th ed.). Elk Grove Village, IL: American Academy of Pediatrics.

vascular access if necessary, and initiating antibiotic treatment if clinically indicated. In addition, the referring team should continue to be in contact with the tertiary center while the transport team is enroute if the neonate deteriorates or if any new issues are identified (Cornette, 2004b; Das & Leuthner, 2004; Stroud et al., 2013; Wright, 2000).

THE NEONATAL TRANSPORT PROGRAM

The AAP Section of Transport Medicine (Insoft & Schwartz, 2015) has stated that neonatal transports require "A qualified, highly trained and well-prepared and equipped team" (p. 1). It is generally the responsibility of the tertiary center of the regional system to provide the neonatal transport service. The transport team should serve as an extension of the unit the neonate is going to and provide that level of care at the referring facility (Insoft & Schwartz, 2015; Messner, 2011; Stroud et al., 2013). The neonatal transport program should be tailored to meet the needs identified by the entire regional program. There are specific elements that should be part of every transport program, including an identified medical director and a neonatal or perinatal coordinator. In addition to providing neonatal transports, the regional program should have an educational mission and have a process for quality assurance for the transport team, the tertiary center, and the other facilities in the region (Cornette, 2004a; Insoft & Schwartz, 2015; Kilpatrick et al., 2017; Lupton & Pendray, 2004; National Association of Neonatal Nurses [NANN], 2010; Stroud et al., 2013; Woodward et al., 2002). An example of this type of regional outreach program is the New Hampshire Perinatal Program, which has been in existence for over 30 years and routinely provides educational opportunities and an on-site review of all shared patients at least yearly with all referring facilities (Frank et al., 1999).

TRANSPORT TEAM COMPOSITION

Many different transport team compositions have been described, and ultimately the team composition should be appropriate for the type of care the neonate requires (Cornette, 2004a; Colyer, Sorensen, Wiggins, & Struwe, 2018; Davies, Bickell, & Tibby, 2010; Fenton et al., 2004; Fenton & Leslie, 2009; Insoft & Schwartz, 2015; Karlsen et al., 2011; Lee et al., 2002; Leppälä, 2010; Leslie & Stephenson, 2003; Lupton & Pendray; 2004; NANN, 2010; Stroud et al., 2013). A national survey by Karlsen et al. (2011) identified 26 different types of neonatal transport team compositions. There were 335 respondents to this survey, and only one team did not include either a neonatal nurse practitioner (NNP) or RN on the neonatal transport team. A recent study by Colyer et al. (2018) has suggested that an RN/paramedic team may present an additional type of configuration for a neonatal specialty transport team.

The role of the NNP has been compared with the pediatric house-staff as a member of the transport team (Cornette, 2004a, 2004b; Fenton et al., 2004; Fenton & Leslie, 2009; Leslie & Stephenson, 2003). There is ample evidence that the care provided by NNPs is at least comparable and potentially improved due to the consistency and experience this role brings to the transport process. In addition, it is less and less frequent that pediatric house-staff are involved in neonatal transports, mainly due to restrictions on duty hours and limited clinical time spent in neonatal units. Because of these constraints, it is now generally recommended that pediatric house-staff not be part of the transport team unless they receive additional training (Fenton & Leslie, 2009; Woodward et al., 2002).

Lee et al. (2002) analyzed three different compositions of transport teams: an EMT, an RN team, or a combined team of RN and RT. An MD would accompany any of these teams if the condition of the neonate warranted that level of care; however, the analysis did not show that the presence of a physician affected the outcome of the transport. The patient outcomes of the three types of teams were not significantly different. A cost analysis was performed and the RN team was found to be the most cost-effective model for most transports, followed by the combined team, and then the EMT team.

The survey by Karlsen et al. (2011) classified the transport team as being either unit-based or dedicated. The two most common unit-based team compositions in this survey were RN–RT or RN–RT–NNP. The unit-based teams were staffed by neonatal intensive care personnel, who were responsible for patient care when not on transport, similar to the RN team and combined team in the cost analysis by Lee et al. (2002). Unit-based teams generally performed fewer than 200 transports per year.

Dedicated teams in this survey were most commonly composed of RN–RT or RN–RN. The dedicated teams usually had a volume of over 200 neonatal transports per year and covered a geographical distance of greater than 100 miles. Only about 37% of these teams transported neonates exclusively; 50% of the dedicated teams were combined neonatal–pediatric teams.

Fenton and Leslie (2009) have suggested that the professional background of the transport team members is less important than the training each member of the team receives in terms of providing excellent patient care, performing procedural skills, communicating with the family and referring facility providers, and being part of the quality assurance process of the regional transport system. The AAP Section of Transport Medicine (Insoft & Schwartz, 2015) and NANN (2010) have developed guidelines for the interprofessional training of the neonatal transport team. The composition of the transport team should always be appropriate for the level of care the neonate will require in order to ensure a safe, effective, and efficient transfer to the tertiary or quaternary facility (Stroud et al., 2013).

TRANSPORT TEAM TRAINING

The neonatal transport team must possess the skills to provide care at both the referring facility and in a mobile environment (Insoft & Schwartz, 2015). Team configuration may vary depending upon the anticipated needs of the neonate. Each team member should have defined roles and responsibilities, but an understanding of other team members' roles is essential (Insoft & Schwartz, 2015). The educational process for members of the transport team should include didactic lectures, observation of the transport process, and clinical training including procedures with defined metrics for ensuring competencies. In addition, the importance of effective and efficient communication must be a part of the education curriculum. Neonatal transports are generally a low-volume, high-risk endeavor and the use of simulation training is becoming increasingly commonplace in team training (Campbell & Dadiz, 2016; Insoft & Schwartz, 2015; LeFlore & Anderson, 2008; Stroud et al., 2013). Quality and safety metrics also need to be incorporated—and in some cases developed—in transport team training, as well as in ongoing assessment of the team. Some potential metrics include adverse events on transport, medication errors, mobilization time, pain assessments, procedural skills such as intubation and umbilical catheter placement, thermoregulation, and use of "lights and sirens" during the transport (Bigham & Schwartz, 2013; Campbell & Dadiz, 2016; Colyer et al., 2018; Davidson, Utarnachitt, Mason, & Sawyer, 2018; Duby et al., 2018; Insoft & Schwartz, 2015; McLean, Gothard, Parrish, & Bigham, 2017; Reichert, Gothard, Schwartz, & Bigham, 2016; Stroud et al., 2013).

MODE OF TRANSPORTATION

Neonatal transports generally occur by ambulance, fixed wing aircraft, helicopter, or boat (Insoft & Schwartz, 2015; Karlsen et al., 2011; Leppälä, 2010; Lupton & Pendray, 2004; NANN, 2010). The first recorded helicopter transport in the United States occurred in 1967 in Illinois (Perry, 2017). Other modes of transportation have been reported, including walking or riding in a rickshaw (Mori et al., 2007). If more than one mode of transportation is available, the decision should be based upon the condition of the neonate and the distance to the tertiary facility. To ensure the safety of the transport team and neonate, weather conditions may also need to be taken into account.

In the survey by Karlsen et al. (2011) the majority of transports were by ground. Generally speaking, for shorter distances ground transport is the preferable mode. For distances that will require 2 hours or more of travel time one way, air transport may be more appropriate (Karagol, Zenciroglu, Ipek, Kundak, & Okumus, 2011; Lupton & Pendray, 2004). Transport by helicopter is the most expensive and ambulance the least expensive (Insoft & Schwartz, 2015; Lupton & Pendray, 2004; Wright, 2000). Whatever mode of transportation is used, the team must be oriented to and comfortable with the configuration and equipment of the ground or air ambulance.

STABILIZATION BY THE TRANSPORT TEAM

Once the transport team has arrived at the referring facility, they should introduce themselves and receive a hand-off from the local team. This hand-off is critical, as it will inform the transport team about care already received, prevent unnecessary duplication of care, and help guide the next steps (Wright, 2000). A successful hand-off will help expedite transporting the neonate to the tertiary facility safely. Exhibit IV.1 provides an example of information to be included in the hand-off to the transport team.

Once the hand-off is accomplished, the transport team should assess the neonate, continue with the stabilization, and provide any additional care to ensure a safe and efficient transfer to the tertiary center. It is crucial that prior to transport, the neonate has a stable airway, receives any cardiovascular support needed, vascular access is ensured if necessary, and appropriate medications have been provided. Continued close attention should also be paid to thermoregulation and glucose homeostasis (Cornette, 2004b; Fenton et al., 2004; Leslie & Stephenson, 2003). The neonate should also have pain assessments performed and documented during the transport process (Reichert et al., 2016). Special consideration should be paid to ensuring that all tubes and catheters are in good position and secure; an accidental extubation or dislodgement of an umbilical line could result in destabilizing an already fragile neonate (McLean et al., 2017).

Additional transport therapies that may be unique to the neonatal population include whole-body cooling for infants with concern for hypoxic ischemic encephalopathy or phototherapy for infants nearing exchange transfusion criteria for hyperbilirubinemia (Banda, 2016; Bellini & Risso, 2016; Bourque et al., 2018; Chaudhary, Farrer, Broster, McRitchie, & Austin, 2013; Waterham et al., 2015). These therapies may require the transport team to bring additional equipment such as cooling packs or mattresses for active whole-body cooling or a bilirubin blanket.

Communication by the transport team back to the tertiary center is an essential part of the stabilization and transport process (Harbour & Oddi, 2016; Wilson, Kochar, Whyte-Lewis, Whyte, & Lee, 2017). The Joint Commission (2017) recommends the use of standardized tools and methods to improve communication and hand-offs. A quality improvement project by Wilson et al. (2017) used the SBAR tool (Situation, Background, Assessment, Recommendation) to improve communication between the transport team and the medical control officer.

TRANSPORT EQUIPMENT

The transport equipment allows the neonatal transport team to bring many aspects of the tertiary unit to the referring facility. The team members need to be comfortable using all the equipment and as much as possible it should be standardized in terms of location, type, and so forth. When choosing transport equipment, there are

Box IV.2

TRANSPORT BAG EQUIPMENT

Medications

- Antibiotics
- Anticonvulsants
- Code medications
- Inotropic agents
- Intravenous solutions
  - Dextrose 5% and 10%
  - Normal saline
- Prostaglandins
- Intubation premedications
- Surfactant

Respiratory Equipment

- Endotracheal tubes
- End-tidal carbon monoxide monitoring
- Laryngoscope and blades
- Resuscitation bag and masks
- Laryngeal mask airways
- Continuous positive airway pressure prongs
- Portable blood gas analyzer

Additional Equipment

- Monitoring
  - ECG leads
  - O_2 saturation probes
  - Transducer
  - Temperature probes

(*continued*)

Box IV.2 (*continued*)

- Procedural
  - Umbilical catheter insertion
  - Chest tube insertion
- Vascular access
  - IV catheters
  - Intra-osseous needles
- Miscellaneous
  - Decompression tubes
  - Equipment for sterile procedures
    - Gown, mask, gloves, provodone-iodine, chlorhexidine, alcohol
  - Point of care glucose monitoring
  - Suction catheters
  - Tube and catheter stabilizing equipment
  - Reference manuals

several important considerations. Safety should be an overriding concept and all equipment should meet all federal, state, and local regulations. The equipment should have the ability to run by both electricity and battery power. It will need to withstand changes in temperature and, if air transport is used, changes in altitude.

The transport isolette is the primary tool used by the neonatal transport team. It needs to be able to safely transport and keep warm a neonate weighing less than 1 kg up to 5 to 6 kg. The neonate should be visible and easily accessible to the team throughout the transport. The transport isolette should have additional equipment mounted to it including a cardiorespiratory monitor, IV pumps, air and oxygen tanks, oxygen blender for appropriate O_2 delivery, and a transport ventilator. There should also be space to add additional equipment if necessary, such as inhaled nitric oxide (Cornette, 2004b; Fenton et al., 2004; Insoft & Schwartz, 2015; Leppälä, 2010; Lupton & Pendray, 2004; Lutman & Petros, 2008; NANN, 2010).

In addition to the isolette and mounted equipment, the transport team will need to bring other smaller, but equally important items that are usually kept ready to go in transport bags. This will allow the team to perform procedures and stabilize the neonate with equipment that is familiar to them. Each transport program should decide upon the specific items to be brought; Box IV.2 lists common equipment to be found in transport bags.

DOCUMENTATION

The regional transport service should have the ability to document all transport calls and advice given to the referring center. There should also be documentation regarding the time of phone calls and dispatch of the transport team. Leslie and Fenton (2012) have suggested that individual transports be defined as planned, unplanned, or time-critical. If a transport is designated as time-critical, the transport team should be able to be mobilized in 30 minutes or less.

The referring facility should provide the transport team with copies of the neonate's medical record that includes a delivery summary, initial presentation, and summary of the stabilization process, including laboratory values. A copy of the maternal history, including pertinent prenatal information, should also be included. Hard copies or CDs of x-rays or other imaging studies should also be available to the transport team (Cornette, 2004b; Das & Leuthner, 2004; Leppälä, 2010).

Prior to the departure of the transport team, it is imperative that consent forms authorizing the transport be obtained and signed. There should be documentation of consent from the parents to transport their infant to the tertiary center. There may also be state, local, or third-party consent forms that need to be signed by the referring provider and a member of the transport team who is receiving care of the neonate (Cornette, 2004b; Lupton & Pendray, 2004).

Documentation by the neonatal transport team should include a flow sheet for vital signs, respiratory status, intake and output, and a brief description of interventions provided. A full note by the transport team leader describing the transport should be entered into the neonate's chart at the tertiary center. This note should include the time of arrival at the referring facility, time of arrival at the tertiary center, mode of transportation, and care given during the transport, both at the referring facility and enroute. It is recommended that a copy of this note be sent to the referring provider as well as the neonate's primary care provider.

FAMILY-CENTERED CARE DURING TRANSPORT

The transport of a critically ill neonate is particularly stressful for parents who may or may not have anticipated the birth of an ill neonate and may not be able to immediately go to the receiving facility to fully participate in the care of their infant (Buchanan, 2009; Das & Leuthner, 2004; Dulkerian et al., 2011; Duritza, 2009; Franklin, 2006; Hawthorne & Killen, 2006; Hogan & Logan, 2004; Leppälä, 2010; Macnab et al., 1999; Mullaney et al., 2014; Steeper, 2002; Wilman, 1997). It has been suggested that early parental participation in the care of their infant helps to foster the parent–infant relationship. Parental separation from their infant, which is inherent in the transport process, can adversely impact the successful development of this relationship (Franklin, 2006; Obeidat, Bond, & Callister, 2009). The neonatal transport team needs to be cognizant of this and try to facilitate parental involvement in the care of their infant during the transport process.

The first way parents participate in the care of their infant is by information sharing. Steeper (2002) has noted that there is a lack of information about how parents perceive the communication they receive about their infant during the transport process. Until more definitive information is available, the transport team should use the guidance of communication strategies already identified for parents whose infants are in the NICU (Howland, 2007; Saunders, Abraham, Crosby, Thomas, & Edwards, 2003; Sharp, Strauss, & Lorch, 1992). This communication should begin when the local team identifies the need for transport. The parents should be informed of the reason the neonate needs to be transported for a higher level of care, the name of the facility he/she is going to, when the transport team is expected to arrive, the mode of transportation, and if it is possible for the mother to be transferred to the tertiary facility or if she can be discharged to travel to the receiving facility (Das & Leuthner, 2004; Leppälä, 2010; NANN, 2010; Wright, 2000).

For the parents and family of an ill neonate, their first experience with the neonatal intensive care team will be the transport team. Most neonatal units pride themselves on providing family-centered care, realizing that the parents and family are not visitors to the neonatal unit, but a part of the team caring for the ill neonate. If this is truly believed, family participation in the care of their infant needs to begin during the transport process. Once the transport team arrives, they need to continue to keep parents informed as the local team has. The transport team needs to introduce themselves, and parents should be given the opportunity to stay with their infant during the stabilization by the transport team (NANN, 2010). Parents should be told what the assessments of the transport team are, any additional procedures to be done in the referring facility or that may be necessary during the transport process, and be given the opportunity to ask questions. If the parents have not been able to be present while readying the neonate for transport, the team should go to the mother's room so that they can see and touch their infant prior to leaving the referring facility.

Many transport teams also provide the parents with some written information about the NICU the neonate is going to that includes the phone number to the unit as well as a map for the parents to use. The team should ensure that the parents have a photograph of their infant; if not, the team should have the ability to provide one. Parents will also need information about the anticipated duration of the transport, and if they will not be accompanying the baby, they should receive a phone call from the transport team once the infant has safely arrived in the NICU.

SUMMARY

The transport of an ill neonate from a Level I or Level II facility will always be a stressful and challenging experience. The transport process begins with the identification of the ill neonate, transitions through the transport team, and ends with admission to the NICU. A well-developed regional neonatal or perinatal program helps to ensure the smooth transition of the neonate from the referring to the receiving facility. The goal of the neonatal transport team, a part of the regional program, is to provide high-quality, safe, efficient, and family-centered care to the ill neonate prior to arrival at the tertiary unit.

V

Introduction to Vascular Access

Elizabeth L. Sharpe

INTRODUCTION

As the threshold of viability continues to recede, the challenge of nourishing the premature survivors has grown. Premature infants and medically and surgically complex term infants require optimal amounts of protein, carbohydrates, and fats to achieve growth, and the method of delivering these nutrients is crucial to their safe delivery. Current traditionally utilized vascular access devices for neonates include umbilical catheters, peripherally inserted central catheters (PICCs), central venous catheters, midline catheters, and peripheral intravenous (PIV) devices, with the addition of recently available extended dwell peripheral intravenous catheters (EPIV; see Table V.1).

The process of selection of the device should consider the individual patient's needs and results following a risks versus benefits analysis. These considerations include the chemical properties of the therapy such as osmolarity, pH, and irritant or vesicant properties, specific patient needs, and the intended duration of therapy. The Centers for Disease Control and Prevention (CDC) recommends using "a midline catheter or peripherally inserted central catheter (PICC), instead of a short peripheral catheter, when the duration of IV therapy will likely exceed six days" (O'Grady et al., 2011, p. 26). Early standards of practice provided for medications with a pH of less than 5 or greater than 9 as a sole factor, indicating the need for central venous access (Infusion Nurses Society [INS], 2011). Current decision making for the type of intravenous or central venous access should be based on multiple factors including anticipated duration of therapy, vesicant properties and number of infusates, patient conditions, and osmolarity greater than 600 mOsm/L (Gorski, Hagle, & Bierman, 2015).

The most commonly used first-line intravenous device is the peripheral intravenous device (PIV). These are often inserted in the veins in the hands and feet with distal to proximal progression should repeated PIVs be required. PIVs are used for nonirritant solutions or medications with dextrose concentrations of 12.5% or less (Alexander, Corrigan, Gorski, Hankins, & Perucca, 2010).

Umbilical arterial catheters (UACs) may be placed initially when frequent blood sampling and monitoring is indicated. The UAC catheter tip should be located between T6 and T9 for high position and L3 and L4 for low position (Said & Rais-Bahrami, 2013a). It is recommended to limit UAC duration to no more than 5 days (O'Grady et al., 2011).

Umbilical venous catheters (UVCs) may be placed initially for infusion of total parenteral nutrition, medications, and blood administration. The UVC catheter tip should be located in the inferior vena cava near the junction with the right atrium (Said & Rais-Bahrami, 2013b). It is recommended to limit UVC duration to 7 days to minimize risk of central line–associated bloodstream infection (Butler-O'Hara, D'Angio, Hoey, & Stevens, 2012).

Midline catheters can be utilized for infusion of medications and fluids with osmolarity less than 900 mOsm/L (Gorski et al., 2016). The midline catheter can be placed in basilic, cephalic, or median cubital position with the catheter tip maintained below the axilla. In infants, a midline catheter can also be placed in the lower extremity veins with the catheter tip maintained below the groin and in scalp veins with the catheter tip maintained in the jugular vein above the clavicle (Gorski et al., 2016). Midline catheters can remain in place as patient needs require and there are no signs of complications. Midline catheters are utilized for nonirritant solutions or medications with dextrose concentrations of 12.5% or less.

Recently available EPIV catheters are being inserted in similar locations to midline catheters and are used for nonirritant solutions or medications with dextrose concentrations of 12.5% or less (Chenoweth, Guo, & Chan, 2018).

PICCs are now commonly used to administer total parenteral nutrition and hyperosmolar medications in neonatal intensive care. When properly maintained, PICCs provide reliable long-term access for delivery of parenteral nutrition and hyperosmolar or irritant medications, fewer interruptions in therapy, decreased incidence of painful procedures and stress to infants, and fewer opportunities for needlestick exposure to healthcare providers. The disadvantages include: the need for radiographic confirmation of catheter tip location with insertion and following repositioning, specialized training required, risk for extravasation, phlebitis, pericardial and pleural effusion, occlusion, thrombosis, infection, and migration or dislodgement (see Table V.2).

The key indications for a PICC are the anticipated need for long-term parenteral nutrition or hyperosmolar medications. Typical patient profiles are extreme prematurity, diagnoses with delayed feedings, patients with congenital anomalies limiting vascular options, and those requiring long-term vascular access for nutrition or treatment. The most commonly used veins for PICC placement are the basilic, cephalic, greater and lesser saphenous,

TABLE V.1

TYPES OF INTRAVENOUS DEVICES

Type of Device	Intended Duration	Average Dwell Time	Type of Infusion	Optimal Tip Location
Peripheral intravenous	Short term	47 hours (Legemaat et al., 2016; Leick-Rude & Haney, 2006)	Nonirritant, isotonic solutions D12.5% or less (Pettit, 2003)	Peripheral
Midline	5–7 days	8.7 days to as many as 80 days (Leick-Rude & Haney, 2006; Wyckoff, 1999)	Nonirritant, isotonic solutions D12.5% or less	Upper portion of extremity, below axilla, above clavicle, away from areas of flexion
Extended dwell peripheral intravenous	Up to 29 days	4 days ± 2.3 days (Chenoweth et al., 2018)	Nonirritant, isotonic solutions D12.5% or less	Below the shoulder
Peripherally inserted central catheters	More than 6 days to long term	17 days to indefinitely as needed (Goldwasser, Baia, Kim, Taragin, & Angert, 2017)	Parenteral nutrition, vesicant therapy, infusates pH <5 or >9, >600 mOsm/L >D12.5%	Lower 1/3 of SVC or IVC above level of diaphragm
Percutaneous central venous catheter	5–7 days	5–7 days	Parenteral nutrition, vesicant therapy, infusates pH <5 or >9, >600 mOsm/L	Lower 1/3 of SVC or IVC above level of diaphragm

IVC, inferior vena cava; SVC, superior vena cava.

TABLE V.2

PREVENTION AND MANAGEMENT OF PICC COMPLICATIONS

Complication	Risk Factors	Prevention	Management
Central line–associated bloodstream infection	Prematurity Inexperienced or untrained caregivers Multiple manipulations of catheter Prolonged dwell time Contamination of catheter hub or needleless connector	Central line bundle elements including: Specially trained personnel Maximum sterile barrier precautions Maintaining an occlusive dressing Meticulous catheter care Hub hygiene Chlorhexidine or povidone iodine for skin antisepsis Limiting breaks in line Daily review of line necessity	Intravenous antibiotic therapy Removal of catheter if unable to clear infection or if gram-negative bacilli, *Staphylococcus aureus,* or *Candida* (Benjamin et al., 2001; Karadag-Oncel et al., 2015)
Occlusion	Low flow rates <0.5 mL/hours Inadequate flushing	Flushing before and after incompatible medications Maintaining adequate minimum infusion rates (0.5–2 mL/hours)	Clearing agents specific to etiology may be used Thrombolytics can be instilled according to manufacturer's directions
Phlebitis	Catheter tip outside the SVC or IVC Rapid or traumatic insertion Cephalic or saphenous vein insertion Catheter mobility due to inadequate securement	Use smallest size catheter that will accommodate therapy Screen infusates for irritant or vesicant properties, hyperosmolarity, or extreme pH (<5 or >9). Maintain secure occlusive dressing Position catheter tip in SVC or IVC Slow gentle insertion technique	Warm compresses over the vein every 4 hours and elevation of the extremity Often resolves spontaneously If it does not resolve or worsens after 24 hours, may need to discontinue the catheter

(*continued*)

TABLE V.2

PREVENTION AND MANAGEMENT OF PICC COMPLICATIONS (*continued*)

Complication	Risk Factors	Prevention	Management
Thrombosis	Catheter tip outside SVC or IVC Catheter mobility Left-sided insertion in upper extremity Protein C, protein S, or antithrombin deficiencies	Use smallest size catheter that will accommodate therapy Position catheter tip in SVC or IVC	Management and diagnostics include: Venogram Antithrombolytics Removal of catheter
Extravasation	Catheter tip outside SVC or IVC Irritant or hyperosmolar infusions	Evaluate infusion needs in device selection Position catheter tip in SVC or IVC for optimal hemodilution Frequent, at least hourly site assessment	Radiographic confirmation of catheter tip location Treat specific to area of extravasation Remove catheter
Pericardial/ pleural effusion	Catheter tip outside SVC or IVC Inadequate securement	Position catheter tip in SVC or IVC for optimal hemodilution Frequent, at least hourly site assessment Maintain secure dressing	Stop infusion Chest x-ray and echocardiogram for pericardial effusion Attempt to aspirate blood from catheter while awaiting imaging Withdraw catheter to proper position in SVC or IVC Repeat radiographic confirmation
Migration/ dislodgement	Loose or inadequate dressings Tension on tubing and catheter	Frequent, at least hourly site assessment Maintain secure dressing	Reevaluate catheter tip location Determine if catheter tip location is appropriate for therapy required Consider catheter exchange or alternate site if new tip location is not satisfactory

IVC, inferior vena cava; PICC, peripherally inserted central catheters; SVC, superior vena cava.

posterior auricular, and temporal. Other veins that may be utilized include the external jugular, axillary, femoral, and popliteal. As venous anatomy progresses from distal toward the head, the size of these vessels increases in diameter, creating optimal blood flow for hemodilution to minimize vessel damage. In the upper extremity, the basilic and cephalic veins flow directly into the axillary vein, then the subclavian vein, then the brachiocephalic vein into the superior vena cava (SVC). In the scalp, the posterior auricular and temporal veins flow directly into the jugular vein, then into the subclavian vein, the brachiocephalic, and the SVC. For catheters inserted into the veins of the upper extremity or scalp, the optimal catheter tip location is in the SVC (Food and Drug Administration, 1989; Gorski et al., 2016; Wyckoff & Sharpe, 2015). In the lower extremities, the greater and lesser saphenous veins flow directly into the femoral vein, then the iliac, then the inferior vena cava (IVC). For catheters inserted into the veins in the lower extremities, the optimal catheter tip location is in the IVC between the right atrium and diaphragm (Wyckoff & Sharpe, 2015). Radiographic confirmation should be obtained following catheter insertion and any adjustments to reposition the catheter, and if signs or symptoms suspicious for a complication are present.

Insertion Procedure

- Evaluate needs and duration of intended therapy.
- Discuss with family and obtain informed consent.
- Perform physical assessment for vein selection.
- Measure distance from intended insertion site along vein track to SVC for upper extremity or scalp vessels or IVC for lower extremity vessels.
- Gather insertion kit, catheter, introducer, sterile gloves, maximum sterile barriers, and other needed supplies.
- Prepare patient for procedure, including pharmacologic and developmental comfort measures.
- Don hair covering and mask.
- Perform hand hygiene.
- Prepare sterile field and equipment.
- Prepare catheter by flushing and trimming to premeasured length.
- Position patient as developmentally appropriate.
- Prepare insertion site by disinfecting skin with antimicrobial agent. Chlorhexidine gluconate or povidone iodine may be used. Chlorhexidine may be used with caution in premature infants or infants less than 2 months of age. These products may cause irritation or chemical burns.
- Utilize maximum sterile barrier precautions to isolate the extremity or insertion site.
- Apply sterile tourniquet.
- Insert introducer bevel up at 15° to 30° angle and observe for blood return. Once blood return is obtained, if using an over-the-needle sheath introducer, remove the needle.

- Remove tourniquet.
- Place catheter in introducer lumen using nontoothed or protected forceps and thread catheter in small increments to premeasured depth.
- Remove introducer per manufacturer's directions.
- Apply gentle pressure to site until bleeding stops.
- Verify inserted and externally lying catheter length.
- If a catheter with stylet is used, remove stylet at this time.
- Aspirate to confirm blood return and flush to confirm patency.
- Attach luer-lock extension tubing if not in catheter apparatus.
- Remove povidone iodine from skin and allow to dry.
- Secure catheter to skin and apply sterile transparent occlusive dressing.
- Obtain radiographic confirmation of catheter tip location in SVC or IVC.
- Reposition catheter if not in SVC or IVC.
- Obtain radiographic reconfirmation of catheter tip location if adjustments are made.
- Document procedure, any repositioning, radiographic confirmation, premedication, catheter specifics (including brand and lot number), trimmed length, inserted length, and patient tolerance.

Points for Practice in PICC Maintenance

- Be sure that the catheter tip location correlates with type of infusion.
- Infusions should be no greater than D12.5 if catheter tip location is not central in SVC or IVC.
- Secure and dress catheter to enable visualization of insertion site.
- Change dressing if it becomes loose, nonocclusive, moist, or soiled.
- Maintain adequate minimum infusion rates to prevent occlusion.
- Flush with no smaller than a 10 mL syringe per manufacturer's directions.
- If locking of catheter is desired, flush with minimal volumes of normal saline or heparin as specified in facility protocols (INS, 2008).

Assessment of the catheter and site at least hourly supports early detection to avoid or minimize potential impact of complications.

Central line–associated bloodstream infection (CLABSI) is defined as a primary bloodstream infection in a patient who had a central line within the 48-hour period before the development of the bloodstream infection and is not bloodstream related to an infection at another site (O'Grady et al., 2011). Numerous campaigns successfully directed at CLABSI prevention have included a bundled approach of simultaneously practiced strategies often in collaboration with other facilities (Fisher et al., 2013; Shepherd et al., 2015; Wilder, Wall, Haggard, & Epperson, 2016). Some of these bundle components included: hand hygiene, maximum sterile barrier precautions for insertion, a dedicated team, chlorhexidine for skin antisepsis, chlorhexidine-impregnated dressings, sterile tubing changes, two-person dressing changes, needleless connector scrub hygiene, closed medication systems, and daily evaluation of line necessity for timely removal of the line when no longer needed (Taylor et al., 2011; Wilder et al., 2016). A care bundle is a group of practices that individually impact outcomes but, when applied together, dramatically improve outcomes (Institute for Healthcare Improvement, 2016). The implementation of evidence-based central line care across statewide collaboratives has significantly reduced CLABSIs (Piazza et al., 2016; Shepherd et al., 2015).

Specially trained personnel play a key role in preventing and detecting complications (Holzmann-Pazgal et al., 2012; Legemaat, Jongerdena, van Rens, Zielman, & van den Hoogen, 2015; Taylor et al., 2011). Personnel who care for patients with central lines should receive specialized training in catheter insertion, care, and maintenance (O'Grady et al., 2011). While not every complication is preventable, the effects can be minimized by early detection. Frequent monitoring of vascular access sites at least hourly can play a critical role in managing complications and producing positive outcomes (Gorski et al., 2016; Wyckoff & Sharpe, 2015).

EVIDENCE-BASED PRACTICE FOR PICCs

Healthcare providers caring for infants with vascular access should be aware of the risks of complications, especially infection, and incorporate the latest evidence-based practice to support minimizing complications. It has been reported that 18 of every 100 babies experienced an iatrogenic event with 87% of these preventable, 20% due to catheters, and 15% due to nosocomial infection, with severely ill and small infants at highest risk (Kugelman et al., 2008; Srulovici et al., 2012). Practices regarding insertion, catheter tip location, care, and maintenance have traditionally reflected knowledge primarily gained from the adult and pediatric population. Fortunately, new evidence specific to neonates continues to emerge to drive evidence-based care for vascular devices in infants. The benefit of decreased risk of complications associated with optimal catheter tip location has been demonstrated (Colacchio, Deng, Northrup, & Bizzarro, 2012; Goldwasser et al., 2017). The implementation of a team approach using specially trained personnel has been associated with desirable outcomes (Wilder et al., 2016). Practices regarding appropriate device selection, catheter tip location, maintenance, and CLABSI prevention reflect evidence of successful strategies that continue to evolve and should be incorporated to continue to increase care outcomes.

TECHNOLOGICAL ADVANCES FOR PICCs

As technologic advances permit the miniaturization of equipment, greater options for PICC care are becoming available for safer insertion and maintenance of these tiny lifelines. The use of ultrasound, infrared technology, modern transilluminators, and modified Seldinger technique can facilitate PICC insertion and provide new solutions for locating and accessing challenging infant vasculature (Elkhunovich et al., 2017; Sharma, Farahbakhsh, & Tabatabaii, 2018).

Newborn Whole-Body Cooling Protocol

Georgia R. Ditzenberger and Susan Tucker Blackburn

INTRODUCTION

Hypoxic ischemic encephalopathy (HIE) is an injury to the brain caused by systemic hypoxemia, ischemia, or a combination of the two conditions.

I. OBJECTIVE

To provide whole-body cooling to eligible newborns with HIE.

II. GENERAL INFORMATION

A. Whole-body cooling therapy will be provided to newborns meeting eligibility criteria. The neonatologist or pediatric neurologist will evaluate the newborn and determine whether the newborn meets the criteria for whole-body cooling.
B. The newborn will undergo whole-body cooling therapy to achieve and maintain an esophageal temperature of 33.5°C.
C. Cooling therapy is a 72-hour period of maintaining the esophageal body temperature at 33.5°C.
D. On completion of 72 hours of body cooling, the newborn will be rewarmed over a 6-hour period.
    1. A physician or neonatal nurse practitioner (NNP) must complete the whole-body cooling order set in the electronic chart to initiate this protocol.
    2. A physician or NNP must complete the rewarming order set in the electronic chart to initiate rewarming the newborn.
E. Risks to newborn
    1. Blood pressure changes: either hypo- or hypertension
    2. Respiratory pattern changes; may require ventilator support
    3. Abnormal clot formation
    4. Skin breakdown
    5. Metabolic acidosis

III. IMPLEMENTATION

A. Equipment and supplies
    1. Radiant warmer
    2. Electric cooling unit with a probe adapter cable and one set of connecting hoses
    3. One newborn-sized (22 × 33 inches) cooling blanket
    4. Two single patient use esophageal probes (one for esophageal temperature and one for skin temperature monitoring)
    5. Distilled/sterile water
    6. Tape to secure esophageal probe
B. Electric cooling unit set up: follow manufacturer's guidelines
    1. Fill the water reservoirs; monitor water level while unit is in use and add water as needed.
    2. Connect the hoses.
    3. Be sure the power switch is OFF prior to inserting the power plug into a grounded receptacle.
    4. Once the unit is plugged into a grounded receptacle, turn the unit on.
    5. Press and hold test lights button.
        a. Observe that all lights function properly.
        b. Confirm that the audible alarm sounds are functioning.
    6. Place the blanket on the radiant warmer.
    7. The blanket should be flat and the two hose clamps OPEN to allow the blanket to fill.
    8. Water will begin to circulate into the blanket.
        a. Check for leaks.
        b. Do not use pins or sharp objects on the blanket.
    9. After the blanket has filled, check the water level in the reservoir; refill as needed to keep the green line on the float visible.
    10. Do not overfill the reservoir.
C. Precool the blanket before the newborn is placed on the blanket.
    1. Operate the electric cooling unit in the manual control mode.
    2. Change the temperature scale by pressing the celsius/fahrenheit button to display "celsius."

3. Set the temperature desired to 33.5°C.
4. The unit will cool as required to bring the blanket temperature to the set point.

D. Temperature probes
1. Esophageal probe insertion
   a. Soften the esophageal probe prior to insertion by placing it in warm water for a few minutes.
   b. Do NOT use lubricants.
   c. Nasal placement of the probe is preferred.
   d. Position the esophageal temperature probe in the lower third of the esophagus.
   e. Measure the distance from the nares to the ear to the sternum minus 2 cm.
   f. Mark the probe with an indelible pen before inserting.
   g. Secure the probe by taping it to the newborn's nose.
   h. Probe position may be confirmed with the next routine chest radiographic examination.
   i. Connect the esophageal probe to the probe adapter cable and plug into the probe jack on the electric cooling unit.
2. Skin probe
   a. Position over abdomen; affix to skin with radiant warmer temperature probe reflective patch.
   b. Skin temperature probe and cable are compatible with the cardiorespiratory monitor and are connected directly into the monitor's temperature module.

E. Cooling the newborn
1. Place the newborn directly on the cooling blanket on the radiant warmer in supine position.
   a. The newborn's entire head and body should be resting on the cooling blanket.
   b. There should be nothing between the newborn and the cooling blanket (no receiving blankets, cloth diapers, gel pads, etc.).
2. The radiant warmer must be off.
3. Any other exogenous heat source must be off.
4. Change the electric cooling unit to automatic control mode.
   a. Make sure the set point is 33.5°C.
   b. The unit will cool as required to bring the newborn's esophageal temperature to the set point.

F. Maintain the set point at 33.5°C.
1. This is the desired esophageal temperature for the next 72 hours.
2. Once the newborn's esophageal temperature reaches the set point of 33.5°C, a single blanket layer, such as a thick receiving blanket, may be used between the newborn and the cooling blanket to minimize soiling the cooling blanket.
3. Patient temperature display will flash until the newborn's temperature is within 1°C of the set point.
4. Expect some fluctuation around the set point; it should not be more than ± 1°C.

G. Monitor temperatures
1. Record the esophageal, skin, axillary, and blanket water temperatures in the electronic patient record:
   a. Every 15 minutes for 2 hours
   b. Then every hour for 4 hours
   c. Then every 2 hours until completion of the 72 hours of cooling

H. Assess skin integrity, perfusion, vital signs, and potential complications every hour.

IV. REWARMING THE NEWBORN

A. Verify that the rewarming order set is in the electronic patient chart.
1. Newborn is rewarmed gradually, increasing the esophageal temperature at a rate of 0.5°C per hour over a 6-hour period.
   a. Every hour, increase the electric cooling unit set point by 0.5°C.
   b. During rewarming, temperatures should be recorded every hour until the skin temperature is stable at 36.5°C.
2. At the end of the 6-hour rewarming period, turn on the radiant warmer skin control 0.5°C higher than the newborn's current skin temperature.
3. Continue to increase the radiant warmer skin control by 0.5°C every hour until the newborn's axillary temperature is 36.5°C.
   a. Avoid rewarming any faster than 6 hours.
   b. Avoid axillary temperatures greater than 37°C.
4. Remove the cooling blanket from beneath the newborn.
5. Remove the esophageal probe and discard.

VII

Neuroprotective Interventions

Leslie B. Altimier and Raylene M. Phillips

INTRODUCTION

There is ample evidence that neuroprotective family-centered developmental care in the neonatal intensive care unit (NICU) results in improved neonatal and neurodevelopmental outcomes, decreased lengths of stay, decreased costs, increased family satisfaction, and even enhanced employee satisfaction once a culture of change has been accomplished (Als et al., 1994; Als et al., 2004; Altimier & Phillips, 2013; Cooper, Gallagher, Sternesky, Ledsky, & Berns, 2007; Melnyk et al., 2006; Phillips, 2015). However, implementing the known principles of neuroprotective family-centered developmental care in the NICU and creating the needed culture changes have often been fraught with internal and external challenges.

The earlier in gestation a baby is born, the more vulnerable is its fragile brain and the more critical it is to provide effective and consistent neuroprotective care from the moment of birth to protect and support optimal brain development. Because developmental care is primarily about neuroprotection (although it affects many other aspects of infant development), the term *neuroprotection* is utilized throughout these guidelines and interventions. The creation of neuroprotective interventions as guidelines for NICUs to implement within their units should be based on the most up-to-date, evidence-based best practices that are supported by research and literature, as well as subject matter expertise. Recognizing that the need for neuroprotective care is ongoing and dynamic, each guideline should include an overall goal, recommendations, rationale, supporting data, and measures of accountability. Any long-term change involving new knowledge, skills, and behaviors will take time and meticulous planning, as well as adequate resources and administrative support to make sure new practices will be adopted by all.

Neuroprotective developmental care is grounded in evidence by research from a number of disciplines including nursing, medicine, neuroscience, and psychology (Als, 2009; Altimier, Kenner, & Damus, 2015; Bastani, Rajai, Farsi, & Als, 2017; Bergman, 2015; Burnett, Cheong, & Doyle, 2018; Gao, Lin, Grewen, & Gilmore, 2017; Montirosso et al., 2016). Improvements in health outcomes, neurodevelopment, lengths of stays, hospital costs, as well as staff and parent satisfaction have been documented when neuroprotective education and subsequent change of care practices were implemented (Altimier, 2015a, 2015b; Altimier et al., 2015; Altimier, Eichel, Warner, Tedeschi, & Brown, 2005; Cardin et al., 2015; Coughlin, 2008; Dungca, Allison, & Watson, 2011; Hendricks-Muñoz & Mayers, 2014; Hendricks-Muñoz, Prendergast, Caprio, & Wasserman, 2002; Liaw, Yang, Chang, Chou, & Chao, 2009; Lockridge, 2018; Ludwig, Steichen, Khoury, & Krieg, 2008; Phillips, 2015).

For the implementation of neuroprotective developmental care to be successful, all NICU staff must have the knowledge and skills to effectively implement this care, and there must be cooperation and collaboration between all healthcare providers and ancillary and support staff. Additional organizational support from the executive leadership team and nursing, medical, allied health, and support services is warranted. While practice changes can be arbitrarily imposed by administration, sustained cultural change rarely occurs in this manner. In order to establish neuroprotective family-centered developmental care as the norm in any unit, all staff that are affected by changes in care should be intimately involved, and at the least represented in the process. Guidelines should provide flexibility to support individual organizational needs, yet be structured enough to provide clear expectations for their implementation in order to hold all staff accountable. In addition to time and effort spent on teaching neuroprotective caregiving skills, it is worthwhile to spend time on evaluating the amount of changes occurring currently in the NICU as well as the level of motivation and team building attitudes among the multidisciplinary staff who will be implementing those skills.

Despite the stressors that accompany an ever-changing environment, many staff appear to manage the effects of perceived stressors and continue to deliver high-quality care, while others struggle. People experience stress when they perceive that events are placing excessive demands on them. Perceptions determine whether a given situation is experienced as an excessive demand or perceived as a challenging task or an opportunity, and these perceptions depend on the way in which an individual interprets the situation.

Multiple environmental changes experienced concurrently in a NICU can cause perceptions of work-related stress, which can lead to high staff turnover, decreased engagement, and decreased satisfaction. Environmental stressors in the nursing profession

include unpredictable staffing and scheduling, lack of role clarity, low involvement in decision making, and poor support, which are all likely to increase the level of stress and lead to job burnout. Studies reveal that the perception of stress in the practice environment has a direct impact on patient safety, patient experience, and staff decision making, as well as staff health and well-being, and can lead to burnout and ultimately affect productivity and employee retention (Braithwaite, 2008; Carter & Tourangeau, 2012; Larrabee et al., 2010; Pannell & Rowe, 2017).

One of the most popular models presenting how environmental stressors translate into the experience of stress has been developed by Lazarus and Folkman (1984). In that model, stress is defined as a relationship with the environment that exceeds an individual's ability to cope. Resilience is a self-regulatory mechanism and has been recognized as a significant personality factor involved in the process of coping. Resilience has been defined as a mental characteristic conducive to endurance, flexible adjustment, and mobilization to act in problematic situations (Ogińska-Bulik & Juczyński, 2008). Resilience helps tolerate negative emotions and experienced failures. Stress resilience can help an individual move forward in a positive way while maintaining equilibrium and some sense of control over his or her environment, despite significant stress or adversity (Larrabee et al., 2010). Resilience may be an important resource protecting nurses against negative effects of occupational stress. Research has demonstrated that sources of resilience include two main factors—personal factors and environmental-systemic factors. Interaction between these two factors contributes to the emergence of resilience and resilient attributes (Herrman et al., 2011), traits that are important to actively cultivate in any environment where rapid change is occurring.

While experiencing a high level of stress, nurses frequently deny the existence of difficult situations and additionally blame themselves for their emergence. Denial and self-blame, which are both maladaptive coping strategies, are categorized as escape and avoidance coping strategies (Carver & Connor-Smith, 2010). There are numerous difficult situations in the NICU that nurses experience, such as deterioration of an infant's health, complicated diagnoses, and death of a patient, as well as complicated family situations. Denial is a unique strategy used at the beginning of a stressful situation and it may prove beneficial due to temporary distance to the situation. Nevertheless, it disturbs and prevents effective coping. Self-blame, on the other hand, is a strategy manifesting helplessness, and it is defined as criticizing oneself for stressful circumstances. Utilizing self-blame and/or denial as coping strategies is not conducive to adjusting to difficult situations and actually is conducive to anxiety, depression, and overall poor mental health among nurses (Mark & Smith, 2011).

Mróz (2015) found a negative correlation between perceived stress and resilience. Results indicated that a low level of perceived stress is related to a high level of resilience, showing that the ability to adapt to and solve problems in a flexible manner is conducive to perceiving various problems as not stressful (Mróz, 2015). Similar results have proven that resilience interpreted as positive thinking, flexibility, assuming responsibility, and separating work and life is conducive to the ability to maintain the work–life balance among nurses (Kim & Windsor, 2015). Resilience also protects nurses against development of the symptoms of posttraumatic stress disorder (PTSD; Mealer, Jones, & Moss, 2012), and the level of perceived stress and job burnout (Mróz, 2014).

Benner's Novice to Expert model states that a bedside nurse is considered an expert after 5 years of nursing experience (Benner, 1984). It is frequently believed that more tenured nurses have more life and clinical experiences, and therefore can more easily develop stress resiliency. Findings from recent studies contradict this belief and find no correlation between age, experience, and resiliency (Lowe, 2013; Pannell & Rowe, 2017; Rushton, Batcheller, Schroeder, & Donohue, 2015). Nurses who have learned to adapt and thrive in the midst of adversity are recognized as resilient. Resilience is an attribute that can be developed and enhanced through education and support. Characteristics implemented by resilient nurses to cope with challenging work environments included supportive social networks, optimism, having a resilient role model, and a spiritual frame of reference (Mealer et al., 2012).

Although skills are critical in nursing, they may not be the key factor in reducing the perception of work-related stress. Enhanced critical thinking and decision-making skills, augmented composure and ability to function under stress, improved personal confidence, increased ability to listen more fully and nonreactively, and augmented feelings of empowerment in supportive and caring work environments may be the key to stress resilience.

Knoster's Managing Complex Change Model is a useful framework to utilize when introducing transformational change management principles in busy work environments. According to Knoster, there are six key elements required for effective change: vision, consensus, skills, incentives, resources, and an action plan (Knoster, 1995). To drive complex changes successfully, an organization needs to activate all six components, defined as follows:

VISION

The key to an effective strategy is to create a vision within a defined architecture. A vision is a clearly imagined view of the end state of change. No change should proceed without a clear vision of the goal and an understanding of the strategic path required to get there. A vision should convey two things: where you are going, and why you are going there. Building a shared vision is a critical factor in managing change. It is the starting point for goals and provides the launch pad for action and the parameters for problem solving.

Without a strategic vision, there will be *confusion* and therefore a lack of direction.

Structure in processes and in the organization is necessary to drive a strategic vision. Gaps in necessary policies, procedures, and/or guidelines must first be identified. Time must be spent early in the process to create interprofessional evidence-based best practices within the structure of policies, procedures, and guidelines that include defined standards and accountability metrics for all staff to follow. These must be organized, communicated, implemented, and audited for compliance in an organized fashion with clearly delineated expectations. Strong leadership is necessary to facilitate and sustain a cultural transformation.

CONSENSUS

Consensus includes cooperation, collaboration, and collegiality.

- Cooperation—agreement on ideas, values, purposes, shared understanding
- Collaboration—working together in an atmosphere of support and encouragement
- Collegiality—development of a learning community gaining skills and expertise together

Without consensus, there will be *sabotage*, where unwilling or unconvinced staff can actively work against the willing. Negativity of counterarguments can drag everyone down and prevent action.

SKILLS

Any cultural change requires a change in behaviors. Staff, and people in general, easily revert to old behaviors (habits) given the opportunity. Ensuring that new, changed behaviors take hold is where education and training come into play. A comprehensive training program is suggested in order to hardwire new skills required for staff to work in the "new" environment and to fulfill the new vision. Once the vision is established and the structure is identified, it is necessary to build the skills needed to realize the vision.

Without the appropriate competencies and skills needed to achieve the vision, there will be *anxiety*. Anxiety is inevitable in those who feel they do not have the necessary knowledge or expertise to cope with or to implement new situations, and also in those that have little faith in the training to provide them with knowledge and skills. Fear is a key generator of resistance to change and providing the opportunity to acquire needed skills is a key mitigating factor.

INCENTIVES

After the "Why?" in vision, the most common question those affected by change will ask is, "What's in it for me?" Incentives should spring directly from the vision for the organizational change. While rewards are given for accomplishments achieved, incentives are enticements to accomplish the change. Incentives can be intrinsic or extrinsic and can help motivate the workforce to acquire and maintain new skills. The types of incentives required to produce cultural change are those that impact the work itself. Incentives to change must be commensurate with the level of change demanded. Streamlining workflows and simplifying ease of use is a huge incentive and far more likely to be accepted than non–work-related incentives.

Without incentives, there will be *resistance* from those who see nothing in the changes for them, no moral meaning, no personal meaning, and/or no benefit. Resistant staff have the conviction that things are just fine as they are and see no need to change. If the change is perceived to increase the burden on individuals for an extended period, resistance, along with frustration and anxiety, will increase.

RESOURCES

In addition to meticulous planning, any significant change in culture or practices will also require a commitment by hospital administration and clinical leadership to allocate adequate resources needed, allowing the vision to be achieved. Resources include everything—and everyone—needed to make the change happen, such as the following:

- Physical resources
- Any items that people feel are necessary to enable them to make the required changes
- Use of existing knowledge or expertise within the organization or outside it
- Existing staff used as a resource, including management team members
- Emotional or social support/collegiality
- Development of knowledge, expertise, and skills through effective training programs
- Extra staffing
- New equipment
- Time given to development, planning, and reflection

Without the necessary resources, there will be *frustration*. If teams do not have the tools, money, time, information, and people necessary to adequately implement the changes needed to ensure success, outcomes will remain the same and the team will become frustrated and lose faith in the possibility of successful change. It is common for clinical leadership to create a vision that is shared by staff, but does not have the endorsement and backing of hospital administration and therefore lacks the resources needed to implement or maintain the change. Without administrative support, a change significant enough to improve patient or family outcomes is unlikely. It is critically important to include hospital administration and clinical leadership early in the process of designing and planning any significant change process.

ACTION PLAN

The action plan, based on specific achievable goals and objectives, is a way to make sure your organization's vision is made concrete. The action plan must spell out how the goals are to be reached, articulate who is responsible, specify the desired results and outcomes, and lay out a timeline for achieving the goals. The results of each action plan demonstrated through an organized cycle of improvement, such as the PDSA (Plan, Do, Study, Act) cycle, and their impact on the vision must be shared, communicated, and, if at all possible, published.

Action planning is a continuous thread across all phases—it is the change process. Although presented as the final component of the change framework, it should be viewed as the foundation of the systems' transformational change process. Clearly understood metrics for accountability are necessary for success. Rewards and consequences must be established for holding staff accountable to the action plan.

Without an action plan, staff feel like they are on a never-ending *treadmill*, doing what they have always done in the way they have always done it and therefore not succeeding in working in new ways, and not achieving new goals.

CREATING A CULTURE OF CHANGE

Organizational change is essentially cultural change, which demands shifts in behavior and beliefs. Staff typically go through the stages of acculturation as they accept (or reject) the newly established culture. Utilizing a team-based framework, the authors define acculturation as a two-way process where both cultures (the old and the new ways of working) come together to create one desired unit culture. Values are transferred, and beliefs are adopted to create behavioral changes necessary to achieve the vision. Acculturated staff become stakeholders in the process and engage in the transformational change.

The Knoster model is a helpful way for planning and operationalizing, studying and evaluating, as well as diagnosing what might be needed when plans go awry. Often, there is a sense that something is wrong with the change process, but no one understands how to resolve or determine the root of the problem. The Knoster model is a powerful tool to connect the symptom with the missing or misappropriated components of change, make a diagnosis, and propose a therapeutic recommendation. If those leading the process of change fail to put any one of these elements in place, the change efforts will not succeed as intended and may fail.

Implementing neuroprotective interventions (NPIs) as outlined in the Neonatal Integrative Developmental Care Model framework requires such a plan. Defining NPIs is just a start. To fully incorporate the identified NPIs into a unit's culture, a thorough process of transformational change is required. Milette, Martel, da Silva, and Coughlin McNeil (2017a, 2017b) outline several existing organizational implementation strategies for developmental care, including the NIDCAP program (Als et al., 1994), the Wee Care Neuroprotective NICU program (Altimier et al., 2015), and strategies outlined by Coughlin (2016), which were modelled from the Wee Care Program (Milette et al., 2017a, 2017b). Utilizing Knoster's Managing Complex Change Model with organizational leaders across the world, the Wee Care Neuroprotective NICU program, NPIs, and Small Baby Guidelines have all been operationalized with measurable criteria and attributes, and each has demonstrated success (Altimier et al., 2015; Altimier & Phillips, 2018; Cardin et al., 2015; Coughlin, 2008; Dungca et al., 2011; Hendricks-Muñoz et al., 2002; Lockridge, 2018; Ludwig et al., 2008; Phillips, 2015).

The Neonatal Integrative Developmental Care Model utilizes NPIs as strategies to support optimal synaptic neural connections, promote normal development, and prevent disabilities. Seven neuroprotective core measures for family-centered developmental care of the premature neonate are depicted on petals of a lotus as the Healing Environment, Partnering with Families, Positioning and Handling, Safeguarding Sleep, Minimizing Stress and Pain, Protecting Skin, and Optimizing Nutrition. The overlapping petals of the model demonstrate the integrative nature of developmental care (see Figure VII.1).

Each core measure has a standard(s) with a policy or protocol that guides care of the infant/family as it relates to that specific core measure. Corresponding infant characteristics, which are measurable reflections of the desired core measure outcomes, are identified, and specific goals target the improvements/outcomes desired. Clinical applications include NPIs that define and specify the actions required to meet the goal(s). These must be evidence-based, reliably applied, and scientifically valid.

A description of each core measure, along with teamwork and collaboration, is reviewed in detail in "The Neonatal Integrative Developmental Care Model: Advanced Clinical Applications of the Seven Core Measures for Neuroprotective Family-Centered Developmental Care" (Altimier & Phillips, 2016). Table VII.1 further details the NPIs outlined by Altimier and Phillips (2016), with an expanded scope, given the dynamic nature of neuroprotective care.

SUMMARY

Organizational change happens naturally all the time for better or for worse. When there is a specific aim—like the implementation of NPIs—there must be specific efforts in change management to align an organization's culture (i.e., beliefs and ways of behaving) to the new interventions or change practices. The Knoster model provides a solid framework, comprised of components that are easily remembered but no more easily accomplished than any other model. No organizational change model is perfect. No one model can guarantee a desired outcome. Only the change champions in an organization and those who take part in the change can make the outcomes align with the vision that forms the basis for the future state. Resistance to change is a natural reaction when people are asked to do something they have not done before, or perhaps even more when they are asked to do something they have done before, but in a different way. Overcoming the associated symptoms, confusion, sabotage, anxiety, resistance, frustration, and, treadmill effect is the aim of great organizational change management, however it is accomplished.

TABLE VII.1

PROTOCOL FOR THE IMPLEMENTATION OF NEUROPROTECTIVE INTERVENTIONS FOR INFANTS IN THE NICU RELATED TO THE SEVEN CORE MEASURES OF NEUROPROTECTIVE FAMILY-CENTERED DEVELOPMENTAL CARE

Core Measure # 1: Healing Environment

(Altimier, 2015b; Altimier & Phillips, 2013, 2018; Altimier & White, 2019; Bergman, 2015; Craig et al., 2015; S. Hall, Hynan, et al., 2015; Phillips, 2015, 2019; Robison, 2003; White, Smith, & Shepley, 2013)

Standard: A policy/procedure/guideline on the Healing Environment including physical space and privacy as well as the protection of the infant's sensory system exists and is followed throughout the infant's stay.

Infant Characteristics	Goals	Neuroprotective Interventions
Stability of the infant's autonomic, sensory, motoric, and state regulation systems	An environment will be maintained that promotes healing by minimizing the impact of the artificial extrauterine NICU environment on the developing infant's brain. The central role of mother/parent will be recognized and prioritized as the developmentally expected environment for all newborn mammals.	**General** • Educate, coach, and mentor parents on the importance of creating a healing environment that protects the developing sensory system of the preterm infant. Emphasize their central role in the healing environment as parents and as active members of the caregiving team. **Skin-to-Skin Contact** • Facilitate early, frequent, and prolonged SSC, recognizing that SSC with mother/parent is the developmentally expected habitat for all newborn mammals. • Make zero separation between parents and infant a priority whenever possible. • Provide comfortable and safe reclining chair or adult bed for early, frequent, and prolonged SSC. **Space** • Maintain a private and safe environment for the infant and family that consists of a minimum of 120 square feet per patient. • Provide organized, uncluttered space for the family in order to support comfortable and private caregiving interactions with their baby. • When renovations are planned, advocate for single family rooms and promote utilization of the latest standards from the *Recommended Standards for Newborn ICU Design* at www3.nd.edu/~nicudes. **Tactile** • Provide a neutral thermal environment for the infant incorporating the following factors: Facilitate early, frequent, and prolonged SSC. • If ELBW, provide humidity during the first 2 weeks after birth (50% humidity is provided to the infant in SSC). • Provide care in SSC or incubator until infant can maintain own temperature. **Vestibular** • Change infant's position gently and slowly without sudden movements. • Eliminate moving infant beds to different spaces to accommodate staffing patterns. **Olfactory** • Maintain a scent-free and fragrance-free unit. • Minimize exposure to noxious odors. • Expose infant to mother's scent via SSC, breast pad, soft cloth, or Snoedel.

(*continued*)

TABLE VII.1

PROTOCOL FOR THE IMPLEMENTATION OF NEUROPROTECTIVE INTERVENTIONS FOR INFANTS IN THE NICU RELATED TO THE SEVEN CORE MEASURES OF NEUROPROTECTIVE FAMILY-CENTERED DEVELOPMENTAL CARE (*continued*)

Infant Characteristics	Goals	Neuroprotective
		Gustatory • Position infant with hands near face. • Provide colostrum or expressed MOM oral care per protocol. • Provide positive oral feeding experiences as outlined in Optimizing Nutrition section. **Auditory** • Support infants with consistently calm, relaxing environment with muted sounds and lighting between and during caregiving interactions. • Be mindful of own voice and other sounds produced in the NICU. • Monitor sound levels to maintain sound levels of <50 decibels. • Silence alarms as quickly as possible and avoid unnecessary alarms. • Comfort crying infants as quickly as possible. • Expose infant to audible maternal/paternal voice, encouraging parents to quietly talk and sing to their infant. **Visual** • Provide adjustable light levels up to a maximum of 60 fc. • Gently shield infant's eyes during care if overhead light is needed. • Be mindful of structuring an infant's visual field to support alert wakefulness as appropriate, transition to sleep, or quiet, restful sleep. • Minimize purposeful visual stimulation until 37 weeks' gestation. **Overall Healing Environment** • Consider all sources of light, sound, movement, smell, and taste confronting an infant during care and eliminate all inappropriate or unnecessary sources of stimulation. • Create and implement an individualized developmental care plan for each infant. • Provide guidance to parents on how to create and sustain a healing environment with respect to sensory exposures and experiences. • When renovating the NICU environment, advocate for optimal family support spaces and resource supports.

TABLE VII.1

PROTOCOL FOR THE IMPLEMENTATION OF NEUROPROTECTIVE INTERVENTIONS FOR INFANTS IN THE NICU RELATED TO THE SEVEN CORE MEASURES OF NEUROPROTECTIVE FAMILY-CENTERED DEVELOPMENTAL CARE (*continued*)

Core Measure # 2: Partnering With Families

(Altimier et al., 2015a; Altimier & Phillips, 2013, 2018; Altimier & White, 2019; Bergman, 2014, 2015; Craig et al., 2015; Hall, Ryan, Beatty, & Grubbs, 2015; Kenner, Press, & Ryan, 2015; Phillips, 2019; Purdy, Craig, & Zeanah, 2015; Sullivan & Altimier, 2007)

Standard 1: A policy/procedure/guideline on Partnering With Families to include unlimited access to ensure round-the-clock information and access to their baby exists and is followed throughout the infant's stay.
Standard 2: There is a specific mission statement addressing Partnering With Families.
Standard 3: NICU staff are competent in educating, coaching, and mentoring parents in infant caregiving skills and in providing psychosocial support to NICU families.

Infant Characteristics	Goals	Neuroprotective Interventions
Infant's response to parental interactions	• Family-centered care is supported from birth or as soon as a NICU stay is anticipated (antenatally if possible). • Parents will be viewed not as "visitors" but as equal and vital members of the caregiving team with zero separation supported and encouraged (24 hours/day). • Parents will be supported and encouraged as the primary and most important caregivers for their infant, incorporating them as full participatory, essential healing partners within the NICU caregiving team. • Infant will develop emotional connection and secure attachment with parents. • Parents who lose a baby before, during, or shortly after birth, or later in the NICU, will be supported at all points of care.	• Make zero separation between parents and infant a priority. • Facilitate early, frequent, and prolonged SSC, recognizing that SSC supports secure bonds of attachment between parents and their infant, which is necessary for normal development. • Support families in a warm, respectful, and welcoming manner. • Actively listen to families' feelings and concerns (both verbal and nonverbal) and respond with appropriate action when needed. • Accommodate the presence of families in the NICU and encourage participation in medical rounds and nursing handoffs. • Provide parents with full access and input to both written and electronic medical records with medical interpretation as needed. • Communicate the infant's medical, nursing, and developmental needs in a culturally appropriate and understandable way. • Share information with families in a tone of voice that preserves confidentiality. • Educate, coach, and mentor parents in becoming active participants in their baby's care in supporting their infant's optimal development. • Educate parents on infant attachment, developmental, and safety issues. • Encourage families to personalize their infant's bed space and make the NICU environment more homelike. • Support breast milk expression and breastfeeding. • Include and support sibling and extended family participation as desired by parents. • Provide social networking opportunities for parents of premature infants in the NICU. • Provide peer-to-peer support with parents who have gone through similar NICU stays. • A Family Advisory Council will be consulted for involvement in the design of P & P, and deign strategies. • Honor both Health Insurance Portability and Accountability Act and safety concerns while in the NICU. • Encourage and empower parents as they develop confidence in their own abilities to continue caring for their baby when going home. • Provide staff education related to principles of family-centered care and how to support parents' caregiving roles. • Acknowledge where the family is in regard to stages of grief and loss and provide individualized and appropriate resources as needed. • Provide anticipatory guidance regarding the increased risks of anxiety and depression commonly experienced by NICU parents, recognizing they all may handle the NICU experience differently. • Provide psychosocial support for all members of the family, including grandparents and the baby's siblings, and make referrals to professional resources as needed.

(*continued*)

TABLE VII.1

PROTOCOL FOR THE IMPLEMENTATION OF NEUROPROTECTIVE INTERVENTIONS FOR INFANTS IN THE NICU RELATED TO THE SEVEN CORE MEASURES OF NEUROPROTECTIVE FAMILY-CENTERED DEVELOPMENTAL CARE (*continued*)

Core Measure # 3: Positioning and Handling

(Altimier et al., 2015; Altimier & Phillips, 2013, 2016, 2018; Charafeddine et al., 2018; Craig et al., 2015; Danner-Bowman & Cardin, 2015; Hunter, Lee, & Altimier, 2015; Jeanson, 2013; Phillips, 2015; Robison, 2003; Spilker & Rosenblum, 2016)

Standard: A policy/procedure/guideline on Positioning and Handling exists and is followed throughout the infant's stay that includes educating, coaching, and mentoring parents on how to position and handle their infant.

Infant Characteristics	Goals	Neuroprotective Interventions

• Autonomic stability during handling
• Ability to maintain tone and flexed postures with and without supports
	• Autonomic stability will be maintained throughout positioning changes and handling activities as well as during periods of rest and sleep.
	• Parents will be educated, coached, and mentored in how to position and handle their infant.
	• Preventable positional deformities will be eliminated or minimized by maintaining infants in a midline, flexed, contained, and comfortable position throughout their NICU stay.
	• The caregiver sees herself or himself in partnership with the baby so that caregiving procedures are performed "with" the infant rather than "to" the infant.
	• Infants will be provided developmentally appropriate stimulation/play as they mature (i.e., mobiles, swings, etc.).
		• Facilitate early, frequent, and prolonged SSC, recognizing that SSC promotes optimal flexed positioning in full ventral contact with parent's chest, enhancing warmth and physiologic stability.
		• Anticipate, prioritize, and support the infant's individualized needs during each caregiving interaction to minimize stressors known to interfere with normal development.
		• Educate staff (medical, nursing, and therapists) about the importance of doing cares or procedures "with" the infant, not "to" the infant. Support staff in seeing the infant as an active participant in the caregiving activity or procedure.
		• Educate, coach, and mentor parents in how to position, contain, and handle their infant in a developmentally appropriate manner.
		• Educate parents how to engage with their infant when doing caregiving activities so as to make an emotional connection rather than simply to complete a task.
		• Provide infants with positioning supports needed to maintain optimal tone and position and to remain either in a quiet, restful sleep or a relaxed, comfortable wakeful state.
		• Utilize a validated and reliable positioning assessment tool (i.e., Infant Positioning Assessment Tool [IPAT]) routinely to ensure appropriate positioning and encourage accountability.
		• Maintain a midline, flexed, contained, and comfortable position at all times utilizing appropriate positioning aids and boundaries.
		• Promote hand to mouth/face contact.
		• Provide appropriate ventral support when infant is prone to ensure flexed shoulders/hips.
		• Avoid doing procedures with infant in a prone position where he/she is unable to use self-comforting abilities.
		• Provide swaddling when bathing and weighing to reduce stress.
		• Let behavioral cues of stress or relaxation guide infant care.
		• Assess infant sleep–wake cycle to evaluate appropriate timing of positioning and caring.
		• Reposition infant with cares and minimally every 4 hours.
		• Provide four-handed support during positioning and caring activities of extremely preterm infants.
		• When providing caregiving activities,
		  • Collect all supplies prior to approaching infant so infant is not left unattended or unsupported once hands-on care has begun.
		  • Seek another person to support infant care during a potentially stressful experience, including bathing and weighing.
		  • Include parents in providing support when available and willing.

(*continued*)

TABLE VII.1

PROTOCOL FOR THE IMPLEMENTATION OF NEUROPROTECTIVE INTERVENTIONS FOR INFANTS IN THE NICU RELATED TO THE SEVEN CORE MEASURES OF NEUROPROTECTIVE FAMILY-CENTERED DEVELOPMENTAL CARE (*continued*)

Core Measure # 4: Safeguarding Sleep

(Altimier & Phillips, 2013, 2016; Altimier & White, 2019; Craig et al., 2015; Graven, 2006; Graven & Browne, 2008)

Standard 1: A policy/procedure/guideline on Safeguarding Sleep exists and is followed throughout the infant's stay.
Standard 2: A policy/procedure/guideline on Safe Sleep Practices exists and is followed prior to discharge.

Infant Characteristics	Goals	Neuroprotective Interventions
• Infant sleep–wake states, cycles, and transitions • Infant's maturity and readiness for Back-to-Sleep protocol	• Infant sleep–wake states will be assessed before initiating all caregiving activities. • Prolonged periods of uninterrupted sleep will be protected. • Infants will be transitioned to Back-to-Sleep protocol when developmentally appropriate.	• Educate all NICU staff (medical, nursing, and therapists) about the importance of sleep for normal infant brain development. • Educate, coach, and mentor parents on sleep–wake states and how to promote sleep in their infant, recognizing the importance of sleep to healing, growth, and brain development. • Facilitate early, frequent, and prolonged SSC, recognizing that SSC promotes development of more mature sleep cycles. • Utilize a validated and reliable scale to assess sleep–wake states to promote sleep and plan caregiving activities. • Protect quiet sleep states by providing flexibility in timings of care. Individualize all caregiving activities by clustering cares based on infant sleep–wake states. Take care not to overstress infant with too many clustered cares at once. • If necessary, to arouse a sleeping infant, approach using a soft voice/whisper followed by gentle touch. • Support smooth transitions back to restful sleep with supportive positioning and containment before stepping away from bedside. • Promote a quiet environment to ensure uninterrupted sleep. • Protect the eyes from direct light exposure and maintain low levels of ambient light. • Use incubator covers to protect the infant from direct light. • Provide some daily exposure to light, preferably including shorter wavelengths, for entrainment of the circadian rhythm. • Avoid (when possible) high doses of sedatives and drugs that can depress the endogenous firing of cells, thus interfering with visual development, rapid and non–rapid eye movement sleep cycles, and, therefore, optimal brain development. • Provide developmental care appropriate for the age and maturation of the infant, including supportive positioning for very preterm infants, to promote restful sleep. • Assure infant is able to maintain normal sleep pattern during Back-to-Sleep well before discharge and role model this behavior in the NICU. • Provide tummy time/prone-to-play time routinely for infants that are on Back-to-Sleep protocol. • Coach, educate, and mentor parents about the importance and rationale for Safe Sleep practices and tummy time.

TABLE VII.1

PROTOCOL FOR THE IMPLEMENTATION OF NEUROPROTECTIVE INTERVENTIONS FOR INFANTS IN THE NICU RELATED TO THE SEVEN CORE MEASURES OF NEUROPROTECTIVE FAMILY-CENTERED DEVELOPMENTAL CARE (*continued*)

Core Measure # 5: Minimizing Stress and Pain		
(Altimier & Phillips, 2013, 2016, 2018; Benoit et al., 2016; Craig et al., 2015; Johnston et al., 2014; Phillips, 2015, 2019; Robison, 2003)		
Standard: A policy/procedure/guideline on the assessment and management of pain exists and is followed throughout the infant's stay.		
Infant Characteristics	**Goals**	**Neuroprotective Interventions**
Behavioral cues indicating stress or self-regulation	Promote self-regulation and neurodevelopmental organization.	• Acknowledge the many sources of stress and pain in the developmentally unexpected and artificial environment of the NICU for preterm and sick infants. • Educate all NICU staff (medical, nursing, and therapists) how to recognize infant behavioral signs of stress and pain for preterm and term infants and how to utilize developmentally appropriate comfort measures. • Facilitate early, frequent, and prolonged SSC, recognizing that the infant's stress level is usually significantly lower when in SSC with parents. • Educate, coach, and mentor parents on infant behavioral cues related to stress and pain and how to provide their infant with nonpharmacologic support during stressful or painful procedures. • Utilize a validated and reliable pain assessment tool to evaluate the need for pharmacologic support. • Provide nonpharmacologic support (SSC, breast milk, sucrose, pacifier) with all minor invasive interventions. • Provide midline, flexion, and containment with all positioning to promote comfort. • Provide therapeutic positioning aids to promote supportive positioning. • Use swaddling for weighing and bathing to reduce stress. • Provide individualized care in a manner that anticipates, prioritizes, and supports the needs of infants to minimize stress and pain. • Talk softly to babies before, during, and after a painful or stressful procedure or caregiving event to provide forewarning and sympathy, and to let them know when the procedure is over.

(*continued*)

TABLE VII.1

PROTOCOL FOR THE IMPLEMENTATION OF NEUROPROTECTIVE INTERVENTIONS FOR INFANTS IN THE NICU RELATED TO THE SEVEN CORE MEASURES OF NEUROPROTECTIVE FAMILY-CENTERED DEVELOPMENTAL CARE (*continued*)

Core Measure # 6: Protecting Skin		
(Altimier & Phillips, 2013, 2016, 2018; Craig et al., 2015; Phillips, Chantry, & Gallagher, 2005; Robison, 2003; Visscher, Adam, Brink, & Odio, 2015; Visscher & Narendran, 2014)		
Standard: A policy/procedure/guideline on Skin Care exists and is followed throughout the infant's stay.		
Infant Characteristics	**Goals**	**Neuroprotective Interventions**
Maturity and integrity of infant skin	• Reduce transepidermal water loss of ELBW infants. • Maintain skin integrity of the infant from birth to discharge. • Provide developmentally appropriate infant massage.	• Facilitate early, frequent, and prolonged SSC, recognizing that the skin is a conduit of nerve impulses to the brain; thus, healthy, intact skin promotes brain development. • Educate, coach, and mentor parents on skin care, swaddled bathing, and delivery of developmentally appropriate infant massage. • Provide parents with guidance on how to protect their baby's skin and its many functions, including its role as a conduit of neurosensory information to the brain. • Utilize a validated and reliable skin assessment tool (i.e., Braden Q) on admission and routinely according to hospital protocol. • Provide individualized care in a manner that anticipates, prioritizes, and supports the needs of infants to optimize neuromotor development. • Provide humidity for ELBW infants during the first 2 weeks after birth (50% humidity is provided with SSC). • Provide appropriate positioning support utilizing gel products when needed to prevent skin breakdown. • Examine position of nasal prongs per protocol to protect against breakdown of nasal septum. • Minimize use of adhesives and use caution when removing adhesives to prevent epidermal stripping. • Avoid soaps and routine use of emollients. • Use water only for bathing infants $<$1,000 g. • Use pH neutral cleansers for bathing infants $>$1,000 g. • When bathing, do swaddled bathing in bed or tub (to reduce stress and promote relaxation) with overhead warmer (to prevent risk of hypothermia). • Priority should be given to parents to bathe their infant whenever possible. • Provide bathing no more than every 72–96 hours.

(*continued*)

TABLE VII.1

PROTOCOL FOR THE IMPLEMENTATION OF NEUROPROTECTIVE INTERVENTIONS FOR INFANTS IN THE NICU RELATED TO THE SEVEN CORE MEASURES OF NEUROPROTECTIVE FAMILY-CENTERED DEVELOPMENTAL CARE (*continued*)

Core Measure # 7: Optimizing Nutrition

(Altimier & Phillips, 2013, 2016, 2018; Craig et al., 2015; Hall, Ryan, et al., 2015; Purdy et al., 2015; Robison, 2003)

Standard 1: A policy/procedure/guideline on Optimizing Nutrition (cue-based/infant-driven breastfeeding or bottlefeeding), which includes infant readiness, quality of feeding, and caregiver techniques, is followed throughout the infant's stay.
Standard 2: A policy/procedure/guideline on SSC (kangaroo care) exists and is followed throughout the infant's stay.

Infant Characteristics	Goals	Neuroprotective Interventions
• Physiologic stability with feeding and handling • Feeding readiness cues • Coordinated suck/swallow/breathing throughout breastfeeding or bottlefeeding • Endurance to maintain nutritional intake and support growth	• Feeding will be safe, functional, nurturing, and developmentally appropriate. • Optimized nutrition will be enhanced by individualizing all feeding care practices. • Oral aversions will be prevented by ensuring that eating is a positive experience for infants. • Infants of breastfeeding mothers will be competent at breastfeeding prior to discharge.	• Support and encourage the expression of MOM to support an optimum milk supply. • Facilitate early, frequent, and prolonged SSC, recognizing that SSC causes a spike in prolactin, thus facilitating milk production, and promotes earlier initiation as well as longer duration of breastfeeding. • Minimize negative perioral stimulation (adhesives, suctioning, etc.). • Utilize indwelling gavage tubes rather than intermittent tubes. • Promote positive oral stimulation and NNS at mother's breast during gavage feeds (no need for breasts to be pumped for very preterm infants). • Provide taste and smell of breast milk through oral care with gavage feedings when mother is not present, holding infant and using an appropriately sized pacifier for NNS. • Utilize a validated and reliable Infant-Driven Readiness—Feeding—Caregiving Scale. • Individualize care by incorporating cue-based/infant-driven feeding practices. • Ensure every feeding experience is a positive, pleasant, and nurturing experience. • Promote side-lying position close to parent/caregiver when bottlefeeding. • Educate, coach, and mentor parents about infant feeding cues, and guide them with pacing and other feeding techniques to provide positive and supportive oral feeding experiences for their infant. • Encourage preterm infants to practice suckling when in SSC whenever they are interested. • Support and encourage breastfeeding well before discharge. • Have a discharge feeding plan in place before discharge, including outpatient breastfeeding support if needed.

TABLE VII.1

PROTOCOL FOR THE IMPLEMENTATION OF NEUROPROTECTIVE INTERVENTIONS FOR INFANTS IN THE NICU RELATED TO THE SEVEN CORE MEASURES OF NEUROPROTECTIVE FAMILY-CENTERED DEVELOPMENTAL CARE (*continued*)

Teamwork and Collaboration

(Altimier et al., 2015; Altimier & Phillips, 2016; Axelin, Outinen, Lainema, Lehtonen, & Franck, 2018; Craig et al., 2015; Gausvik, Lautar, Miller, Pallerla, & Schlaudecker, 2015; Hall, Cross, et al., 2015; Hall, Cross, et al., 2015; Hall, Ryan, et al., 2015; Robison, 2003; Rushton et al., 2015)

Standard 1: An interdisciplinary team of caregivers, supported by clinical leadership and hospital administration, works together collaboratively to support the infant's and family's goals.
Standard 2: Hospital leadership facilitates education related to self-care of all NICU staff to prevent burnout, compassion fatigue, and secondary PTSD.
Standard 3: A policy/procedure/guideline on roles and responsibilities of team members and collaboration exists and is followed.

Infant Characteristics	Goals	Neuroprotective Interventions
Infant and family are central to each team member's plans, decisions, and caregiving	• An individualized developmentally appropriate environment is provided for every infant and family. • NICU staff feel supported by hospital administration, clinical leadership, and by their peers in providing optimal neuroprotective family-centered developmental care to infants and families. • Parents feel supported in their NICU experience, feel valued as full and active members of the NICU team, and feel assured that their baby is getting the best medical and developmental care possible.	• Educate all staff about the principles and practices of neuroprotective family-centered developmental care. • Support and value parents as the primary caregivers by educating, coaching, and mentoring parents to be active members of the NICU caregiving team. • Incorporate structured interdisciplinary rounding (to include parents) into the team's practice. • Provide as much space and comfort as possible for family involvement in caregiving, keeping charts and equipment well organized and avoiding clutter. • Include parents in all medical and nursing decision making. • Share pertinent information with colleagues, as appropriate, about family involvement, strengths, and challenges in relation to their infant's NICU stay. • Develop strategies to provide psychosocial support for NICU parents as needed. • Respect and support the roles of other individuals and disciplines when caring for infants, and support each other through mentoring relationships. • Prior to performing a procedure, care, or examination on an infant under the care of another team member (or parent), discuss needs of that team member to mutually agree on the timing. • Consistently share information about the infant's behavioral competencies, vulnerabilities, and thresholds when communicating with colleagues during rounds or shift change. • Willingly and proactively assist colleagues to provide support for infants in their care during potentially stressful care activities or painful procedures. • Ensure all infants and families are treated consistently with support, dignity, and respect by all team members, and constructively confront team members (staff or parents) if discrepancies are noted. • Educate staff on the differences and value of cultural practices other than their own. • Educate staff on optimal methods of communication with parents in distress. • Educate staff on elements of self-care to proactively prevent and minimize burnout, compassion fatigue, and secondary PTSD. • Ensure that channels of communication between nursing staff and their supervisors are clear with an outlet to access support. • Educate staff about methods for improving and expanding family-centered developmental care in the NICU, including ongoing assessments and quality improvement projects. • Ensure support from hospital administration and clinical leadership to share in the vision and provide needed resources for funding, education, equipment, and personnel. • Plan and schedule team building activities to encourage interdisciplinary professional relationships among staff, maintain motivation for ongoing collaboration, and inspire future improvements.

ELBW, extremely low birth weight; MOM, mother's own milk; NICU, neonatal intensive care unit; NNS, nonnutritive sucking; PTSD, posttraumatic stress disorder; SSC, skin-to-skin contact.

APPENDIX A

Neonatal Nurses and Interconception Care

Merry-K. Moos

INTRODUCTION

Healthcare providers and policy makers are increasingly aware that efforts to prevent reproductive casualties that begin in prenatal care are starting too late to affect primary prevention (Centers for Disease Control and Prevention [CDC], 2006). As a result, preconception and interconception cares have become a focus for healthcare interactions with women of childbearing age. Preconception and interconception health are defined as "Any intervention provided to women of childbearing age, regardless of pregnancy desire, to improve the health outcomes of women, newborns and children" (Dean et al., 2012). Knowledge of interconception care is important for NICU nurses because of their ongoing interactions with individual women when they visit their infants. This ongoing relationship allows the NICU nurse to observe the new mother's health status, her self-care practices, and her use of health and medical resources. Thus, the nurse may observe a woman becoming withdrawn, depressed, or anxious; she may observe that she is missing meals or stress eating; the nurse may note lack of sleep and lack of support.

Identification of a new mother's healthcare needs gives the NICU staff the opportunity to provide education, guidance, and support to the mother as they perform their usual care. NICU nurses can help identify maternal medical needs and health risks and assist new mothers in addressing their own health even as they focus on the well-being of their neonate.

Examples for each include the following:

- Strategies for taking care of self include encouraging
  - Time away from unit to eat meals
  - Healthy snacks
  - Taking breaks to walk in and around the hospital
  - Talking about her feelings about the baby's situation and encourage discussing fears, concerns, self-blame with the unit social worker and with her usual provider.
- Strategies for minimizing risks to women's own health and future reproductive outcomes include encouraging:
  - Women to maintain or become smoke free
  - Healthy approaches to stress reduction
  - Waiting the optimal time (18–60 months) before becoming pregnant again (Conde-Agudelo, Rosas-Bermudez, & Kafury-Goeta, 2006)
  - Attending postpartum visit(s) with healthcare provider
  - Use of an over-the-counter (OTC) daily multivitamin with folic acid after prenatal vitamins are depleted
  - Follow up with their usual provider for any medical needs identified during pregnancy (e.g., severe preeclampsia resulting in extreme prematurity, diabetes mellitus resulting in respiratory distress syndrome in infant, etc.)
  - Early identification and referral for signs and symptoms of anxiety and depressive disorder
  - Take the lead in linking a woman with the unit social worker or other resources as indicated for her own well-being

APPENDIX B

Conversion Table to Standard International (SI) Units

Component	Present Unit	×	Conversion Factor	=	SI Unit
Clinical Hematology					
Erythrocytes	per mm^3		1		10^6/L
Hematocrit	%		0.01		(1)vol RBC/vol whole blood
Hemoglobin	g/dL		10		g/L
Leukocytes	per mm^3		1		10^6/L
Mean corpuscular hemoglobin concentration (MCHC)	g/dL		10		g/L
Mean corpuscular volume (MCV)	μm^3		1		fL
Platelet count	$10^3/mm^3$		1		10^9/L
Reticulocyte count	%		10		10^{-3}
Clinical Chemistry					
Acetone	mg/dL		0.1722		mmol/L
Albumin	g/dL		10		g/L
Aldosterone	ng/dL		27.74		pmol/L
Ammonia (as nitrogen)	µg/dL		0.7139		µmol/L
Bicarbonate	mEq/L		1		mmol/L
Bilirubin	mg/dL		17.1		µmol/L
Calcium	mg/dL		0.2495		mmol/L

Component	Present Unit	×	Conversion Factor	=	SI Unit
Calcium ion	mEq/L		0.50		mmol/L
Carotenes	µg/dL		0.01836		µmol/L
Ceruloplasmin	mg/dL		10.0		mg/L
Chloride	mEq/L		1		mmol/L
Cholesterol	mg/dL		0.02586		mmol/L
Complement, C_3 or C_4	mg/dL		0.01		g/L
Copper	µg/dL		0.1574		µmol/L
Cortisol	µg/dL		27.59		nmol/L
Creatine	mg/dL		76.25		µmol/L
Creatinine	mg/dL		88.40		µmol/L
Digoxin	ng/mL		1.281		nmol/L
Epinephrine	pg/mL		5.458		pmol/L
Fatty acids	mg/dL		10.0		mg/L
Ferritin	ng/mL		1		µg/L
α-Fetoprotein	ng/mL		1		µg/L
Fibrinogen	mg/dL		0.01		g/L
Folate	ng/mL		2.266		nmol/L
Fructose	mg/dL		0.05551		mmol/L
Galactose	mg/dL		0.05551		mmol/L
Gases					
PO_2	mm Hg (= torr)		0.1333		kPa
PCO_2	mm Hg (= torr)		0.1333		kPa
Glucagon	pg/mL		1		ng/L
Glucose	mg/dL		0.05551		mmol/L
Glycerol	mg/dL		0.1086		mmol/L
Growth hormone	ng/mL		1		µg/L
Haptoglobin	mg/dL		0.01		g/L

Component	Present Unit	×	Conversion Factor	=	SI Unit
Hemoglobin	g/dL		10		g/L
Insulin	µg/L		172.2		pmol/L
	mU/L		7.175		pmol/L
Iron	µg/dL		0.1791		µmol/L
Iron-binding capacity	µg/dL		0.1791		µmol/L
Lactate	mEq/L		1		mmol/L
Lead	µg/dL		0.04826		µmol/L
Lipoproteins	mg/dL		0.02586		mmol/L
Magnesium	mg/dL		0.4114		mmol/L
	mEq/L		0.50		mmol/L
Osmolality	mOsm/kg H_2O		1		mmol/kg H_2O
Phenobarbital	mg/dL		43.06		µmol/L
Phenytoin	mg/L		3.964		µmol/L
Phosphate	mg/dL		0.3229		mmol/L
Potassium	mEq/L		1		mmol/L
	mg/dL		0.2558		mmol/L
Protein	g/dL		10.0		g/L
Pyruvate	mg/dL		113.6		µmol/L
Sodium ion	mEq/L		1		mmol/L
Steroids					
17-hydroxycorticosteroids	mg/24 h		2.759		µmol/d
17-ketosteroids	mg/24 h		3.467		µmol/d
Testosterone	ng/mL		3.467		nmol/L
Theophylline	mg/L		5.550		µmol/L
Thyroid tests					
Thyroid-stimulating hormone	µU/mL		1		mU/L
Thyroxine (T_4)	µg/dL		12.87		nmol/L

Component	Present Unit	×	Conversion Factor	=	SI Unit
Thyroxine free	ng/dL		12.87		pmol/L
Triiodothyronine (T_3)	ng/dL		0.01536		nmol/L
Transferrin	mg/dL		0.01		g/L
Triglycerides	mg/dL		0.01129		mmol/L
Urea nitrogen	mg/dL		0.3570		mmol/L
Uric acid (urate)	mg/dL		59.48		µmol/L
Vitamin A (retinol)	µg/dL		0.03491		µmol/L
Vitamin B_{12}	pg/mL		0.7378		pmol/L
Vitamin C (ascorbic acid)	mg/dL		56.78		µmol/L
Vitamin D					
Cholecalciferol	µg/mL		2.599		nmol/L
25 OH-cholecalciferol	ng/mL		2.496		nmol/L
Vitamin E (alpha-tocopherol)	mg/dL		23.22		µmol/L
D-xylose	mg/dL		0.06661		mmol/L
Zinc	µg/dL		0.1530		µmol/L
Energy	kcal		4.1868		kj (kilojoule)
Blood pressure	mm Hg (= torr)		1.333		mbar

introduction, 539
liver transplantation, 612–615
long-term consequences, 540
multidimensional pain assessment tools in newborns, 541
multidimensional tools, 540–542
neonatal nurse's role and responsibilities, 555
neurodevelopment perception, 540
parents, 555
peripheral transduction and transmission, 539
specific types, 553–555
pathologic anemia
chronic anemia, newborn, 342–343
fetal–maternal transfusion, 341
hemorrhage, 341
iatrogenic blood loss, 342
internal hemorrhage, 343
obstetrical accidents, 343
twin-to-twin transfusion, 341–343
persistent pulmonary hypertension, 136
pharmacologic management
acetaminophen, 552–553
adjunctive drugs, 553
benzodiazepines, 553
chloral hydrate, 553
commonly used drugs for analgesia in neonates, 544
diazepam, 553
fentanyl, 545
LMX 4%, 552
management at EOL, 555
methadone, 545–546

newborn (*cont.*)
midazolam, 553
morphine, 543
nonopioid analgesics, 552
opioids, 543
painful procedures commonly performed in the NICU, 554
preemptive analgesia for mechanical ventilation, 553–555
prevention of opioid withdrawal symptoms, 545
procedural pain, 553
tetracaine 4% Gel, 552
topical application of local anesthetics, 552
physical examination
blood pressure ranges in different weight groups, 79
physiologic anemia
gestational age and birth weight, 347
oxygen affinity between adult and fetal hemoglobin, 347
principal action of human recombinant erythropoietin, 346
treatment, 347
positioning, 55
preparation for delivery, 50–54
pulmonary physiology
acid–base balance, 130
blood gas analysis and acid–base balance, 127–131
oxyhemoglobin equilibrium curves, 129
renal transplantation
dialysis, 619–620
kidney transplant surgery, 619
