DEDICATION

his text is dedicated to the students of human anatomy and physiology. Helping students develop a working knowledge of anatomy and physiology is a satisfying challenge, and we have a great appreciation for the effort and enthusiasm of so many who want to know more. It is difficult to imagine anything more exciting, or more important, than being involved in the process of helping people learn about the subject we love.

ABOUT THE AUTHORS

Rod Seeley, Trent Stephens, and Phil Tate in Dubuque, Ia, where they met to discuss the plan for the eighth edition. The bluffs of the Mississippi River can be seen in the background retreat to collaborate on their textbooks. The Grand Tetons are pictured in the background.

ROD R. SEELEY

Professor of Physiology at Idaho State University

Rod has extensive experience teaching introductory biology, anatomy and physiology, pathobiology, endocrinology, and more advanced physiology courses. He has won numerous teaching awards and is actively involved in the supervision of doctoral students in biological education. With a B.S. in zoology from Idaho State University and an M.S. and Ph.D. in zoology from Utah State University, Rod has built a solid reputation as an author of journal and other professionally related articles, as well as a public lecturer.

TRENT D. STEPHENS

Professor of Anatomy and Embryology at Idaho State University

An award-winning educator and researcher, Trent Stephens teaches human anatomy, human head and neck anatomy, and human embryology. He also has many years of experience teaching neurobiology. His skill as a biological illustrator has greatly influenced the illustrations in this textbook. He has a B.S. in microbiology and a B.S. in zoology, as well as an M.S. in zoology from Brigham Young University. His Ph.D. in anatomy is from the University of Pennsylvania. Trent is actively involved in research on limb development and birth defects caused by thalidomide. He has authored numerous papers in these fields.

PHILIP TATE

Instructor of Anatomy and Physiology at Phoenix College

Phil Tate earned a B.S. in zoology, a B.S. in mathematics, and an M.S. in ecology at San Diego State University and a Doctor of Arts (D.A.) in biological education from Idaho State University. He is an award-winning instructor who has taught a wide spectrum of students at the four-year and community college levels. Phil has served as the annual conference coordinator, president-elect, president, and past president of the Human Anatomy and Physiology Society (HAPS).

INDEX I-0

PREFACE

Anatomy and Physiology is designed to help students develop a solid understanding of the concepts of anatomy and physiology and to use this knowledge to solve problems. This is accomplished via a carefully planned learning system that serves as the framework for virtually all the elements in the text. From the opening chapter previews to the end-of-chapter multi-level review questions, *Anatomy and Physiology* is the textbook that will motivate and teach your students who are going into health-related careers.

AUDIENCE

Anatomy and Physiology is written for the two-semester anatomy and physiology course. The writing is comprehensive enough to provide the depth necessary for those courses not requiring prerequisites, and yet presented with such clarity that it nicely balances the thorough coverage. Clear descriptions and exceptional illustrations combine to help students develop a solid understanding of the concepts of anatomy and physiology and to also teach them how to use that information.

WHAT SETS THIS BOOK APART?

Seeley Learning System—Connecting Students to Their Future

It begins with the micrograph on the chapter-opening page, carefully chosen to pique interest and bring into focus a close-up view of the subject at hand. Accompanying text previews the material to come and even includes a mini-review, complete with relevant page numbers. Once into the core of the chapter, students will benefit from an abundance of clinical content, step-by-step Process Figures, in-chapter Review and Predict Questions, macro-to-micro art, unique Homeostasis Summary Figures, cadaver images, and more. A Chapter Summary provided in outline form covers all the main points of the chapter and serves as an excellent study guide. Finally, the Review and Comprehension Questions, and the Critical Thinking Questions, based on Bloom's Taxonomy, allow students to test their understanding in stages of comprehension. Within this learning system are three major emphases:

1. **Clinical Coverage**—*New Case Studies Build on Rich Clinical Foundation*

Examples of diseases, responses to exercise, clinical case studies, aging, and environmental conditions are all used to explain how our bodies function and to describe the consequences when systems do not operate normally. These conditions are also used to enhance comprehension of the relationship between structure and function. *Anatomy and Physiology* has always had a strong emphasis on clinical material. In the eighth edition, that emphasis

x

is now strengthened with the addition of *Case Studies*. These brief, real-life scenarios, combined with the popular *Clinical Asides*, the more in-depth *Clinical Focus Readings*, and the *Systems Pathology* spreads, provide a thorough clinical education that fully supports surrounding textual material. Also new, the *Clinical Genetics Essays* emphasize the connection between genetics and certain diseases and frequently tie in with *Clinical Focus Readings*.

2. **Critical Thinking**—*Recall Isn't Enough—Learning Needs to Be Developed and Applied*

A critical thinking approach is integrated throughout this textbook. It can be found in the way the narrative and the figures are designed and coordinated; in the way Process Figures explain step-by-step how mechanisms respond to a variety of stimuli; in the way Homeostasis Summary Figures explain the means by which homeostasis is maintained; and in the way Clinical Aside Boxes, Clinical Focus Readings, and new Case Studies encourage students to apply information they have learned to practical “real-life” scenarios. Finally, critical thinking is especially integrated into the way the unique Predict Questions and Critical Thinking Questions encourage students to go beyond rote memorization.

3. **Exceptional Art**—*Accuracy, Consistency, Logic Underscore Visuals*

The illustrations in *Anatomy and Physiology* are also an integral part of the Seeley Learning System. Accurate, attractive, and clearly presented, the visual program enhances comprehension in a number of ways: Tables are often combined with illustrations, relevant photos are side-by-side with drawings, cadaver photos are included where appropriate, step-by-step Process Figures explain physiologic processes, and the distinctive Homeostasis Summary Figures include explanations that are necessary to understand mechanisms and their roles in the maintenance of homeostasis. The images reflect a contemporary style and are coordinated so that colors and styles of structures in multiple figures are consistent with one another throughout the book. See the “Guided Tour” following this Preface for more details on the unique Seeley Learning System in *Anatomy and Physiology*.

Clarity and Comprehensiveness—The Right Amount of Information Presented Clearly

Not everything that is known about human anatomy and physiology can be included in a single book, and new information is accumulating at a rapid pace. For example, molecular techniques continue to identify the mechanisms that control gene expression, reveal how genes determine the structural and functional characteristics of humans, and demonstrate how alterations of genes can be responsible for abnormalities and diseases in humans. A major challenge in writing any textbook is to clearly present vital

concepts that are consistent with the massive body of contemporary knowledge in a way that encourages readers to grasp these key concepts and think critically by applying them to realistic situations. *Anatomy and Physiology* is written in succinct, understandable language. We continue to improve this aspect of the text because we believe that content must be presented and explained clearly and in sufficient detail to support critical thinking. All of us make a concerted effort to maintain congruity between the explanations and the problems presented in each chapter. Whether or not critical thinking is a major emphasis in your course, this text is a valuable asset for students because of its depth and understandable language.

EIGHTH EDITION CHANGES— WHAT'S NEW?

The eighth edition of *Anatomy and Physiology* is the result of extensive analysis of the text and evaluation of input from contributing authors and instructors who have thoroughly reviewed chapters. We are grateful to these professionals and have used their constructive comments in our continuing efforts to enhance the strengths of our textbook.

Contributing Authors

Five contributing authors have extensively examined and, where appropriate, revised material in 10 of the 29 chapters. Beyond what they have contributed to their specific chapters, these talented professors brought a fresh perspective to the entire book. They have worked very closely with us to produce up-to-date and clear presentations that are consistent with the objectives of this textbook.

Clinical Case Studies

Reviewers of the seventh edition asked for more real-life scenarios, such as the kind their students may encounter. New Case Studies now appear in nearly all the chapters. They are brief examples of how alterations in anatomy and physiology result in diseases and include suggestions on how they can be treated. The Case Studies often illustrate how multiple systems are affected and how they respond in an attempt to maintain homeostasis. Each of the Case Studies is followed by a Predict Question, which helps students think critically about the application of anatomical and physiologic concepts to the situation and predict the consequences of additional changes.

Genetics Coverage

Modern genetics has made it possible to understand the connection between the structure of genes on chromosomes and many diseases. Some of these diseases that have a genetic basis are highlighted in new Clinical Genetics essays. To provide an early overview of genetic concepts, essential material has been taken from chapter 29, updated, and moved to chapter 3. These include conditions that result from inheritance or mutations in single genes that are dominant, recessive, or X-linked, such as neurofibromatosis, cystic fibrosis, and Duchenne muscular dystrophy, respectively. Conditions that involve alteration of multiple genes

that are inherited, such as Type 2 diabetes mellitus and celiac disease, and those that involve mutations in multiple genes, such as cancer, are also described. These text revisions and new content will better prepare students to understand the relationship between genetics and many of the cases they may encounter in health-related careers.

Anatomy & Physiology | REVEALED® Integration

This is the first edition of *Anatomy and Physiology* to feature chapter correlations to the popular AP | REVEALED® student tutorial. Students across the country are improving their grades using this unique multimedia study aid that offers “melt-away” layers of dissection, animations, imaging, and self-testing to study cadaver specimens. The appropriate section, or body system, within the tutorial is listed on all applicable chapter opening pages. Even more specific connections between AP | REVEALED® and the text can be found on a correlation guide on the ARIS website that accompanies this textbook.

Instructor Resource Guide

McGraw-Hill Higher Education has developed several resources to assist professors teaching anatomy and physiology. To take advantage of this content and to make creating your lectures easier, this edition features a bound-in Resource Guide with listings of available case studies, animations, exercises, images, questions, and so on all in one handy chart and arranged by chapters.

Improved Art

Substantial changes have been made to improve the clarity of the art in the eighth edition. We have created 34 new figures, and two-thirds of the remaining art program has been revised to improve the quality of the illustrations. Additionally, over 40 new photographs have been added to this edition. Some of the enhancements include

- New photomicrographs of connective tissues show low and high power magnifications.
- Homeostasis Summary Figures were revised to provide a more concise and easy-to-read review of the mechanisms that maintain homeostasis. These figures have also been improved by adding a “Start” icon, making it easier to follow the color-coded directional arrows when the value of a variable increases or decreases.
- More Process Figures have been added to the text and several have been improved.

Refined and Updated Narrative

The eighth edition has undergone a complete examination and revision. Reports of new discoveries have been researched and evaluated. We have listened to suggestions from instructors who teach anatomy and physiology, as well as to our contributing authors, and have consequently scrutinized the text carefully. Explanations have been made clearer, terminology made more consistent, content reorganized to enhance clarity, facts corrected or updated, questions revised or added, and figure captions modified.

ACKNOWLEDGMENTS

A great deal of effort is required to produce a heavily illustrated textbook such as *Anatomy and Physiology*. Many hours of work are required to organize and develop the components of the textbook while creating and designing illustrations, but no text is solely the work of the authors. It is not possible to adequately acknowledge the support and encouragement provided by our loved ones. They have had the patience and understanding to tolerate our absences and our frustrations. They have also been willing to provide assistance and unwavering support.

Many hands besides our own have touched this text, guiding it through various stages of development and production. We wish to express our gratitude to the staff of McGraw-Hill for their help and encouragement. We sincerely appreciate Publisher Michelle Watnick, Sponsoring Editor James Connelly, and Developmental Editor Kathy Loewenberg for their many hours of work, suggestions, and tremendous patience and encouragement. Thanks are gratefully offered to Copy Editor Debra DeBord for carefully polishing our words. We also thank Project Manager Mary Powers, Photo Editor John Leland, Production Supervisor Laura Fuller, and Designer Rick Noel for their time spent turning manuscript into a book; Media Producer Jake Theobald, Project Coordinator Melissa Leick, and Media Project Manager Tammy Juran for their assistance in building the various products that support our text; and Marketing Manager Lynn Kalb-Breithaupt for her enthusiasm in promoting this book. The McGraw-Hill employees with whom we have worked are excellent professionals. They have been consistently

helpful and their efforts are truly appreciated. Their commitment to this project has clearly been more than a job to them.

We are especially grateful to contributing authors Shylaja Akkaraju, Christine Eckel, Jennifer Regan, Andrew Russo, and Cinnamon VanPutte for their involvement in this edition. Discussions with these professionals were delightful, insightful, and valuable. Their input and contributions have made this textbook substantially better.

We also extend our appreciation to the many illustrators who worked on the development and execution of the illustration program, and to those who provided photographs and photomicrographs for the eighth edition of *Anatomy and Physiology*. The art program for this textbook represents a monumental effort, and we are grateful for their contribution to the overall appearance and pedagogical value of the photos and illustrations.

Finally, we sincerely thank the reviewers and the teachers who have provided us with exceptional constructive criticism. The remuneration they received represents only a token payment for their efforts. To review a textbook conscientiously requires a true commitment and dedication to excellence in teaching. Their helpful criticisms and suggestions for improvement were significant in revising the seventh edition. We gratefully acknowledge them by name in the next section.

GUIDED TOUR

THE SEELEY LEARNING SYSTEM—CONNECTING STUDENTS TO THEIR FUTURE

The Seeley Learning System in *Anatomy and Physiology* is designed to help you learn in a systematic fashion. The textual material builds from simple facts to explanations of more complex concepts and is presented within a supporting framework of features that help you review what you have read, evaluate your comprehension of the content, and use what you have learned. Here is how your book can help you learn and improve your grade:

Respiratory System 23

From our first breath at birth, the rate and depth of our breathing is unconsciously matched to our activities, whether studying, sleeping, talking, eating, or exercising. We can voluntarily stop breathing, but within a few seconds we must breathe again. Breathing is so characteristic of life that, along with the pulse, it is one of the first things we check for to determine if an unconscious person is alive.

Breathing is necessary because all living cells of the body require oxygen and produce carbon dioxide. The respiratory system allows the exchange of these gases between the air and the blood, and the cardiovascular system transports them between the lungs and the cells of the body. The capacity to carry out normal activity is reduced without healthy respiratory and cardiovascular systems.

Respiration includes (1) ventilation, the movement of air into and out of the lungs; (2) gas exchange between the air in the lungs and the blood, sometimes called external respiration; (3) the transport of oxygen and carbon dioxide in the blood; and (4) gas exchange between the blood and the tissues, sometimes called internal respiration. The term *respiration* is also used in reference to cell metabolism, which is discussed in chapter 25.

This chapter explains the *functions of the respiratory system* (p. ***), the *anatomy and histology of the respiratory system* (p. ***), *ventilation* (p. ***), *measurement of lung function* (p. ***), *physical principles of gas exchange* (p. ***), *oxygen and carbon dioxide transport in the blood* (p. ***), *regulation of ventilation* (p. ***), and *respiratory adaptations to exercise* (p. ***). The chapter concludes by looking at the *effects of aging on the respiratory system* (p. ***).

Colorized scanning electron micrograph of the lung, showing alveoli, which are small chambers where gas exchange takes place between the air and the blood.

Anatomy & Physiology REVEALED
aprevealed.com
Respiratory System

Chapter Introduction

Each chapter opens with an interesting photomicrograph, which ties in with the topic. The paragraphs that follow introduce the topic and include a brief overview of the key points of the chapter. At the bottom of this page, if applicable, is the correlating system in *Anatomy & Physiology | REVEALED®*, a multimedia study aid that allows you to “melt” away layers of dissection on cadaver specimens, view animations, examine different types of imaging, and take practice quizzes. Just pop in the correct CD, or visit the program online, and go to the system listed in the text for assistance in understanding the chapter material.

4. The pseudostratified ciliated columnar epithelium lining the larynx produces mucus, which traps debris in air. The cilia move the mucus and debris into the pharynx.
5. **Name and describe the three unpaired cartilages of the larynx. What are their functions?**
6. **Distinguish between the vestibular and vocal folds. How are sounds of different loudness and pitch produced by the vocal folds?**
7. **How does the position of the arytenoid cartilages change when a person is simply breathing versus making low-pitched and high-pitched sounds?**

In-Chapter Section Reviews

Review questions at the end of each section *within* the chapter prompt you to test your understanding of key concepts. Use them as a self-test to determine whether you have a sufficient grasp of the information before proceeding to the next section.

Predict Questions

These innovative critical thinking questions encourage you to become an active learner as you read. Predict Questions challenge you to use your understanding of new concepts to solve a problem. Answers to the questions are provided at the end of the book, allowing you to evaluate your responses and to understand the logic used to arrive at the correct answer.

PREDICT 2

Explain what happens to the shape of the trachea when a person swallows a large mouthful of food. Why is this change of shape advantageous?

INSTRUCTIVE ARTWORK MAKES THE DIFFERENCE

A picture is worth a thousand words—especially when you are learning anatomy and physiology. Because words alone cannot convey the nuances of anatomy or the intricacies of physiology, *Anatomy and Physiology* uses a dynamic program of full-color illustrations and photographs to support and further clarify the textual explanations. Brilliantly rendered and carefully reviewed for accuracy and consistency, the precisely labeled illustrations and photos provide concrete, visual reinforcement of important topics discussed throughout the text.

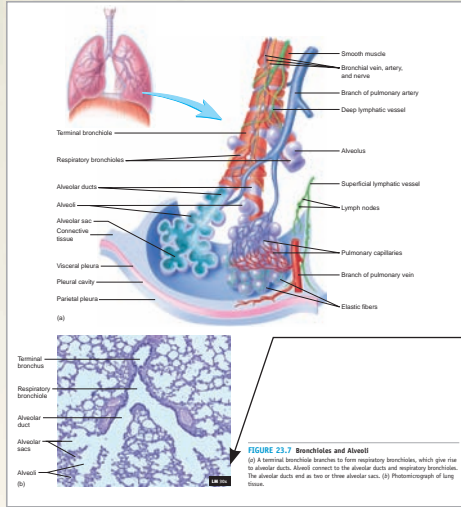

FIGURE 23.7 Bronchioles and Alveoli
(a) A terminal bronchiole branches to form respiratory bronchioles, which give rise to alveolar ducts. Alveoli connect to the alveolar ducts and respiratory bronchioles. The alveolar ducts end as two or three alveolar sacs. (b) Photomicrograph of lung tissue.

Magnifications are indicated to help you estimate the size of structures shown in the photomicrographs.

■ Combination Art

Drawings are often paired with photographs to enhance visualization and comprehension of structures.

■ Histology Micrographs

Light micrographs, as well as scanning and transmission electron micrographs, are used in conjunction with illustrations to present a true picture of anatomy and physiology from the cellular level.

Reference diagrams orient you to the view or plane an illustration represents.

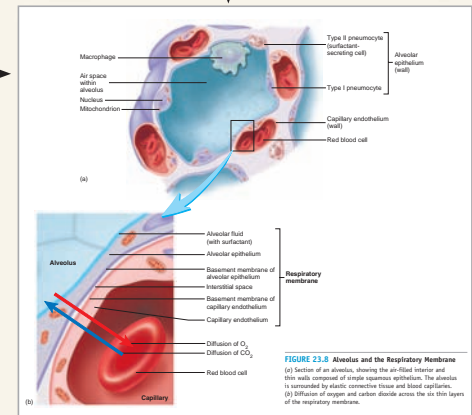

FIGURE 23.8 Alveolus and the Respiratory Membrane
(a) Section of an alveolus, showing the air-filled interior and the wall composed of simple squamous epithelium. The alveolus is surrounded by elastic connective tissue and blood capillaries. (b) Diffusion of oxygen and carbon dioxide across the six thin layers of the respiratory membrane.

■ Macro-to-Micro Art

Illustrations depicting complex structures or processes combine macroscopic and microscopic views to help you see the relationships between increasingly detailed drawings.

■ Atlas-Quality Cadaver Images

Clearly labeled photos of dissected human cadavers provide detailed views of anatomical structures, capturing the intangible characteristics of actual human anatomy that can be appreciated only when viewed in human specimens.

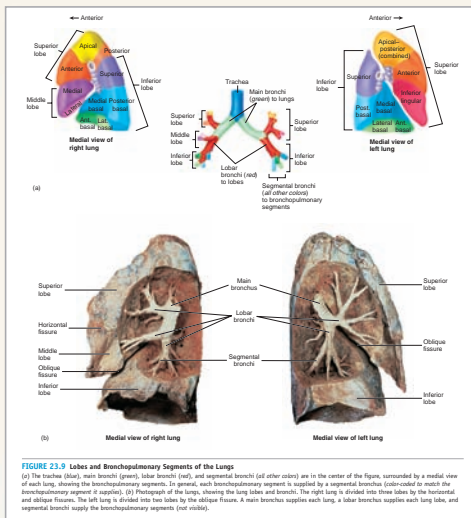

FIGURE 23.9 Lobes and Bronchopulmonary Segments of the Lungs
(a) The trachea (blue), main bronchi (green), lobar bronchi (red), and segmental bronchi (all other colors) are in the center of the figure, surrounded by a medial view of each lung, showing the bronchopulmonary segments. In general, each bronchopulmonary segment is supplied by a segmental bronchus (color-coded to match the bronchopulmonary segment it supplies). (b) Photograph of the lungs, showing the lung lobes and bronchi. The right lung is divided into three lobes by the horizontal and oblique fissures. The left lung is divided into two lobes by the oblique fissure. A main bronchus supplies each lung; a lobar bronchus supplies each lung lobe; and segmental bronchi supply the bronchopulmonary segments (not visible).

■ Realistic Anatomical Art

The anatomical figures in *Anatomy and Physiology* have been carefully drawn to convey realistic, three-dimensional detail. Richly textured bones and artfully shaded muscles, organs, and vessels lend a sense of realism to the figures that helps you envision the appearance of actual structures within the body. The colors used to represent different anatomical structures have been applied consistently throughout the book to help you easily identify structures in every figure.

FIGURE 23.10 Effect of the Muscles of Respiration on Thoracic Volume
(a) Muscles of inspiration at the end of expiration. (b) Muscles of inspiration at the end of inspiration.

CLINICAL CONTENT PUTS KNOWLEDGE INTO PRACTICE

Anatomy and Physiology provides clinical examples to demonstrate the application of basic knowledge in interesting and relevant clinical context. Exposure to clinical information is especially beneficial if you are planning on using your knowledge of anatomy and physiology in a health-related career.

■ New! Clinical Genetics

Today's anatomy and physiology student knows that a basic understanding of genetics is critical to learning about various diseases and their impact on the human body. This information takes on more importance almost daily as genetic research continues to contribute to possible cures. New to this edition, Clinical Genetics boxes define diseases, describe symptoms and genetic components, and discuss possible treatments.

CLINICAL GENETICS

Alpha-1 Antitrypsin Deficiency

Empysema (em-fi-ze' mā) is a condition in which lung alveoli become progressively destroyed and enlarged. Individuals suffering from emphysema experience shortness of breath and coughing. Chemicals in cigarette smoke damage lung tissues and stimulate inflammation. As part of the inflammatory response, neutrophils and macrophages release **proteases**, which are enzymes that break down proteins. Proteases in the lungs provide protection against some bacteria and foreign substances. Too much protease activity, however, can be harmful because it results in the breakdown of lung tissue proteins, especially elastin in elastic fibers. **Alpha-1 antitrypsin (AAT)**, which is synthesized in the liver, is a **protease inhibitor (Pi)**. Normally, AAT inhibits protease activity, preventing the destruction of lung tissue. Excess protease production stimulated by cigarette smoke, however, can cause lung damage, leading to emphysema.

Although cigarette smoking is the major risk factor for emphysema, approximately 1%–2% of emphysema cases are due to a deficiency of AAT caused by defects of the AAT gene located on chromosome 14. Multiple alleles for AAT have been identified. The normal allele is designated M. Individuals who are homozygous for the normal allele are designated PiMM, and they produce normal levels of AAT. That is, each M gene is responsible for 50% of the AAT produced. The most common abnormal allele is designated Z. Individuals with only one copy of Z (PiMZ) have about 60% of normal levels of AAT, which is sufficient to prevent protease damage. Individuals with two copies of the Z allele (PiZZ) produce only about 15%–20% of normal AAT levels. Smoking by these individuals accelerates the development of emphysema by 10–15 years. Other variant alleles cause different levels of AAT. The most severe form results in no AAT and the development of emphysema by age 30, even in nonsmokers.

Treatment of AAT deficiency follows the normal course of treatment for emphysema. Stopping smoking reduces the destruction of lung tissue by removing the stimulus for excess protease activity. Drugs, such as danazol and tamoxifen, can stimulate increased AAT production in the liver. In addition, individuals may receive intravenous infusions of AAT, a process called **alpha-1 antitrypsin augmentation**.

Effect of Spinal Cord Injury on Ventilation

The diaphragm is supplied by the phrenic nerves, which arise from spinal nerves C3–C5 (see figure 12.16), descend along each side of the neck to enter the thorax, and pass to the diaphragm. The intercostal muscles are supplied by the intercostal nerves (see figure 12.15), which arise from spinal nerves T1–T11 and extend along the spaces between the ribs. Spinal cord injury superior to the origin of the phrenic nerves causes paralysis of the diaphragm and intercostal muscles and results in death unless artificial respiration is provided. A high spinal cord injury below the origin of the phrenic nerves causes paralysis of the intercostal muscles. Even though the diaphragm can function maximally, ventilation is drastically reduced because the intercostal muscles no longer prevent the thoracic wall from collapsing inward. Vital capacity is reduced to about 300 mL. With low spinal cord injury, below the origin of the intercostal nerves, both the diaphragm and the intercostal muscles function normally.

■ Clinical Topics

Interesting clinical sidebars reinforce or expand on the facts and concepts discussed within the narrative. Once you have learned a concept, applying that information in a clinical context shows you how your new knowledge can be put into practice.

■ Clinical Focus

These in-depth boxed essays explore relevant topics of clinical interest. The subjects covered include pathologies, current research, sports medicine, exercise physiology, and pharmacology.

CLINICAL FOCUS

Cough and Sneeze Reflexes

The function of both the cough reflex and the sneeze reflex is to dislodge foreign matter or irritating material from the respiratory passages. The bronchi and trachea contain sensory receptors that are sensitive to foreign particles and irritating substances. The cough reflex is initiated when the sensory receptors detect such substances and initiate action potentials that pass along the vagus nerves to the medulla oblongata, where the cough reflex is triggered.

The movements resulting in a cough occur as follows: Approximately 2.5 L of air are inspired; the vestibular and vocal folds close tightly to trap the inspired air in the lungs; the abdominal muscles contract to force the abdominal contents up against the diaphragm; and the muscles of expiration contract forcefully.

As a consequence, the pressure in the lungs increases to 100 mm Hg or more. Then the vestibular and vocal folds open suddenly, the soft palate is elevated, and the air rushes from the lungs and out the oral cavity at a high velocity, carrying foreign particles with it.

The sneeze reflex is similar to the cough reflex, but it differs in several ways. The source of irritation that initiates the sneeze reflex is in the nasal passages instead of in the trachea and bronchi, and the action potentials are conducted along the trigeminal nerves to the medulla oblongata, where the reflex is triggered. During the sneeze reflex, the soft palate is depressed so that air is directed primarily through the nasal passages, although a considerable amount passes through the oral cavity. The rapidly flowing air dislodges particulate matter from the nasal passages and can propel it a considerable distance from the nose. About 17%–25% of people have a photic sneeze reflex, in which exposure to bright light, such as the sun, can stimulate a sneeze reflex. The pupillary reflex causes the pupils to constrict in response to bright light. It is speculated that the complicated "wiring" of the pupillary and sneeze reflexes are intermixed in some people so that, when bright light activates a pupillary reflex, it also activates a sneeze reflex. Sometimes the photic sneeze reflex is fancifully called ACHOO, which stands for autosomal dominant compelling helio-ophthalmic outburst. As the name suggests, the reflex is inherited as an autosomal-dominant trait. A person needs to inherit only one copy of the gene to have a photic sneeze reflex.

New! Case Studies

New to this edition, these specific yet brief examples of how alternations of structure and/or function result in diseases help you better understand the practical application of anatomy and physiology. These boxed summaries are placed strategically in the text, so that you can immediately start to see connections between learned concepts and real events.

Systems Pathology

These spreads explore a specific disorder or condition related to a particular body system. Presented in a simplified case study format, each Systems Pathology box begins with a patient history followed by background information about the featured topic.

because of the depletion of the PCL and a reduction in the water content of mucus, which causes the mucus to be thicker than normal (figure B).

A standard test for CF diagnosis is the **sweat-chloride test**, in which the chemical **pilocarpine** (pi-lo-kaar'pen) is swabbed onto the skin and a mild electric current is applied. Pilocarpine is a muscarinic agent that stimulates receptors in the sweat glands (see "The Influence of Drugs on the Autonomic Nervous System," chapter 16). The mild electric current drives the medication into the skin, producing localized sweating and avoiding systemic drug effects. The sweat that is produced is collected and tested for abnormally high levels of salt (NaCl). Normally, sweat glands produce a very dilute liquid, which cools the body without depleting salt from it. In CF, the malfunctioning CFTR results in a failure to absorb the normal amount of NaCl from sweat, resulting in high NaCl content in sweat.

Although CF tends to be primarily associated with respiratory malfunctions, the production of thickened mucus also has profound digestive tract effects. In fact, the original name of the disease was cystic fibrosis of the pancreas because, in 90% of CF patients, the pancreas is gradually destroyed and infiltrated by fibrous

cyts. The pancreatic ducts of CF patients can become obstructed with sticky mucus, which prevents the secretion of adequate amounts of digestive enzymes, particularly fat-digesting enzymes. Children with CF can have severe nutritional deficiencies because of the decreased absorption of proteins and fat-soluble vitamins, such as vitamins A, D, E, and K. To aid food digestion and promote growth, children with CF may be given powdered digestive enzymes. Supplemental overnight feeding through a gastrostomy (gas-tro-'to-me) tube (stomach tube, T-tube) may also be beneficial.

The main goal of CF treatment is to reduce lung infections, clear the lungs of mucus, improve airflow, and maintain sufficient calories and nutrition. People with CF must undergo **chest physical therapy**, also called **chest clapping** or **chest percussion**. This involves manually pounding the back and chest for 30 to 40 minutes three or four times daily to dislodge mucus trapped in the chest. Automated chest clappers are preferred by some CF patients.

Antibiotics may be prescribed to help control lung infections. Mucus-thinning drugs, such as Pulmozyme, and bronchodilators can be inhaled to improve mucus clearance and open airways. Eventually, if breathing problems

become too severe or the patient becomes resistant to antibiotics, a lung transplant may be necessary. The downside of a lung transplant is the need to take immunosuppressive drugs for life to prevent rejection of the transplanted lungs. These drugs produce side effects, such as increased susceptibility to infections, diabetes, tumors, and osteoporosis. The upside of lung transplantation is that it is a partial "cure" because the transplanted lung cells do not have the genetic defect. However, cells with the defective CFTR gene are still present elsewhere in the body. Scientists are also investigating the use of gene therapy, wherein a copy of the normal CFTR gene is inserted into epithelial cells by a harmless virus. So far, the effects of gene therapy have lasted for only a few days. With treatment, the current life expectancy for persons with cystic fibrosis is into the mid-30s. In 95% of CF cases, the patient dies due to complications from lung infections.

PREDICT 16

As cystic fibrosis becomes advanced, what happens to forced expiratory volume in 1 second (FEV1), residual volume, and physiologic dead space?

SYSTEM INTERACTIONS	Effect of Cystic Fibrosis on Other Systems
SYSTEM	INTERACTIONS
Integumentary	Two to five times the normal amount of salt is secreted in sweat, which can cause rapid dehydration in hot conditions. Clubbing is an enlargement of the fingertips and toes due to a proliferation of connective tissue; the mechanism that produces clubbing is unclear, but it may be related to insufficient oxygen delivery, which stimulates an inflammatory response.
Skeletal	Low bone density is common because insufficient vitamin D is absorbed from the diet when the pancreatic ducts become blocked.
Cardiovascular	Lung disease may eventually cause the right ventricle of the heart to fail due to the increased force necessary to pump blood into damaged lungs.
Digestive	Mucus blockage of pancreatic ducts and liver bile ducts decreases fat digestion capabilities, resulting in bowel blockage; foul-smelling, greasy stools; and chronic diarrhea. Autodigestion of the pancreas by enzymes trapped in the pancreas can occur. Liver duct blockage may eventually lead to cirrhosis of the liver and gallstones.
Respiratory	Mucus buildup causes coughing, wheezing, and recurrent chest infections because bacteria are not effectively removed. Eventually, lung bleeding (hemoptysis) or collapsed lung (atelectasis) may result. There may also be polyps in the nasal cavity and paranasal sinuses due to thickening of the mucosa. Frequent instances of sinusitis are common.
Reproductive	Ninety-eight percent of men with CF are infertile because of a failure of the ductus deferens to develop. Up to 20% of women with CF may experience infertility related to mucus blockage of the uterine tubes or depression of the menstrual cycle because of malnutrition.
Immune	A decrease in innate immunity occurs because the thickened mucus in the respiratory tract impairs cilia movement. The beating of cilia in the respiratory tract is one of the important mechanical mechanisms that prevents the entry of microorganisms into the body.

CASE STUDY

Asthma

Will is an 18-year-old track athlete in seemingly good health. Despite suffering from a slight cold, Will went jogging one morning with his running buddy, Al. After a few minutes of exercise, Will felt that he could hardly get enough air. Even though he stopped jogging, he continued to breathe rapidly and wheeze forcefully. Because his condition was not improving, Al took him to the emergency room of a nearby hospital.

The emergency room doctor used a stethoscope to listen to air movement in Will's lungs and noted that movement was poor. In addition, she ordered an arterial blood gas measurement for Will. He had a P_{O_2} of 60 mm Hg and a PCO_2 of 30 mm Hg. Although Will had no previous history of asthma, the emergency room doctor was convinced that he was having an asthma attack.

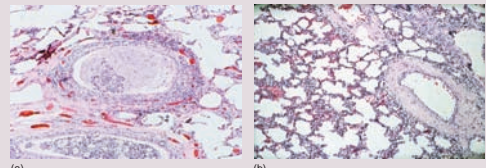

Asthma is a clinical condition characterized by airway inflammation, which episodically results in shortness of breath, coughing, and wheezing due to bronchoconstriction. An asthma attack can be provoked by viral infections, exercise, or exposure to environmental irritants, such as pollen or cigarette smoke (see "Disorders of the Respiratory System," p. ***).

PREDICT 15

- Are Will's arterial blood gas values above or below normal (see figure 23.16)?
- Why did the asthma attack cause Will to breathe more rapidly (see figure 23.22)?
- Why did the asthma attack cause Will to wheeze forcefully?
- Did Will's rapid, forceful wheezing restore homeostasis? Explain.
- Explain Will's blood P_{O_2} and P_{CO_2} values.
- Is Will's blood pH lower or higher than normal? What effect does this blood pH normally have on respiration rate? Why didn't that happen?
- Explain how β -adrenergic agents (see "The Influence of Drugs on the Autonomic Nervous System," chapter 16) or inhaled glucocorticoids (see chapter 18) can help Will.

SYSTEMS PATHOLOGY

Cystic Fibrosis

Nicole is a 2-year-old who has experienced recurrent bouts of coughing and wheezing. Two months ago, she was diagnosed with bronchitis after suffering from an upper respiratory tract viral infection. Her condition worsened despite treatment with inhaled bronchodilators and steroids. Also, she has not been gaining weight, despite having a good appetite, and her stools are frequent, loose, foul-smelling, and greasy.

Nicole's parents have become worried about her persistent cough and lack of growth. Furthermore, Nicole's mother wonders whether a salty taste on Nicole's skin is due to a side effect of the medication she has been taking. The family medical history shows that Nicole's parents and 4-year-old sister are healthy, but her maternal grandmother has chronic bronchitis, seemingly

FIGURE B Bronchioles in Normal Lungs, Compared with Bronchioles in CF Lungs
 (a) In normal lung tissue, bronchioles are the passageways for airflow. (b) In patients with CF, the bronchioles are obstructed with thickened mucus and airflow is restricted.

← An Interactions Table at the end of every Systems Pathology reading summarizes how the condition impacts each body system.

SPECIALIZED FIGURES CLARIFY TOUGH CONCEPTS

Studying physiology does not have to be an intimidating task mired in memorization. *Anatomy and Physiology* uses two special types of illustrations to help you not only learn the steps involved in specific processes but also apply this knowledge as you predict outcomes in similar situations. Process Figures organize the key occurrences of physiologic processes in an easy-to-follow format. Homeostasis Summary Figures detail the mechanisms of homeostasis by illustrating the means by which a system regulates a parameter within a narrow range of values.

■ Process Figures

Process Figures break down physiologic processes into a series of smaller steps, allowing you to build your understanding by learning each important phase.

1. A secretion introduced into the digestive tract or food within the tract begins in one location.
2. Segments of the digestive tract alternate between contraction and relaxation.
3. Material (*brown*) in the intestine is spread out in both directions from the site of introduction.
4. The secretion or food is spread out in the digestive tract and becomes more diffuse (*lighter color*) through time.

Circled numbers indicate the sequence within the artwork and correspond to numbered explanations. The numbers are placed carefully, allowing you to zero right in to where the action described in each step takes place.

PROCESS FIGURE 24.3 Segmental Contractions

Process Figures and Homeostasis Summary Figures are identified next to the figure number. The accompanying caption provides additional explanation.

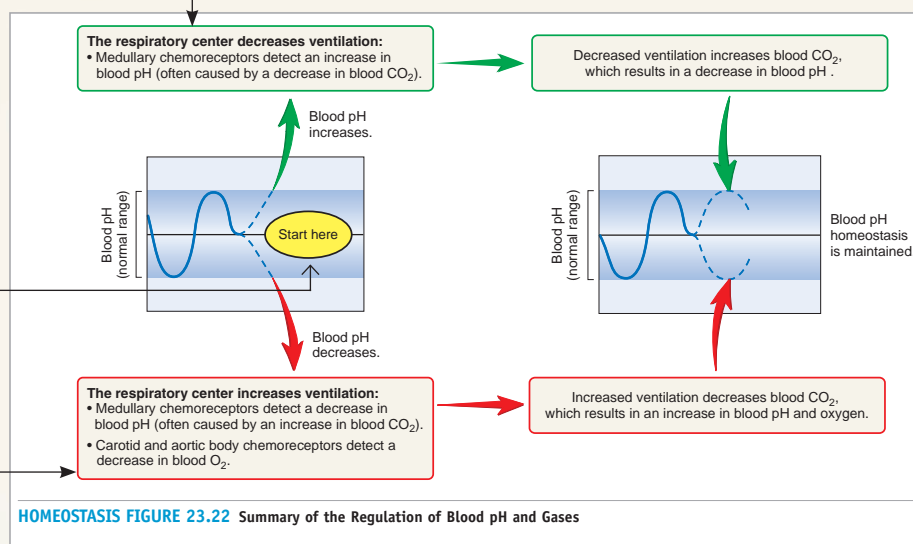

■ Homeostasis Summary Figures

These specialized flowcharts illustrate the mechanisms that body systems use to maintain homeostasis.

The normal range for a given value is represented by the graphs in the center of each figure. Begin at the new yellow "Start" oval and follow the green arrows to learn about the chain of events triggered by an increase in the variable, or follow the red arrows for events resulting from a decrease in the variable.

Changes caused by a decrease of a variable outside its normal range are shown in the red boxes across the bottom of the figure.

Changes caused by an increase of a variable outside its normal range are shown in the green boxes across the top.

STUDY FEATURES ENSURE SUCCESS

Learning anatomy and physiology is, in many ways, like learning a new language. Mastering the terminology is critical to building your knowledge base. Once you understand many of the word roots, the task becomes easier. This textbook includes a variety of vocabulary aids, helpful chapter summaries, and multi-level review questions to offer you the very best learning system available.

Other respiratory system infections include the bacterial infections **diphtheria** (dif-thē'rē-ă), **whooping cough** (per-tūs'is), and **tuberculosis** (tū-ber'kū-lō'sis) and the fungal infections **histoplasmosis** (his'tō-plaz-mō'sis) and **coccidioidomycosis** (kok-sid-ē-oy'dō-mī-kō'sis). Vaccines against diphtheria and whooping cough are part of the normal vaccination procedure for children in the United States.

Key terms are set in boldface where they are defined in the chapter, and most terms are included in the glossary at the end of the book. Pronunciation guides are provided for difficult words. Because knowing the original meaning of a term can enhance understanding and retention, derivations of key words are given when they are relevant. Additionally, a handy list of prefixes, suffixes, and combining forms is printed on the inside back cover as a quick reference to help you identify commonly used word roots. A list of abbreviations used throughout the text is also provided.

Chapter Summary

The summary outline briefly states the important facts and concepts covered in each chapter to provide a convenient “big picture” of the chapter content.

SUMMARY

Respiration includes the movement of air into and out of the lungs, the exchange of gases between the air and the blood, the transport of gases in the blood, and the exchange of gases between the blood and tissues.

Functions of the Respiratory System (p. ●●●)

The major functions of the respiratory system are gas exchange, regulation of blood pH, voice production, olfaction, and protection against some microorganisms.

Anatomy and Histology of the Respiratory System (p. ●●●)

Nose

1. The nose consists of the external nose and the nasal cavity.
2. The bridge of the nose is bone, and most of the external nose is

Trachea

1. The trachea connects the larynx to the main bronchi.
2. The trachealis muscle regulates the diameter of the trachea.

Tracheobronchial Tree

1. The trachea divides to form two main bronchi, which go to the lungs. The main bronchi divide to form lobar bronchi, which divide to form segmental bronchi, which divide to form bronchioles, which divide to form terminal bronchioles.
2. The trachea to the terminal bronchioles is a passageway for air movement.
 - The area from the trachea to the terminal bronchioles is ciliated to facilitate the removal of inhaled debris.
 - Cartilage helps hold the tube system open (from the trachea to the bronchioles).
 - Smooth muscle controls the diameter of the tubes (terminal bronchioles).
3. Terminal bronchioles divide to form respiratory bronchioles, which

Review and Comprehension

These multiple-choice practice questions cover the main points of the chapter. Completing this self-test helps you gauge your mastery of the material. Answers are provided in Appendix E.

REVIEW AND COMPREHENSION

1. The nasal cavity
 - a. has openings for the paranasal sinuses.
 - b. has a vestibule, which contains the olfactory epithelium.
 - c. is connected to the pharynx by the nares.
 - d. has passageways called conchae.
 - e. is lined with squamous epithelium, except for the vestibule.
2. The nasopharynx
 - a. is lined with moist stratified squamous epithelium.
 - b. contains the pharyngeal tonsil.
 - c. opens into the oral cavity through the fauces.
 - d. extends to the tip of the epiglottis.
 - e. is an area through which food, drink, and air pass.
3. The larynx
 - a. connects the oropharynx to the trachea.
 - b. has three unpaired and six paired cartilages.
 - c. contains the vocal folds.
 - d. contains the vestibular folds.
 - e. all of the above.
4. The trachea contains

a. skeletal muscle.	c. C-shaped pieces of cartilage.
b. pleural fluid glands.	d. all of the above.

Critical Thinking

These innovative exercises encourage you to apply chapter concepts to solve problems. Answering these questions helps build your working knowledge of anatomy and physiology while developing reasoning and critical thinking skills. Answers are provided in Appendix F.

CRITICAL THINKING

1. What effect does rapid (respiratory rate equals 24 breaths per minute), shallow (tidal volume equals 250 mL per breath) breathing have on minute ventilation, alveolar ventilation, and alveolar PO_2 and PCO_2 ?
 2. A person's vital capacity is measured while standing and while lying down. What difference, if any, in the measurement do you predict and why?
 3. Ima Diver wanted to do some underwater exploration. She did not want to buy expensive SCUBA equipment, however. Instead, she bought a long hose and an inner tube. She attached one end of the hose to the inner tube so that the end was always out of the water, and she inserted the other end of the hose in her mouth and went diving. What happened to her alveolar ventilation and why? How can she compensate for this change? How does diving affect lung compliance and the work of ventilation?
 4. The bacteria that cause gangrene (*Clostridium perfringens*) are anaerobic microorganisms that do not thrive in the presence of oxygen. Hyperbaric oxygenation (HBO) treatment places a person in a chamber that contains oxygen at three to four times normal atmospheric pressure. Explain how HBO helps in the treatment of gangrene.
- During inspiration, does the left side of the diaphragm move superiorly, move inferiorly, or stay in place?
8. Suppose that the thoracic wall is punctured at the end of a normal expiration, producing a pneumothorax. Does the thoracic wall move inward, outward, or not move?
 9. During normal, quiet respiration, when does the maximum rate of diffusion of oxygen in the pulmonary capillaries occur? The maximum rate of diffusion of carbon dioxide?
 10. There is experimental evidence that the overuse of erythropoietin (EPO; see chapter 19) reduces athletic performance. What side effects of EPO abuse reduce exercise stamina?
 11. Predict what would happen to tidal volume if the vagus nerves were cut, the phrenic nerves were cut, or the intercostal nerves were cut.
 12. You and your physiology instructor are trapped in an overturned ship. To escape, you must swim under water a long distance. You tell your instructor it would be a good idea to hyperventilate before making the escape attempt. Your instructor calmly replies, “What good would that do, since your pulmonary capillaries are already 100% saturated with oxygen?” What would you do and why?

TEACHING^{AND} LEARNING SUPPLEMENTS

McGraw-Hill offers various tools and technology products to support the eighth edition of *Anatomy and Physiology*. Students can order supplemental study materials by contacting their campus bookstore. Instructors can obtain teaching aids by calling the McGraw-Hill Customer Service Department at 1-800-338-3987, by visiting our A&P catalog at www.mhhe.com/ap, or by contacting their local McGraw-Hill sales representative.

ARIS TEXT WEBSITE

The ARIS website that accompanies this textbook includes tutorials, animations, practice quizzing, case studies, lab exercises, and more for students. Instructors

will find a complete electronic homework and course management system where they can create and share course materials and assignments with colleagues in just a few clicks of the mouse. Instructors can also edit questions, import their own content, and create announcements and/or due dates for assignments. ARIS offers automatic grading and reporting of easy-to-assign homework, quizzing, and testing. Also included on the ARIS website is a detailed correlation guide for this text and *Anatomy & Physiology | REVEALED*®.

Check out www.aris.mhhe.com, select your subject and textbook, and start benefiting today!

NEW ONLINE PRESENTATION CENTER FOR INSTRUCTORS

Build instructional materials wherever, whenever, and however you want!

Part of the ARIS website, the Presentation Center is a digital library containing assets, such as photos, artwork, animations, PowerPoints, and other media resources, that can be used to create customized lectures, to visually enhance tests and quizzes, and to design compelling course websites or attractive printed support materials.

Nothing could be easier!

Accessed from your textbook's ARIS website, the Presentation Center's dynamic search engine allows instructors to explore by discipline, course, textbook chapter, asset type, or keyword. Simply browse, select, and download the files needed to build engaging

course presentations. All assets are copyrighted by McGraw-Hill Higher Education but can be used by instructors for classroom purposes. The visual resources included in this collection are located easily within each chapter:

- **Art.** Full-color digital files of all illustrations in the book can be readily incorporated into lecture presentations, exams, or custom-made classroom materials. In addition, all files are pre-inserted into blank PowerPoint slides for ease of lecture preparation.
- **Photos.** The photos collection contains digital files of all the photographs from the text, which can be reproduced for multiple classroom uses.
- **Tables.** Every table that appears in the text has been saved in electronic form for use in classroom presentations and/or quizzes.

In addition to the content found within each chapter, the Presentation Center contains the following multimedia instructional materials:

- **Active Art.** Active Art consists of art files that have been converted to a format that allows the artwork to be edited inside PowerPoint. Each piece can be broken down to its core elements, grouped or ungrouped, and edited to create customized illustrations.
- **Animations.** Numerous full-color animations illustrating physiologic processes are also provided. Harness the visual impact of processes in motion by importing these files into classroom presentations or online course materials.
- **Lecture Outlines.** Specially prepared custom outlines for each chapter are offered in easy-to-use PowerPoint slides.

INSTRUCTOR'S TESTING AND RESOURCE CD

This cross-platform CD-ROM provides a wealth of resources for the instructor. One of the supplements featured on this CD is EZ Test, a flexible and easy-to-use electronic testing program. This program allows instructors to create tests from book-specific items and accommodates a wide range of question types, including the option for instructors to add their own questions. Multiple versions of the test can be created, and any test can be exported for use with course management systems, such as WebCT, BlackBoard, or PageOut. The instructor's manual is also included with this CD.

AP|REVEALED® STUDENT TUTORIAL

AP | REVEALED® is a unique multimedia study aid designed to help you learn and review human anatomy using digital cadaver specimens. Dissections, animations, imaging, and self-tests all work together as an exceptional tool for the study of structure and function.

The AP | REVEALED® CD series includes

Volume 1—Skeletal and Muscular Systems

Volume 2—Nervous System

Volume 3—Cardiovascular, Respiratory, and Lymphatic Systems

Volume 4—Digestive, Urinary, Reproductive, and Endocrine Systems

A new online version of AP | REVEALED® includes the Integumentary System and expanded physiology and histology content.

Visit www.mhhe.com/aprevealed for more information.

VIRTUAL ANATOMY DISSECTION REVIEW (AVAILABLE ONLINE OR AS A CD-ROM)

This multimedia program contains high-quality cat dissection photographs correlated to illustrations and photos of human structures. The format makes it easy to identify and review cat anatomy and to relate the cat specimen to corresponding human structures.

PHYSIOLOGY INTERACTIVE LAB SIMULATIONS (PH.I.L.S)

This unique study tool contains 26 lab simulations that allow students to perform experiments without using expensive lab equipment or live animals. The easy-to-use interface offers students the flexibility to change the parameters of every lab experiment, with no limit to the amount of times they can repeat experiments or modify variables. The power to manipulate each experiment reinforces key physiology concepts by helping students view outcomes, make predictions, and draw conclusions.

MEDIAPHYS TUTORIAL

This physiology study aid offers detailed explanations, high-quality illustrations, and animations to provide a thorough introduction to the world of physiology. MediaPhys is filled with interactive activities and quizzes to help reinforce physiology concepts that are often difficult to understand.

e-INSTRUCTION WITH CPS

The Classroom Performance System (CPS) is an interactive system that allows the instructor to administer in-class questions electronically. Students answer questions via hand-held remote control keypads (clickers), and their individual responses are logged into a gradebook. Aggregated responses can be displayed in graphical form. Using this immediate feedback, the instructor can quickly determine if students understand the lecture topic, or if more clarification is needed. CPS promotes student participation, class productivity, and individual student confidence and accountability. Specially designed questions for e-Instruction to accompany *Anatomy and Physiology* are provided through the book's ARIS website.

TRANSPARENCIES

The set of transparency acetates that accompanies this text includes 1200 full-color images identified by the authors as the most useful figures to incorporate into lecture presentations.

COURSE DELIVERY SYSTEMS

In addition to McGraw-Hill's ARIS course management options, instructors can also design and control their course content with help from our partners WebCT, Blackboard, Top-Class, and eCollege. Course cartridges containing website content, online testing, and powerful student tracking features are readily available for use within these platforms.

The Human Organism

1

What lies ahead is an astounding adventure—learning about the structure and function of the human body and how they are regulated by intricate systems of checks and balances. For example, tiny collections of cells embedded in the pancreas affect the uptake and use of blood sugar in the body. Eating a candy bar results in an increase in blood sugar, which acts as a stimulus. Pancreatic cells respond to the stimulus by secreting insulin. Insulin moves into blood vessels and is transported

to cells throughout the body, where it increases the movement of sugar from the blood into cells, thereby providing the cells with a source of energy and causing blood sugar levels to decrease.

Knowledge of the structure and function of the human body is the basis for understanding disease. In one type of diabetes mellitus, cells of the pancreas do not secrete adequate amounts of insulin. Not enough sugar moves into cells, which deprives them of a needed source of energy, and they malfunction.

Knowledge of the structure and function of the human body is essential for those planning a career in the health sciences. It is also beneficial to nonprofessionals because it helps with understanding overall health and disease, with evaluating recommended treatments, and with critically reviewing advertisements and articles.

This chapter defines *anatomy and physiology* (p. 2). It also explains the body's *structural and functional organization* (p. 2) and provides an overview of the *characteristics of life* (p. 6), *biomedical research* (p. 9), and *homeostasis* (p. 9). Finally, the chapter presents *terminology and the body plan* (p. 12).

The human organism has many membranes that enclose and protect underlying structures. The colorized scanning electron micrograph shows the cells forming the peritoneum, a membrane covering abdominopelvic organs and the inside wall of the abdominopelvic cavity. These cells have many short, hair-like projections called microvilli. The microvilli increase the surface area of the cells, enabling them to secrete a slippery lubricating fluid that protects organs from friction as they rub against one another or the inside of the abdominopelvic wall.

ANATOMY AND PHYSIOLOGY

Anatomy is the scientific discipline that investigates the body's structure. For example, anatomy describes the shape and size of bones. In addition, anatomy examines the relationship between the structure of a body part and its function. Just as the structure of a hammer makes it well suited for pounding nails, the structure of a specific body part allows it to perform a particular function effectively. For example, bones can provide strength and support because bone cells surround themselves with a hard, mineralized substance. Understanding the relationship between structure and function makes it easier to understand and appreciate anatomy.

Anatomy can be considered at many different levels. **Developmental anatomy** is the study of the structural changes that occur between conception and adulthood. **Embryology** (em-brē-ol'ō-jē), a subspeciality of developmental anatomy, considers changes from conception to the end of the eighth week of development. Most birth defects occur during embryologic development.

Some structures, such as cells, are so small that they are best studied using a microscope. **Cytology** (sī-tol'ō-jē) examines the structural features of cells, and **histology** (his-tol'ō-jē) examines tissues, which are cells and the materials surrounding them.

Gross anatomy, the study of structures that can be examined without the aid of a microscope, can be approached from either a systemic or a regional perspective. In **systemic anatomy**, the body is studied system by system, which is the approach taken in this and most other introductory textbooks. A system is a group of structures that have one or more common functions. Examples are the circulatory, nervous, respiratory, skeletal, and muscular systems. In **regional anatomy**, the body is studied area by area, which is the approach taken in most graduate programs at medical and dental schools. Within each region, such as the head, abdomen, or arm, all systems are studied simultaneously.

Surface anatomy is the study of the external form of the body and its relation to deeper structures. For example, the sternum (breastbone) and parts of the ribs can be seen and palpated (felt) on the front of the chest. These structures can be used as anatomical landmarks to identify regions of the heart and points on the chest where certain heart sounds can best be heard. **Anatomical imaging** uses radiographs (x-rays), ultrasound, magnetic resonance imaging (MRI), and other technologies to create pictures of internal structures (see Clinical Focus “Anatomical Imaging,” p. 4). Both surface anatomy and anatomic imaging provide important information about the body for diagnosing disease.

Physiology is the scientific investigation of the processes or functions of living things. Although it may not be obvious at times, living things are ever-changing, not static. The major goals of physiology are to understand and predict the body's responses to stimuli and to understand how the body maintains conditions within a narrow range of values in a constantly changing environment.

Like anatomy, physiology can be considered at many different levels. **Cell physiology** examines the processes occurring in cells and **systemic physiology** considers the functions of organ systems. **Neurophysiology** focuses on the nervous system and **cardiovascular physiology** deals with the heart and blood vessels. Physiology often examines systems rather than regions because portions of a system in more than one region can be involved in a given function.

The study of the human body must encompass both anatomy and physiology because structures, functions, and processes are interwoven. **Pathology** (pa-thol'ō-jē) is the medical science dealing with all aspects of disease, with an emphasis on the cause and development of abnormal conditions, as well as the structural and functional changes resulting from disease. **Exercise physiology** focuses on changes in function, and in structure, caused by exercise.

- 1 **Define anatomy and physiology. Describe different levels at which each can be considered.**
- 2 **Define pathology and exercise physiology.**

STRUCTURAL AND FUNCTIONAL ORGANIZATION

The body can be considered to have six levels of organization: the chemical, cell, tissue, organ, organ system, and complete organism levels (figure 1.1).

1. **Chemical level.** The chemical level involves interactions between atoms, which are tiny building blocks of matter. Atoms can combine to form molecules, such as water, sugar, fats, and proteins. The function of a molecule is related intimately to its structure. For example, collagen molecules are ropelike protein fibers that give skin structural strength and flexibility. With old age, the structure of collagen changes, and the skin becomes fragile and is torn more easily. A brief overview of chemistry is presented in chapter 2.

Anatomical Anomalies

No two humans are structurally identical. For instance, one person may have longer fingers than another person. Despite this variability, most humans have the same basic pattern. Normally, we each have 10 fingers. **Anatomical anomalies** are structures that are unusual and different from the normal pattern. For example, some individuals have 12 fingers.

Anatomical anomalies can vary in severity from the relatively harmless to the life-threatening. For example, each kidney is normally supplied by one blood vessel, but in some individuals a kidney is supplied by two blood vessels. Either way, the kidney receives adequate blood. On the other hand, in the condition called “blue baby” syndrome certain blood vessels arising from the heart of an infant are not attached in their correct locations; blood is not effectively pumped to the lungs, resulting in tissues not receiving adequate oxygen.

1. Chemical level. Atoms (colored balls) combine to form molecules.

2. Cell level. Molecules form organelles, such as the nucleus and mitochondria, which make up cells.

3. Tissue level. Similar cells and surrounding materials make up tissues.

4. Organ level. Different tissues combine to form organs, such as the urinary bladder.

5. Organ system level. Organs such as the urinary bladder and kidneys make up an organ system.

6. Organism level. Organ systems make up an organism.

FIGURE 1.1 Levels of Organization

Six levels of organization for the human body are the chemical, cell, tissue, organ, organ system, and organism levels.

- 2. Cell level.** **Cells** are the basic structural and functional units of organisms, such as plants and animals. Molecules can combine to form **organelles** (or'gă-nelz), which are the small structures that make up cells. For example, the nucleus contains the cell's hereditary information, and mitochondria manufacture adenosine triphosphate (ATP), which is a molecule used by cells for a source of energy. Although cell types differ in their structure and function, they have many characteristics in common. Knowledge of these characteristics and their variations is essential to a basic understanding of anatomy and physiology. The cell is discussed in chapter 3.
- 3. Tissue level.** A **tissue** is a group of similar cells and the materials surrounding them. The characteristics of the cells and surrounding materials determine the functions of the tissue.

The numerous different tissues that make up the body are classified into four basic types: epithelial, connective, muscle, and nervous. Tissues are discussed in chapter 4.

- 4. Organ level.** An **organ** is composed of two or more tissue types that perform one or more common functions. The urinary bladder, heart, skin, and eye are examples of organs (figure 1.2).
- 5. Organ system level.** An **organ system** is a group of organs that have a common function or set of functions and are therefore viewed as a unit. For example, the urinary system consists of the kidneys, ureter, urinary bladder, and urethra. The kidneys produce urine, which is transported by the ureters to the urinary bladder, where it is stored until eliminated from the body by passing through the urethra. In this book, the body is considered to have 11 major organ systems:

CLINICAL FOCUS

Anatomical Imaging

Anatomical imaging has revolutionized medical science. Some estimate that during the past 20 years as much progress has been made in clinical medicine as in all its previous history combined, and anatomical imaging has made a major contribution to that progress. Anatomical imaging allows medical personnel to look inside the body with amazing accuracy and without the trauma and risk of exploratory surgery. Although most of the technology of anatomical imaging is very new, the concept and earliest technology are quite old.

Wilhelm Roentgen (1845–1923) was the first to use **x-rays** in medicine in 1895 to see inside the body. The rays were called x-rays because no one knew what they were. This extremely shortwave electromagnetic radiation (see chapter 2) moves through the body, exposing a photographic plate to form a **radiograph** (rā'dē-ō-graf). Bones and radiopaque dyes absorb the rays and create underexposed areas that appear white on the photographic film (figure A). X-rays have been in common use for many years and have numerous applications. Almost everyone has had a radiograph

taken, either to visualize a broken bone or to check for a cavity in a tooth. A major limitation of radiographs, however, is that they give only a flat, two-dimensional (2-D) image of the body, which is a three-dimensional (3-D) structure.

Ultrasound is the second oldest imaging technique. It was first developed in the early 1950s as an extension of World War II sonar technology and uses high-frequency sound waves. The sound waves are emitted from a transmitter–receiver placed on the skin over the area to be scanned. The sound waves strike internal organs and bounce back to the receiver on the skin. Even though the basic technology is fairly old, the most important advances in the field occurred only after it became possible to analyze the reflected sound waves by computer. Once the computer analyzes the pattern of sound waves, the information is transferred to a monitor, where the result is visualized as an ultrasound image called a **sonogram** (son'ō-gram) (figure B). One of the more recent advances in ultrasound technology is the ability of more advanced computers to analyze changes in position through time and to display those changes as “real-time” movements. Among other medical uses, ultrasound

is commonly used to evaluate the condition of the fetus during pregnancy.

Computer analysis is also the basis of another major medical breakthrough in imaging. **Computed tomographic** (tō'mō-graf'ik) (CT) **scans**, developed in 1972 and originally called **computerized axial tomographic** (CAT) **scans**, are computer-analyzed x-ray images. A low-intensity x-ray tube is rotated through a 360-degree arc around the patient, and the images are fed into a computer. The computer then constructs the image of a “slice” through the body at the point where the x-ray beam was focused and rotated (figure C). It is also possible with some computers to take several scans short distances apart and stack the slices to produce a 3-D image of a part of the body (figure D).

Dynamic spatial reconstruction (DSR) takes CT one step further. Instead of using a single rotating x-ray machine to take single slices and add them together, DSR uses about 30 x-ray tubes. The images from all the tubes are compiled simultaneously to rapidly produce a 3-D image. Because of the speed of the process, multiple images can be compiled to

FIGURE A X-ray

Radiograph produced by x-rays shows a lateral view of the head and neck.

FIGURE D Computed Tomography (CT)

Stacking of images acquired using CT technology.

show changes through time, thereby giving the system a dynamic quality. This system allows us to move away from seeing only static structure and toward seeing dynamic structure and function.

Digital subtraction angiography (an-jē-og' rā-fē) (DSA) is also one step beyond CT scans. A 3-D radiographic image of an organ, such as the brain, is made and stored in a computer. A radiopaque dye is injected into the circulation, and a second radiographic computer image is made. The first image is subtracted from the second one, greatly enhancing the differences, with the primary difference being the presence of the injected dye (figure E).

FIGURE E Digital Subtraction Angiography (DSA)

Lateral view of the head reveals the major blood vessels of the brain.

These computer images can be dynamic and used, for example, to guide a catheter into a carotid artery during angioplasty, which is the insertion of a tiny balloon into a carotid artery to compress material clogging the artery.

Magnetic resonance imaging (MRI) directs radio waves at a person lying inside a large electromagnetic field. The magnetic field causes the protons of various atoms to align (see chapter 2). Because of the large amounts of water in the body, the alignment of hydrogen atom protons is at present most important in this imaging system. Radio waves of certain frequencies, which change the alignment of the hydrogen atoms, then are directed at the patient. When the radio waves are turned off, the hydrogen atoms realign in accordance with the magnetic field. The time it takes the hydrogen atoms to realign is different for various tissues of the body. These differences can be analyzed by computer to produce very clear sections through the body (figure F). The technique is also very sensitive in detecting some forms of cancer and can detect a tumor far more readily than can a CT scan.

Positron emission tomographic (PET) scans can identify the metabolic states of various tissues. This technique is particularly useful in analyzing the brain. When cells are active, they are using energy. The energy they need is supplied by the breakdown of glucose (blood sugar). If radioactively treated, or “labeled,” glucose is given to a patient, the active cells take up the labeled glucose. As the

FIGURE F Magnetic Resonance Imaging (MRI)

Sagittal section of the head and neck.

FIGURE G Positron Emission Tomography (PET)

Transverse section through the skull. The highest level of brain activity is indicated in red, with successively lower levels represented by yellow, green, and blue.

radioactivity in the glucose decays, positively charged subatomic particles called positrons are emitted. When the positrons collide with electrons, the two particles annihilate each other, and gamma rays are given off. The gamma rays can be detected, pinpointing the cells that are metabolically active (figure G).

Whenever the human body is exposed to x-rays, ultrasound, electromagnetic fields, or radioactively labeled substances, a potential risk exists. In the medical application of anatomical imaging, the risk must be weighed against the benefit. Numerous studies have been conducted and are still being done to determine the outcomes of diagnostic and therapeutic exposures to x-rays.

The risk of anatomical imaging is minimized by using the lowest possible doses that provide the necessary information. For example, it is well known that x-rays can cause cell damage, particularly to the reproductive cells. Thus, the number of x-rays and the level of exposure are kept to a minimum; the x-ray beam is focused as closely as possible to avoid scattering of the rays; areas of the body not being x-rayed are shielded; and personnel administering x-rays are shielded. No known risks exist from ultrasound or electromagnetic fields at the levels used for diagnosis.

FIGURE 1.2 Organs of the Body

the integumentary, skeletal, muscular, nervous, endocrine, cardiovascular, lymphatic, respiratory, digestive, urinary, and reproductive systems. Figure 1.3 presents a brief summary of the organ systems and their functions.

6. *Organism level.* An **organism** is any living thing considered as a whole—whether composed of one cell, such as a bacterium, or of trillions of cells, such as a human. The human organism is a complex of organ systems, all mutually dependent on one another.

3 *From smallest to largest, list and define the body's six levels of organization.*

4 *What are the four primary tissue types?*

5 *Which two organ systems are responsible for regulating the other organ systems (see figure 1.3)? Which two are responsible for support and movement?*

6 *What are the functions of the integumentary, cardiovascular, lymphatic, respiratory, digestive, urinary, and reproductive systems (see figure 1.3)?*

PREDICT 1

In one type of diabetes, the pancreas (an organ) fails to produce insulin, which is a chemical normally made by pancreatic cells and released into the circulation. List as many levels of organization as you can in which this disorder could be corrected.

CHARACTERISTICS OF LIFE

Humans are organisms, sharing characteristics with other organisms. The most important common feature of all organisms is life. Organization, metabolism, responsiveness, growth, development, and reproduction are life's essential characteristics.

Organization is the condition in which the parts of an organism have specific relationships to each other and the parts interact to perform specific functions. Living things are highly organized. All organisms are composed of one or more cells. Cells in turn are composed of highly specialized organelles, which depend on the precise organization of large molecules. Disruption of this organized state can result in loss of functions, even death.

Metabolism (mě-tab'ō-lizm) is all of the chemical reactions taking place in an organism. It includes an organism's ability to break down food molecules, which it uses as a source of energy and raw materials to synthesize its own molecules. Energy is also used when one part of a molecule moves relative to another

part, resulting in a change in shape of the molecule. Changes in molecular shape in turn can change the shape of cells, which can produce movements of the organism. Metabolism is necessary for vital functions, such as responsiveness, growth, development, and reproduction.

Integumentary System

Provides protection, regulates temperature, reduces water loss, and produces vitamin D precursors. Consists of skin, hair, nails, and sweat glands.

Skeletal System

Provides protection and support, allows body movements, produces blood cells, and stores minerals and fat. Consists of bones, associated cartilages, ligaments, and joints.

Muscular System

Produces body movements, maintains posture, and produces body heat. Consists of muscles attached to the skeleton by tendons.

Lymphatic System

Removes foreign substances from the blood and lymph, combats disease, maintains tissue fluid balance, and transports fats from the digestive tract. Consists of the lymphatic vessels, lymph nodes, and other lymphatic organs.

Respiratory System

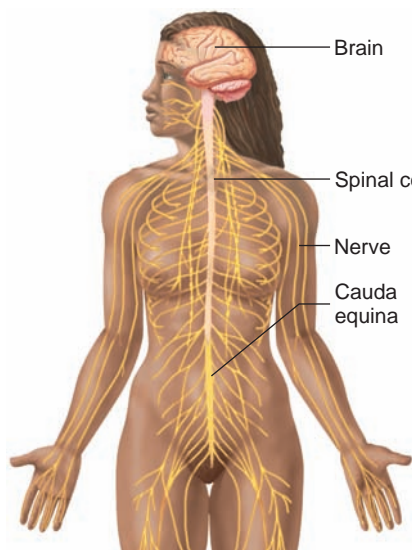

Exchanges oxygen and carbon dioxide between the blood and air and regulates blood pH. Consists of the lungs and respiratory passages.

Digestive System

Performs the mechanical and chemical processes of digestion, absorption of nutrients, and elimination of wastes. Consists of the mouth, esophagus, stomach, intestines, and accessory organs.

FIGURE 1.3 Organ Systems of the Body

Nervous System

A major regulatory system that detects sensations and controls movements, physiologic processes, and intellectual functions. Consists of the brain, spinal cord, nerves, and sensory receptors.

Endocrine System

A major regulatory system that influences metabolism, growth, reproduction, and many other functions. Consists of glands, such as the pituitary, that secrete hormones.

Cardiovascular System

Transports nutrients, waste products, gases, and hormones throughout the body; plays a role in the immune response and the regulation of body temperature. Consists of the heart, blood vessels, and blood.

Urinary System

Removes waste products from the blood and regulates blood pH, ion balance, and water balance. Consists of the kidneys, urinary bladder, and ducts that carry urine.

Female Reproductive System

Produces oocytes and is the site of fertilization and fetal development; produces milk for the newborn; produces hormones that influence sexual functions and behaviors. Consists of the ovaries, vagina, uterus, mammary glands, and associated structures.

Male Reproductive System

Produces and transfers sperm cells to the female and produces hormones that influence sexual functions and behaviors. Consists of the testes, accessory structures, ducts, and penis.

FIGURE 1.3 (continued)

Responsiveness is an organism's ability to sense changes in its external or internal environment and adjust to those changes. Responses include such things as moving toward food or water and away from danger or poor environmental conditions. Organisms can also make adjustments that maintain their internal

environment. For example, if body temperature increases in a hot environment, sweat glands produce sweat, which can lower body temperature back toward normal levels.

Growth happens when cells increase in size or number, which produces an overall enlargement of all or part of an organism. For

example, a muscle enlarged by exercise has larger muscle cells than an untrained muscle, and the skin of an adult has more cells than the skin of an infant. An increase in the materials surrounding cells can also contribute to growth. For instance, the growth of bone results from an increase in cell number and the deposition of mineralized materials around the cells.

Development includes the changes an organism undergoes through time; it begins with fertilization and ends at death. The greatest developmental changes occur before birth, but many changes continue after birth, and some continue throughout life. Development usually involves growth, but it also involves differentiation and morphogenesis. **Differentiation** is change in cell structure and function from generalized to specialized, and **morphogenesis** (mōr-fō-jen'ĕ-sis) is change in the shape of tissues, organs, and the entire organism. For example, following fertilization, generalized cells specialize to become specific cell types, such as skin, bone, muscle, or nerve cells. These differentiated cells form the tissues and organs.

Reproduction is the formation of new cells or new organisms. Without reproduction, growth and development are not possible. Without reproduction of the organism, species become extinct.

BIOMEDICAL RESEARCH

Studying other organisms has increased our knowledge about humans because humans share many characteristics with other organisms. For example, studying single-celled bacteria provides much information about human cells. Some biomedical research, however, cannot be accomplished using single-celled organisms or isolated cells. Sometimes other mammals must be studied. For example, great progress in open-heart surgery and kidney transplantation was made possible by perfecting surgical techniques on other mammals before attempting them on humans. Strict laws govern the use of animals in biomedical research—laws designed to ensure minimum suffering on the part of the animal and to discourage unnecessary experimentation.

Although much can be learned from studying other organisms, the ultimate answers to questions about humans can be obtained only from humans because other organisms are different from humans in significant ways.

Human Versus Animal-Based Knowledge

Failure to appreciate the differences between humans and other animals led to many misconceptions by early scientists. One of the first great anatomists was a Greek physician, Claudius Galen (ca. 130–201). Galen described a large number of anatomical structures supposedly present in humans but observed only in other animals. For example, he described the liver as having five lobes. This is true for rats, but not for humans, who have four-lobed livers. The errors introduced by Galen persisted for more than 1300 years until a Flemish anatomist, Andreas Vesalius (1514–1564), who is considered the first modern anatomist, carefully examined human cadavers and began to correct the textbooks. This example should serve as a word of caution: Some current knowledge in molecular biology and physiology has not been confirmed in humans.

7 Describe six characteristics of life.

8 Why is it important to realize that humans share many, but not all, characteristics with other animals?

HOMEOSTASIS

Homeostasis (hō'mē-ō-stā'sis) is the existence and maintenance of a relatively constant environment within the body. A small amount of fluid surrounds each cell of the body. For cells to function normally, the volume, temperature, and chemical content—conditions known as **variables** because their values can change—of this fluid must remain within a narrow range. Body temperature is a variable that can increase in a hot environment or decrease in a cold one.

Homeostatic mechanisms, such as sweating or shivering, normally maintain body temperature near an ideal normal value, or **set point** (figure 1.4). Note that these mechanisms are not able to maintain body temperature precisely at the set point. Instead, body temperature increases and decreases slightly around the set point to produce a **normal range** of values. As long as body temperature remains within this normal range, homeostasis is maintained.

The organ systems help control the body's internal environment so that it remains relatively constant. For example, the digestive, respiratory, circulatory, and urinary systems function together so that each cell in the body receives adequate oxygen and nutrients and so that waste products do not accumulate to a toxic level. If the fluid surrounding cells deviates from homeostasis, the cells do not function normally and can even die. Disease disrupts homeostasis and sometimes results in death.

Negative Feedback

Most systems of the body are regulated by **negative-feedback** mechanisms, which maintain homeostasis. *Negative* means that any deviation from the set point is made smaller or is resisted. For example, maintaining normal blood pressure is necessary for homeostasis because pressure is required to move blood from the heart through the tissues. The blood supplies the tissues with oxygen and nutrients

FIGURE 1.4 Homeostasis

Homeostasis is the maintenance of a variable around an ideal normal value, or set point. The value of the variable fluctuates around the set point to establish a normal range of values.

and removes waste products, thus maintaining tissue homeostasis. If blood pressure deviates from its set point, negative-feedback mechanisms return blood pressure toward the set point.

Many negative-feedback mechanisms have three components: a **receptor**, which monitors the value of a variable; a **control center**, which receives information about the variable from the receptor, establishes the set point, and controls the effector; and an **effector**, which produces responses that change the value of the variable. Several negative-feedback mechanisms regulate blood pressure, and they are described more fully in chapters 20 and 21. One negative-feedback mechanism regulating blood pressure is described here. Receptors that monitor blood pressure are located within large blood vessels near the heart and head. A control center located in the brain receives signals sent through nerves from the receptors. The control center evaluates the information and sends signals through nerves to the heart. The heart is the effector, and the heart rate increases or decreases in response to signals from the brain (figure 1.5).

CASE STUDY

Orthostatic Hypotension

Molly is a 75-year-old widow who lives alone. For 2 days, she had a fever and chills and stayed mostly in bed. On rising to go to the bathroom, she felt dizzy, fainted, and fell to the floor. Molly quickly regained consciousness and managed to call her son, who took her to the emergency room, where a diagnosis of orthostatic hypotension was made.

Orthostasis literally means to stand and *hypotension* refers to low blood pressure. **Orthostatic hypotension** is a significant drop in blood pressure on standing. When a person changes position from lying down to standing, blood “pools” within the veins below the heart because of gravity, and less blood returns to the heart. Consequently, blood pressure decreases because the heart has less blood to pump.

PREDICT 2

Although orthostatic hypotension has many causes, in the elderly it can be due to age-related decreased neural and cardiovascular responses. Dehydration can result from decreased fluid intake while feeling ill and from sweating as a result of a fever. Dehydration can decrease blood volume and lower blood pressure, increasing the likelihood of orthostatic hypotension. Use figure 1.6 to answer the following:

- Describe the normal response to a decrease in blood pressure on standing.
- What happened to Molly’s heart rate just before she fainted? Why did Molly faint?
- How did Molly’s fainting and falling to the floor assist in establishing homeostasis (assuming she was not injured)?

If blood pressure increases slightly, the receptors detect the increased blood pressure and send that information to the control center in the brain. The control center causes heart rate to decrease, resulting in a decrease in blood pressure. If blood pressure decreases slightly, the receptors inform the control center, which increases heart rate, thereby producing an increase in blood pressure (figure 1.6). As a result, blood pressure constantly rises and falls within a normal range of values.

Although homeostasis is the maintenance of a normal range of values, this does not mean that all variables are maintained within the same narrow range of values at all times. Sometimes a deviation from the usual range of values can be beneficial. For example, during exercise the normal range for blood pressure differs from the range under resting conditions, and the blood pressure is significantly elevated (figure 1.7). Muscle cells require increased oxygen and nutrients and increased removal of waste products to support their increased level of activity during exercise. Increased blood pressure increases blood delivery to muscles, which maintains muscle cell homeostasis during exercise by increasing the delivery of oxygen and nutrients and the removal of waste products.

- Define homeostasis, variable, and set point. If a deviation from homeostasis occurs, what mechanism restores it?
- What are the three components of many negative-feedback mechanisms? How do they maintain homeostasis?

PREDICT 3

Explain how negative-feedback mechanisms control respiratory rates when a person is at rest and when a person is exercising.

Positive Feedback

Positive-feedback responses are not homeostatic and are rare in healthy individuals. *Positive* implies that, when a deviation from a normal value occurs, the system’s response is to make the deviation even greater (figure 1.8). Positive feedback therefore usually creates a cycle that leads away from homeostasis and, in some cases, results in death.

A cardiac (heart) muscle receiving an inadequate amount of blood is an example of positive feedback. Contraction of cardiac muscle generates blood pressure and moves blood through blood vessels to tissues. A system of blood vessels on the outside of the heart provides cardiac muscle with a blood supply sufficient to allow normal contractions to occur. In effect, the heart pumps blood to itself. Just as with other tissues, blood pressure must be maintained to ensure adequate delivery of blood to cardiac muscle. Following extreme blood loss, blood pressure decreases to the point that delivery of blood to cardiac muscle is inadequate. As a result, cardiac muscle homeostasis is disrupted, and cardiac muscle does not function normally. The heart pumps less blood, which causes the blood pressure to drop even further. This additional decrease in blood pressure means that even less blood is delivered to cardiac muscle, and the heart pumps even less blood, which again decreases the blood pressure (figure 1.9). If the process continues until the blood pressure is too low to sustain the cardiac muscle, the heart stops beating, and death results.

1. Receptors monitor the value of a variable—in this case, receptors in the wall of a blood vessel monitor blood pressure.
2. Information about the value of the variable is sent to a control center. In this case, information is sent by nerves to the part of the brain responsible for regulating blood pressure.
3. The control center compares the value of the variable against the set point.
4. If a response is necessary to maintain homeostasis, the control center causes an effector to respond. In this case, information is sent by nerves to the heart.
5. An effector produces a response that maintains homeostasis. In this case, changing heart rate changes blood pressure.

PROCESS FIGURE 1.5 Negative-Feedback Mechanism: Blood Pressure

Following a moderate amount of blood loss (e.g., after a person donates a pint of blood), negative-feedback mechanisms produce an increase in heart rate and other responses that restore blood pressure. If blood loss is severe, however, negative-feedback mechanisms may not be able to maintain homeostasis, and the

positive-feedback effect of an ever-decreasing blood pressure can develop. Circumstances in which negative-feedback mechanisms are not adequate to maintain homeostasis illustrate a basic principle. Many disease states result from failure of negative-feedback mechanisms to maintain homeostasis. Medical therapy seeks to

HOMEOSTASIS FIGURE 1.6 Summary of Negative Feedback Mechanism: Blood Pressure

Blood pressure is maintained within a normal range by negative-feedback mechanisms.

FIGURE 1.7 Changes in Blood Pressure During Exercise

During exercise, the demand for oxygen by muscle tissue increases. An increase in blood pressure (BP) results in an increase in blood flow to the tissues. The increased blood pressure is not an abnormal or a nonhomeostatic condition but is a resetting of the normal homeostatic range to meet the increased demand. The reset range is higher and broader than the resting range. After exercise ceases, the range returns to that of the resting condition.

overcome illness by aiding negative-feedback mechanisms (e.g., a transfusion reverses a constantly decreasing blood pressure and restores homeostasis).

A few positive-feedback mechanisms do operate in the body under normal conditions, but in all cases they are eventually limited in some way. Birth is an example of a normally occurring positive-feedback mechanism. Near the end of pregnancy, the baby's larger size stretches the uterus. This stretching, especially around the opening of the uterus, stimulates contractions of the uterine muscles. The uterine contractions push the baby against the opening of the uterus and stretch it further. This stimulates additional contractions, which result in additional stretching. This positive-feedback sequence ends only when the baby is delivered from the uterus and the stretching stimulus is eliminated.

FIGURE 1.8 Positive Feedback

Deviations from the normal set point value cause an additional deviation away from that value in either a positive or negative direction.

FIGURE 1.9 Example of Harmful Positive Feedback

A decrease in blood pressure below the normal range causes decreased blood flow to the heart. The heart is unable to pump enough blood to maintain blood pressure, and blood flow to the cardiac muscle decreases. Thus, the heart's ability to pump decreases further, and blood pressure decreases even more.

11 Define positive feedback. Why are positive-feedback mechanisms often harmful?

PREDICT 4

Is the sensation of thirst associated with a negative- or a positive-feedback mechanism? Explain.

TERMINOLOGY AND THE BODY PLAN

You will be learning many new words as you study anatomy and physiology. Knowing the derivation, or **etymology** (et'uh-mol'ō-jē), of these words can make learning them easy and fun. Most words are derived from Latin or Greek, which are very descriptive languages. For example, *foramen* is a Latin word for hole, and *magnum* means large. The foramen magnum is therefore a large hole in the skull through which the spinal cord attaches to the brain.

Prefixes and suffixes can be added to words to expand their meaning. The suffix *-itis* means an inflammation, so appendicitis is an inflammation of the appendix. As new terms are introduced in this book, their meanings are often explained. The glossary and the list of word roots, prefixes, and suffixes on the inside back cover of the book provide additional information about the new terms.

It is very important to learn these new words so that when you speak to colleagues or write reports your message is clear and correct.

FIGURE 1.10 Directional Terms

All directional terms are in relation to a person in the anatomical position: a person standing erect with the face directed forward, the arms hanging to the sides, and the palms of the hands facing forward.

Body Positions

The **anatomical position** refers to a person standing erect with the face directed forward, the upper limbs hanging to the sides, and the palms of the hands facing forward (figure 1.10). A person is **supine** when lying face upward and **prone** when lying face downward.

The position of the body can affect the description of body parts relative to each other. In the anatomical position, the elbow is above the hand, but, in the supine or prone position, the elbow and hand are at the same level. To avoid confusion, relational descriptions are always based on the anatomical position, no matter the actual position of the body. Thus, the elbow is always described as being above the wrist, whether the person is lying down or is even upside down.

12 What is the anatomical position in humans? Why is it important?

13 Define supine and prone.

Directional Terms

Directional terms describe parts of the body relative to each other. Important directional terms are illustrated in figure 1.10 and summarized in table 1.1. It is important to become familiar with these directional terms as soon as possible because you will see them repeatedly throughout the book. *Right* and *left* are retained as

directional terms in anatomical terminology. *Up* is replaced by **superior**, *down* by **inferior**, *front* by **anterior**, and *back* by **posterior**.

In humans, *superior* is synonymous with **cephalic** (se-fal'ik), which means toward the head, because, when we are in the anatomical position, the head is the highest point. In humans, the term *inferior* is synonymous with **caudal** (kaw'däl), which means toward the tail, which would be located at the end of the vertebral column if humans had tails. The terms *cephalic* and *caudal* can be used to describe directional movements on the trunk, but they are not used to describe directional movements on the limbs.

The word *anterior* means that which goes before, and **ventral** means belly. The anterior surface of the human body is therefore the ventral surface, or belly, because the belly “goes first” when we are walking. The word *posterior* means that which follows, and **dorsal** means back. The posterior surface of the body is the dorsal surface, or back, which follows as we are walking.

PREDICT 5

The anatomical position of a cat refers to the animal standing erect on all four limbs and facing forward. On the basis of the etymology of the directional terms, what two terms indicate movement toward the head? What two terms mean movement toward the back? Compare these terms with those referring to a human in the anatomical position.

TABLE 1.1 Directional Terms for Humans

Terms	Etymology*	Definition	Example
Right		Toward the right side of the body	The right ear
Left		Toward the left side of the body	The left eye
Superior	L., higher	A structure above another	The chin is superior to the navel.
Inferior	L., lower	A structure below another	The navel is inferior to the chin.
Cephalic	G. <i>kephale</i> , head	Closer to the head than another structure (usually synonymous with <i>superior</i>)	The chin is cephalic to the navel.
Caudal	L. <i>cauda</i> , a tail	Closer to the tail than another structure (usually synonymous with <i>inferior</i>)	The navel is caudal to the chin.
Anterior	L., before	The front of the body	The navel is anterior to the spine.
Posterior	L. <i>posterus</i> , following	The back of the body	The spine is posterior to the breastbone.
Ventral	L. <i>ventr-</i> , belly	Toward the belly (synonymous with <i>anterior</i>)	The navel is ventral to the spine.
Dorsal	L. <i>dorsum</i> , back	Toward the back (synonymous with <i>posterior</i>)	The spine is dorsal to the breastbone.
Proximal	L. <i>proximus</i> , nearest	Closer to the point of attachment to the body than another structure	The elbow is proximal to the wrist.
Distal	L. <i>di-</i> plus <i>sto</i> , to stand apart or be distant	Farther from the point of attachment to the body than another structure	The wrist is distal to the elbow.
Lateral	L. <i>latus</i> , side	Away from the midline of the body	The nipple is lateral to the breastbone.
Medial	L. <i>medialis</i> , middle	Toward the midline of the body	The bridge of the nose is medial to the eye.
Superficial	L. <i>superficialis</i> , toward the surface	Toward or on the surface (not shown in figure 1.10)	The skin is superficial to muscle.
Deep	O.E. <i>deop</i> , deep	Away from the surface, internal (not shown in figure 1.10)	The lungs are deep to the ribs.

*Origin and meaning of the word: L., Latin; G., Greek; O.E., Old English.

Proximal means nearest, whereas **distal** means distant. These terms are used to refer to linear structures, such as the limbs, in which one end is near another structure and the other end is farther away. Each limb is attached at its proximal end to the body, and the distal end, such as the hand, is farther away.

Medial means toward the midline, and **lateral** means away from the midline. The nose is located in a medial position in the face, and the eyes are lateral to the nose. The term **superficial** refers to a structure close to the surface of the body, and **deep** is toward the interior of the body. The skin is superficial to muscle and bone.

14 List two terms that in humans indicate toward the head.

Name two terms that mean the opposite.

15 List two terms that indicate the back in humans. What two terms mean the front?

16 Define the following terms, and give the word that means the opposite: proximal, lateral, and superficial.

PREDICT 6

Use as many directional terms as you can to describe the relationship between your kneecap and your heel.

Body Parts and Regions

A number of terms are used when referring to different parts or regions of the body (figure 1.11). The upper limb is divided into

the arm, forearm, wrist, and hand. The **arm** extends from the shoulder to the elbow, and the **forearm** extends from the elbow to the wrist. The lower limb is divided into the thigh, leg, ankle, and foot. The **thigh** extends from the hip to the knee, and the **leg** extends from the knee to the ankle. Note that, contrary to popular usage, the terms *arm* and *leg* refer to only a part of the respective limb.

The central region of the body consists of the **head**, **neck**, and **trunk**. The trunk can be divided into the **thorax** (chest), **abdomen** (region between the thorax and pelvis), and **pelvis** (the inferior end of the trunk associated with the hips).

The abdomen is often subdivided superficially into **quadrants** by two imaginary lines—one horizontal and one vertical—which intersect at the navel (figure 1.12a). The quadrants formed are the right-upper, left-upper, right-lower, and left-lower quadrants. In addition to these quadrants, the abdomen is sometimes subdivided into nine **regions** by four imaginary lines: two horizontal and two vertical. These four lines create an imaginary tic-tac-toe figure on the abdomen, resulting in nine regions: epigastric, right and left hypochondriac, umbilical, right and left lumbar, hypogastric, and right and left iliac (figure 1.12b). Clinicians use the quadrants and regions as reference points for locating underlying organs. For example, the appendix is located in the right-lower quadrant, and the pain of an acute appendicitis is usually felt there.

FIGURE 1.11 Body Parts and Regions

The anatomical and common (*in parentheses*) names are indicated for some parts and regions of the body. (a) Anterior view. (b) Posterior view.

17 What is the difference between the arm and the upper limb and the difference between the leg and the lower limb?

18 Describe the quadrant and the nine-region methods of subdividing the abdominal region. What is the purpose of these subdivisions?

PREDICT 7

If a bullet passed through the left upper quadrant in an anterior to posterior direction, which of the following organs could be damaged (see figures 1.2 and 1.12)? gallbladder, heart, kidney, liver, pancreas, spleen, stomach, urinary bladder

Planes

At times, it is conceptually useful to describe the body as having imaginary flat surfaces called **planes** passing through it (figure 1.13). A plane divides, or sections, the body, making it possible to “look

inside” and observe the body’s structures. A **sagittal** (saj’i-tāl) plane runs vertically through the body, separating it into right and left portions. The word *sagittal* literally means “the flight of an arrow” and refers to the way the body would be split by an arrow passing anteriorly to posteriorly. A **median** plane is a sagittal plane that passes through the midline of the body, dividing it into equal right and left halves. A **transverse**, or **horizontal**, plane runs parallel to the ground, dividing the body into superior and inferior portions. A **frontal**, or **coronal** (kōr’ō-nāl, kō-rō’nāl; crown), plane runs vertically from right to left and divides the body into anterior and posterior parts.

Organs are often sectioned to reveal their internal structure (figure 1.14). A cut through the long axis of the organ is a **longitudinal** section, and a cut at right angles to the long axis is a **cross**, or **transverse**, section. If a cut is made across the long axis at other than a right angle, it is called an **oblique** section.

19 Define the three planes of the body.

20 In what three ways can an organ be cut?

FIGURE 1.12 Subdivisions of the Abdomen

Lines are superimposed over internal organs to demonstrate the relationship of the organs to the subdivisions. (a) Abdominal quadrants consist of four subdivisions. (b) Abdominal regions consist of nine subdivisions.

Body Cavities

The body contains many cavities. Some of these, such as the nasal cavity, open to the outside of the body, and some do not. The trunk contains three large cavities that do not open to the outside of the body: the thoracic, the abdominal, and the pelvic (figure 1.15). The rib cage surrounds the **thoracic cavity**, and the muscular diaphragm separates it from the abdominal cavity. The thoracic cavity is divided into right and left parts by a median partition called the **mediastinum** (mē'dē-as-tī'nūm; middle wall). The mediastinum contains the heart, the thymus, the trachea, the esophagus, and other structures, such as blood vessels and nerves. The two lungs are located on each side of the mediastinum.

Abdominal muscles primarily enclose the **abdominal cavity**, which contains the stomach, intestines, liver, spleen, pancreas, and kidneys. Pelvic bones encase the small space known as the **pelvic cavity**, where the urinary bladder, part of the large intestine, and the internal reproductive organs are housed. The abdominal and pelvic cavities are not physically separated and sometimes are called the **abdominopelvic cavity**.

21 What structure separates the thoracic cavity from the abdominal cavity? The abdominal cavity from the pelvic cavity?

22 What structure divides the thoracic cavity into right and left parts?

Serous Membranes

Serous (sēr'ūs) **membranes** cover the organs of the trunk cavities and line the trunk cavities. Imagine an inflated balloon into which a

fist has been pushed (figure 1.16). The fist represents an organ; the inner balloon wall in contact with the fist represents the **visceral** (vis'er-āl; organ) **serous membrane** covering the organ; and the outer part of the balloon wall represents the **parietal** (pā-rī'ē-tāl; wall) **serous membrane**. The cavity, or space, between the visceral and parietal serous membranes is normally filled with a thin, lubricating film of serous fluid produced by the membranes. As organs rub against the body wall or against another organ, the combination of serous fluid and smooth serous membranes reduces friction.

The thoracic cavity contains three serous membrane-lined cavities: a pericardial cavity and two pleural cavities. The **pericardial** (per-i-kar'dē-āl; around the heart) **cavity** surrounds the heart (figure 1.17a). The visceral pericardium covers the heart, which is contained within a connective tissue sac lined with the parietal pericardium. The pericardial cavity, which contains pericardial fluid, is located between the visceral pericardium and the parietal pericardium.

A **pleural** (ploor'āl; associated with the ribs) **cavity** surrounds each lung, which is covered by visceral pleura (figure 1.17b). Parietal pleura line the inner surface of the thoracic wall, the lateral surfaces of the mediastinum, and the superior surface of the diaphragm. The pleural cavity lies between the visceral pleura and the parietal pleura and contains pleural fluid.

The abdominopelvic cavity contains a serous membrane-lined cavity called the **peritoneal** (per'i-tō-nē'āl; to stretch over) **cavity** (figure 1.17c). Visceral peritoneum covers many of the organs of the abdominopelvic cavity. Parietal peritoneum lines the wall of the abdominopelvic cavity and the inferior surface of the diaphragm. The peritoneal cavity is located between the visceral peritoneum and the parietal peritoneum and contains peritoneal fluid.

FIGURE 1.13 Planes of the Body

Planes through the whole body are indicated by "glass" sheets. Actual sections through the head (viewed from the right), abdomen (*inferior view*), and hip (*anterior view*) are also shown.

FIGURE 1.14 Planes Through an Organ

Planes through the small intestine are indicated by “glass” sheets. The views of the small intestine after sectioning are also shown. Although the small intestine is basically a tube, the sections appear quite different in shape.

Inflammation of Serous Membranes

The serous membranes can become inflamed, usually as a result of an infection. **Pericarditis** (per'i-kar-dī'tis) is inflammation of the pericardium, **pleurisy** (ploor'i-sē) is inflammation of the pleura, and **peritonitis** (per'i-tō-nī'tis) is inflammation of the peritoneum.

Mesenteries (mes'en-ter-ēz), which consist of two layers of peritoneum fused together (see figure 1.17c), connect the visceral peritoneum of some abdominopelvic organs to the parietal peritoneum on the body wall or to the visceral peritoneum of other abdominopelvic organs. The mesenteries anchor the organs to the body wall and provide a pathway for nerves and blood vessels to reach the organs. Other abdominopelvic organs are more closely attached to the body wall and do not have mesenteries. Parietal peritoneum covers these other organs, which are said to be **retroperitoneal** (re'trō-per'i-tō-nē'āl; behind the peritoneum). The retroperitoneal organs include the kidneys, the adrenal glands, the pancreas, parts of the intestines, and the urinary bladder (see figure 1.17c).

23 Define serous membranes. Differentiate between parietal and visceral serous membranes. What is the function of the serous membranes?

24 Name the serous membrane-lined cavities of the trunk.

25 What are mesenteries? Explain their function.

26 What are retroperitoneal organs? List five examples.

PREDICT 8

Explain how an organ can be located within the abdominopelvic cavity but not be within the peritoneal cavity.

FIGURE 1.15 Trunk Cavities

(a) Anterior view showing the major trunk cavities. The diaphragm separates the thoracic cavity from the abdominopelvic cavity. The mediastinum, which includes the heart, is a partition of organs dividing the thoracic cavity. (b) Sagittal section of the trunk cavities viewed from the left. The dashed line shows the division between the abdominal and pelvic cavities. The mediastinum has been removed to show the thoracic cavity.

FIGURE 1.16 Serous Membranes

(a) Fist pushing into a balloon. A “glass” sheet indicates the location of a cross section through the balloon. (b) Interior view produced by the section in (a). The fist represents an organ, and the walls of the balloon the serous membranes. The inner wall of the balloon represents a visceral serous membrane in contact with the fist (organ). The outer wall of the balloon represents a parietal serous membrane.

FIGURE 1.17 Location of Serous Membranes

(a) Frontal section showing the parietal pericardium (blue), visceral pericardium (red), and pericardial cavity. (b) Frontal section showing the parietal pleura (blue), visceral pleura (red), and pleural cavities. (c) Sagittal section through the abdominopelvic cavity showing the parietal peritoneum (blue), visceral peritoneum (red), peritoneal cavity, mesenteries (purple), and retroperitoneal organs.

SUMMARY

A functional knowledge of anatomy and physiology can be used to solve problems concerning the body when healthy or diseased.

Anatomy and Physiology (p. 2)

1. Anatomy is the study of the body's structures.
 - Developmental anatomy considers anatomical changes from conception to adulthood. Embryology focuses on the first 8 weeks of development.
 - Cytology examines cells, and histology examines tissues.
 - Gross anatomy emphasizes organs from a systemic or regional perspective.
2. Surface anatomy uses superficial structures to locate deeper structures, and anatomical imaging is a noninvasive technique for identifying deep structures.
3. Physiology is the study of the body's functions. It can be approached from a cellular or systems point of view.
4. Pathology deals with all aspects of disease. Exercise physiology examines changes caused by exercise.

Structural and Functional Organization (p. 2)

1. Basic chemical characteristics are responsible for the structure and functions of life.
2. Cells are the basic structural and functional units of organisms, such as plants and animals. Organelles are small structures within cells that perform specific functions.
3. Tissues are groups of cells of similar structure and function and the materials surrounding them. The four primary tissue types are epithelial, connective, muscle, and nervous tissues.
4. Organs are structures composed of two or more tissues that perform specific functions.
5. Organs are arranged into the 11 organ systems of the human body (see figure 1.2).
6. Organ systems interact to form a whole, functioning organism.

Characteristics of Life (p. 6)

Humans have many characteristics, such as organization, metabolism, responsiveness, growth, development, and reproduction, in common with other organisms.

Biomedical Research (p. 9)

Much of what is known about humans is derived from research on other organisms.

Homeostasis (p. 9)

Homeostasis is the condition in which body functions, body fluids, and other factors of the internal environment are maintained at levels suitable to support life.

Negative Feedback

1. Negative-feedback mechanisms operate to maintain homeostasis.
2. Many negative-feedback mechanisms consist of a receptor, control center, and effector.

Positive Feedback

1. Positive-feedback mechanisms usually increase deviations from normal.
2. Although a few positive-feedback mechanisms normally exist in the body, most positive-feedback mechanisms are harmful.

Terminology and the Body Plan (p. 12)

Body Positions

1. A human standing erect with the face directed forward, the arms hanging to the side, and the palms facing forward is in the anatomical position.
2. A person lying face upward is supine; a person lying face downward is prone.

Directional Terms

Directional terms always refer to the anatomical position, no matter what the actual position of the body (see table 1.1).

Body Parts and Regions

1. The body can be divided into the limbs, upper and lower, and a central region consisting of the head, neck, and trunk regions.
2. Superficially, the abdomen can be divided into quadrants or nine regions. These divisions are useful for locating internal organs or describing the location of a pain or tumor.

Planes

1. Planes of the body
 - A sagittal plane divides the body into right and left parts. A median plane divides the body into equal right and left halves.
 - A transverse (horizontal) plane divides the body into superior and inferior portions.
 - A frontal (coronal) plane divides the body into anterior and posterior parts.
2. Sections of an organ
 - A longitudinal section of an organ divides it along the long axis.
 - A cross (transverse) section cuts at a right angle to the long axis of an organ.
 - An oblique section cuts across the long axis of an organ at an angle other than a right angle.

Body Cavities

1. The mediastinum subdivides the thoracic cavity.
2. The diaphragm separates the thoracic and abdominal cavities.
3. Pelvic bones surround the pelvic cavity.

Serous Membranes

1. Serous membranes line the trunk cavities. The parietal portion of a serous membrane lines the wall of the cavity, and the visceral portion is in contact with the internal organs.
 - The serous membranes secrete fluid, which fills the space between the visceral and parietal membranes. The serous membranes protect organs from friction.
 - The pericardial cavity surrounds the heart, the pleural cavities surround the lungs, and the peritoneal cavity surrounds certain abdominal and pelvic organs.
2. Mesenteries are parts of the peritoneum that hold the abdominal organs in place and provide a passageway for blood vessels and nerves to the organs.
3. Retroperitoneal organs are located “behind” the parietal peritoneum.

REVIEW AND COMPREHENSION

- Physiology
 - deals with the processes or functions of living things.
 - is the scientific discipline that investigates the body's structures.
 - is concerned with organisms and does not deal with different levels of organization, such as cells and systems.
 - recognizes the static (as opposed to the dynamic) nature of living things.
 - can be used to study the human body without considering anatomy.
 - The following are conceptual levels for considering the body.
 - cell
 - chemical
 - organ
 - organ system
 - organism
 - tissue

Choose the correct order for these conceptual levels, from smallest to largest.

 - 1,2,3,6,4,5
 - 2,1,6,3,4,5
 - 3,1,6,4,5,2
 - 4,6,1,3,5,2
 - 1,6,5,3,4,2
- For questions 3–8, match each organ system with its correct function.
- regulates other organ systems
 - removes waste products from the blood; maintains water balance
 - regulates temperature; reduces water loss; provides protection
 - removes foreign substances from the blood; combats disease; maintains tissue fluid balance
 - produces movement; maintains posture; produces body heat
- endocrine system
 - integumentary system
 - lymphatic system
 - muscular system
 - nervous system
 - urinary system
- The characteristic of life that is defined as “all the chemical reactions taking place in an organism” is
 - development.
 - growth.
 - metabolism.
 - organization.
 - responsiveness.
- Negative-feedback mechanisms
 - make deviations from the set point smaller.
 - maintain homeostasis.
 - are associated with an increased sense of hunger the longer a person goes without eating.
 - all of the above.
 - The following events are part of a negative-feedback mechanism.
 - Blood pressure increases.
 - Control center compares actual blood pressure to the blood pressure set point.
 - The heart beats faster.
 - Receptors detect a decrease in blood pressure.

Choose the arrangement that lists the events in the order they occur.

 - 1,2,3,4
 - 1,3,2,4
 - 3,1,4,2
 - 4,2,3,1
 - 4,3,2,1
 - Which of these statements concerning positive feedback is correct?
 - Positive-feedback responses maintain homeostasis.
 - Positive-feedback responses occur continuously in healthy individuals.
 - Birth is an example of a normally occurring positive-feedback mechanism.
 - When the cardiac muscle receives an inadequate supply of blood, positive-feedback mechanisms increase blood flow to the heart.
 - Medical therapy seeks to overcome illness by aiding positive-feedback mechanisms.
 - The clavicle (collarbone) is _____ to the nipple of the breast.
 - anterior
 - distal
 - superficial
 - superior
 - ventral
 - A term that means nearer the attached end of a limb is
 - distal.
 - lateral.
 - medial.
 - proximal.
 - superficial.
 - Which of these directional terms are paired most appropriately as opposites?
 - superficial and deep
 - medial and proximal
 - distal and lateral
 - superior and posterior
 - anterior and inferior
 - The part of the upper limb between the elbow and the wrist is called the
 - arm.
 - forearm.
 - hand.
 - inferior arm.
 - lower arm.
 - A patient with appendicitis usually has pain in the _____ quadrant of the abdomen.
 - left-lower
 - right-lower
 - left-upper
 - right-upper
 - A plane that divides the body into anterior and posterior parts is a
 - frontal (coronal) plane.
 - sagittal plane.
 - transverse plane.
 - The pelvic cavity contains the
 - kidneys.
 - liver.
 - spleen.
 - stomach.
 - urinary bladder.
 - The lungs are
 - part of the mediastinum.
 - surrounded by the pericardial cavity.
 - found within the thoracic cavity.
 - separated from each other by the diaphragm.
 - surrounded by mucous membranes.
 - Given these characteristics:
 - reduce friction between organs
 - line fluid-filled cavities
 - line trunk cavities that open to the exterior of the body

Which of the characteristics describe serous membranes?

 - 1,2
 - 1,3
 - 2,3
 - 1,2,3

22. Given these organ and cavity combinations:

1. heart and pericardial cavity
2. lungs and pleural cavity
3. stomach and peritoneal cavity
4. kidney and peritoneal cavity

Which of the organs is correctly paired with a space that surrounds that organ?

- a. 1,2 b. 1,2,3 c. 1,2,4 d. 2,3,4 e. 1,2,3,4

23. Which of these membrane combinations are found on the surface of the diaphragm?

- a. parietal pleura—parietal peritoneum
- b. parietal pleura—visceral peritoneum
- c. visceral pleura—parietal peritoneum
- d. visceral pleura—visceral peritoneum

24. Mesenteries

- a. are found in the pleural, pericardial, and abdominopelvic cavities.
- b. consist of two layers of peritoneum fused together.
- c. anchor organs, such as the kidneys and urinary bladder, to the body wall.
- d. are found primarily in body cavities that open to the outside.
- e. all of the above.

25. Which of the following organs is *not* retroperitoneal?

- a. adrenal glands c. kidneys e. stomach
- b. urinary bladder d. pancreas

Answers in Appendix E

CRITICAL THINKING

1. Exposure to a hot environment causes the body to sweat. The hotter the environment, the greater the sweating. Two anatomy and physiology students are arguing about the mechanisms involved: Student A claims that they are positive feedback, and student B claims they are negative feedback. Do you agree with student A or student B and why?

2. A male has lost blood as a result of a gunshot wound. Even though bleeding has been stopped, his blood pressure is low and dropping and his heart rate is elevated. Following a blood transfusion, his blood pressure increases and his heart rate decreases. Which of the following statement(s) is (are) consistent with these observations?

- a. Negative-feedback mechanisms can be inadequate without medical intervention.
- b. The transfusion interrupted a positive-feedback mechanism.
- c. The increased heart rate after the gunshot wound and before the transfusion is a result of a positive-feedback mechanism.
- d. a and b
- e. a, b, and c

3. Provide the correct directional term for the following statement:

When a boy is standing on his head, his nose is _____ to his mouth.

4. Complete the following statements, using the correct directional terms for a human being. Note that more than one term can apply.

- a. The navel is _____ to the nose.
- b. The nipple is _____ to the lung.
- c. The arm is _____ to the forearm.
- d. The little finger is _____ to the index finger.

5. In which quadrants and regions are the pancreas and the urinary bladder located?

6. Given the following procedures:

1. Make an opening into the mediastinum.
2. Lay the patient supine.
3. Lay the patient prone.
4. Make an incision through the pericardial serous membranes.
5. Make an opening into the abdomen.

Which of the procedures should be accomplished to expose the anterior surface of a patient's heart?

- a. 2,1,4
- b. 2,5,4
- c. 3,1,4
- d. 3,5,4

7. During pregnancy, which of the mother's body cavities increases most in size?

8. A bullet enters the left side of a man, passes through the left lung, and lodges in the heart. Name, in order, the serous membranes and their cavities through which the bullet passes.

9. A woman falls while skiing and accidentally is impaled by her ski pole. The pole passes through the abdominal body wall and into and through the stomach, pierces the diaphragm, and finally stops in the left lung. List, in order, the serous membranes the pole pierces.

The Chemical Basis of Life

2

Chemicals compose the structures of the body, and the interactions of chemicals with one another are responsible for the functions of the body. Nerve impulse generation, digestion, muscle contraction, and metabolism can be described in chemical terms. Many abnormal conditions and illnesses, as well as their treatments, can also be explained in chemical terms. For example, Parkinson disease, which causes uncontrollable shaking movements, results from a shortage of a chemical called dopamine in certain nerve cells in the brain. It can be treated by giving patients another chemical, which brain cells convert to dopamine.

To understand anatomy and physiology, it is essential to have a basic knowledge of chemistry—the scientific discipline concerned with the atomic composition and structure of substances and the reactions they undergo. This chapter outlines *basic chemistry* (p. 24), *chemical reactions and energy* (p. 32), *inorganic chemistry* (p. 36), and *organic chemistry* (p. 39). It is not a comprehensive review of chemistry, but it does review some of the basic concepts. When necessary, refer back to this chapter when chemical phenomena are discussed later in the book.

The chemical composition of the body's structures determines their function. This colorized scanning electron micrograph shows bundles of collagen fibers (*brown*) and elastic fibers (*blue*). The molecules forming collagen fibers are like tiny ropes, and collagen fibers make tissues strong yet flexible. The molecules forming elastic fibers resemble microscopic coiled springs. The elastic fibers allow tissues to be stretched and then recoil back to their original shape.

BASIC CHEMISTRY

Matter, Mass, and Weight

All living and nonliving things are composed of **matter**, which is anything that occupies space and has mass. **Mass** is the amount of matter in an object, and **weight** is the gravitational force acting on an object of a given mass. For example, the weight of an apple results from the force of gravity “pulling” on the apple’s mass.

PREDICT 1

The difference between mass and weight can be illustrated by considering an astronaut. How does an astronaut’s mass and weight in outer space compare with the astronaut’s mass and weight on the earth’s surface?

The **kilogram (kg)**, which is the mass of a platinum–iridium cylinder kept at the International Bureau of Weights and Measurements in France, is the international unit for mass. The mass of all other objects is compared with this cylinder. For example, a 2.2-pound lead weight or 1 liter (L) (1.06 qt) of water each has a mass of approximately 1 kg. An object with 1/1000 the mass of a kilogram is defined as having a mass of 1 **gram (g)**.

Chemists use a balance to determine the mass of objects. Although we commonly refer to “weighing” an object on a balance, we are actually “massing” the object because the balance compares objects of unknown mass with objects of known mass. When the unknown and known masses are exactly balanced, the gravitational pull of the earth on both of them is the same. Thus, the effect of gravity on the unknown mass is counteracted by the effect of gravity on the known mass. A balance produces the same results on a mountaintop as at sea level because it does not matter that gravitational pull at sea level is stronger than on a mountaintop. It only matters that the effect of gravity on both the unknown and known masses is the same.

Elements and Atoms

An **element** is the simplest type of matter with unique chemical properties. A list of the elements commonly found in the human body is given in table 2.1. About 96% of the weight of the body results from the elements oxygen, carbon, hydrogen, and nitrogen.

An **atom** (*atomos*, indivisible) is the smallest particle of an element that has the chemical characteristics of that element. An element is composed of atoms of only one kind. For example,

TABLE 2.1 Common Elements

Element	Symbol	Atomic Number	Mass Number	Atomic Mass	Percent in Human Body by Weight (%)	Percent in Human Body by Number of Atoms (%)
Hydrogen	H	1	1	1.008	9.5	63.0
Carbon	C	6	12	12.01	18.5	9.5
Nitrogen	N	7	14	14.01	3.3	1.4
Oxygen	O	8	16	16.00	65.0	25.5
Fluorine	F	9	19	19.00	Trace	Trace
Sodium	Na	11	23	22.99	0.2	0.3
Magnesium	Mg	12	24	24.31	0.1	0.1
Phosphorus	P	15	31	30.97	1.0	0.22
Sulfur	S	16	32	32.07	0.3	0.05
Chlorine	Cl	17	35	35.45	0.2	0.03
Potassium	K	19	39	39.10	0.4	0.06
Calcium	Ca	20	40	40.08	1.5	0.31
Chromium	Cr	24	52	52.00	Trace	Trace
Manganese	Mn	25	55	54.94	Trace	Trace
Iron	Fe	26	56	55.85	Trace	Trace
Cobalt	Co	27	59	58.93	Trace	Trace
Copper	Cu	29	63	63.55	Trace	Trace
Zinc	Zn	30	64	65.39	Trace	Trace
Selenium	Se	34	80	78.96	Trace	Trace
Molybdenum	Mo	42	98	95.94	Trace	Trace
Iodine	I	53	127	126.9	Trace	Trace

the element carbon is composed of only carbon atoms, and the element oxygen is composed of only oxygen atoms.

An element, or an atom of that element, often is represented by a symbol. Usually, the first letter or letters of the element's name are used—for example, C for carbon, H for hydrogen, Ca for calcium, and Cl for chlorine. Occasionally, the symbol is taken from the Latin, Greek, or Arabic name for the element—for example, Na from the Latin word *natrium* is the symbol for sodium.

Atomic Structure

The characteristics of matter result from the structure, organization, and behavior of atoms (figure 2.1). Atoms are composed of subatomic particles, some of which have an electric charge. The three major types of subatomic particles are neutrons, protons, and electrons. A **neutron** has no electric charge, a **proton** has one positive charge, and an **electron** has one negative charge. The positive charge of a proton is equal in magnitude to the negative charge of an electron. The number of protons and electrons in each atom is equal, and the individual charges cancel each other. Therefore, each atom is electrically neutral.

Protons and neutrons form the **nucleus** at the center of an atom, and electrons are moving around the nucleus (see figure 2.1). The nucleus accounts for 99.97% of an atom's mass but only 1 ten-trillionth of its volume. Most of the volume of an atom is occupied by the electrons. Although it is impossible to know precisely where any given electron is located at any particular moment, the region where it is most likely to be found can be represented by an **electron cloud**. The likelihood of locating an electron at a specific point in a region correlates with the darkness of that region in the diagram. The darker the color, the greater the likelihood of finding the electron there at any given moment.

Atomic Number and Mass Number

The **atomic number** of an element is equal to the number of protons in each atom, and, because the number of electrons and protons is equal, the atomic number is also the number of electrons. Each element is uniquely defined by the number of protons in the atoms of that element. For example, only hydrogen atoms have one proton, only carbon atoms have six protons, and

FIGURE 2.1 Model of an Atom

The tiny, dense nucleus consists of positively charged protons and uncharged neutrons. Most of the volume of an atom is occupied by rapidly moving, negatively charged electrons, which can be represented as an electron cloud. The probable location of an electron is indicated by the color of the electron cloud. The darker the color in each small part of the electron cloud, the more likely the electron is located there.

only oxygen atoms have eight protons (figure 2.2; see table 2.1). There are 90 naturally occurring elements, but additional elements have been synthesized by altering atomic nuclei. See the periodic table in appendix A for additional information about the elements.

Protons and neutrons have about the same mass, and they are responsible for most of the mass of atoms. Electrons, on the other hand, have very little mass. The **mass number** of an element is the

FIGURE 2.2 Hydrogen, Carbon, and Oxygen Atoms

Within the nucleus, the number of positively charged protons (p^+) and uncharged neutrons (n^0) is indicated. The negatively charged electrons (e^-) are around the nucleus. Atoms are electrically neutral because the number of protons and the number of electrons within an atom are equal.

FIGURE 2.3 Isotopes of Hydrogen

(a) Hydrogen has one proton and no neutrons in its nucleus. (b) Deuterium has one proton and one neutron in its nucleus. (c) Tritium has one proton and two neutrons in its nucleus.

number of protons plus the number of neutrons in each atom. For example, the mass number for carbon is 12 because it has six protons and six neutrons.

PREDICT 2

The atomic number of potassium is 19, and the mass number is 39. What is the number of protons, neutrons, and electrons in an atom of potassium?

Isotopes and Atomic Mass

Isotopes (i'sō-tōpz) are two or more forms of the same element that have the same number of protons and electrons but a different number of neutrons. Thus, isotopes have the *same* atomic number but *different* mass numbers. There are three isotopes of hydrogen: hydrogen, deuterium, and tritium. All three isotopes have one proton and one electron, but hydrogen has no neutrons in its nucleus, deuterium has one neutron, and tritium has two neutrons (figure 2.3). Isotopes can be denoted using the symbol of the element preceded by the mass number (number of protons and neutrons) of the isotope. Thus, hydrogen is ${}^1\text{H}$, deuterium is ${}^2\text{H}$, and tritium is ${}^3\text{H}$.

Individual atoms have very little mass. A hydrogen atom has a mass of 1.67×10^{-24} g (see appendix B for an explanation of the scientific notation of numbers). To avoid using such small numbers, a system of relative atomic mass is used. In this system, a **unified atomic mass unit (u)**, or **dalton (Da)**, is 1/12 the mass of ${}^{12}\text{C}$, a carbon atom with six protons and six neutrons. Thus, ${}^{12}\text{C}$ has an atomic mass of exactly 12 u. A naturally occurring sample of carbon, however, contains mostly ${}^{12}\text{C}$ but also a small quantity of other carbon isotopes, such as ${}^{13}\text{C}$, which has six protons and seven neutrons. The **atomic mass** of an element is the *average* mass of its naturally occurring isotopes, taking into account the relative abundance of each isotope. For example, the atomic mass of the element carbon is 12.01 u (see table 2.1), which is slightly more than 12 u because of the additional mass of the small amount of other carbon isotopes. Because the atomic mass is an average, a sample of carbon can be treated as if all the carbon atoms had an atomic mass of 12.01 u.

The Mole and Molar Mass

Avogadro's number is the number of atoms in exactly 12 g of ${}^{12}\text{C}$. This enormous number is 6.022×10^{23} . A **mole (mol)** of a substance

contains Avogadro's number of entities, such as atoms, ions, or molecules. The **molar mass** of a substance is the mass of one mole of the substance expressed in grams. Because 12 g of ${}^{12}\text{C}$ is used as the standard, the atomic mass of an entity expressed in unified atomic mass units is the same as the molar mass expressed in grams. Thus, carbon atoms have an atomic mass of 12.01 u, and 12.01 g of carbon have Avogadro's number (1 mol) of carbon atoms.

Just as a grocer sells eggs in lots of 12 (a dozen), a chemist groups atoms in lots of 6.022×10^{23} (Avogadro's number, 1 mol). The molar mass is used as a convenient way to determine the number of atoms in a sample of an element. For example, 1.008 g of hydrogen (1 mol) has the same number of atoms as 12.01 g of carbon (1 mol).

PREDICT 3

Are there more or fewer atoms in 12.01 g of carbon than in 12.01 g of magnesium? (*Hint:* Use table 2.1.)

- 1** Define matter. How is the mass and the weight of an object different?
- 2** Define element and atom. What four elements are found in the greatest abundance in humans?
- 3** For each subatomic particle of an atom, state its charge and location. Which subatomic particles are most responsible for the mass and volume of an atom? Which subatomic particles determine atomic number and mass number?
- 4** Define isotopes and give an example. Define atomic mass. Why is the atomic mass of most elements not exactly equal to the mass number?
- 5** What is Avogadro's number? Define a mole and molar mass.

Electrons and Chemical Bonding

The outermost electrons of an atom determine its chemical behavior. When these outermost electrons are transferred, or shared, between atoms, **chemical bonding** occurs. Two major types of chemical bonding are ionic and covalent bonding.

Ionic Bonding

An atom is electrically neutral because it has an equal number of protons and electrons. If an atom loses or gains electrons, the number of protons and electrons are no longer equal, and

**FIGURE 2.4 Ionic Bonding**

(a) A sodium atom loses an electron to become a smaller positively charged ion, and a chlorine atom gains an electron to become a larger negatively charged ion. The attraction between the oppositely charged ions results in ionic bonding and the formation of sodium chloride. (b) The sodium and chlorine ions are organized to form a cube-shaped array. (c) Microphotograph of salt crystals reflects the cubic arrangement of the ions.

a charged particle called an **ion** (i'on) is formed. After an atom loses an electron, it has one more proton than it has electrons and is positively charged. A sodium atom (Na) can lose an electron to become a positively charged sodium ion (Na^+) (figure 2.4a). After an atom gains an electron, it has one more electron than it has protons and is negatively charged. A chlorine atom (Cl) can accept an electron to become a negatively charged chloride ion (Cl^-).

Positively charged ions are called **cations** (kat'i-onz), and negatively charged ions are called **anions** (an'i-onz). Because oppositely charged ions are attracted to each other, cations and anions tend to remain close together, which is called **ionic** (i-on'ik) **bonding**. For example, Na^+ and Cl^- are held together by ionic bonding to form an array of ions called sodium chloride (NaCl), or table salt (see figure 2.4b and c). Some ions commonly found in the body are listed in table 2.2.

Covalent Bonding

Covalent bonding results when atoms share one or more pairs of electrons. The resulting combination of atoms is called a molecule. An example is the covalent bond between two hydrogen atoms

TABLE 2.2 Important Ions		
Common Ions	Symbols	Significance*
Calcium	Ca^{2+}	Part of bones and teeth, blood clotting, muscle contraction, release of neurotransmitters
Sodium	Na^+	Membrane potentials, water balance
Potassium	K^+	Membrane potentials
Hydrogen	H^+	Acid–base balance
Hydroxide	OH^-	Acid–base balance
Chloride	Cl^-	Water balance
Bicarbonate	HCO_3^-	Acid–base balance
Ammonium	NH_4^+	Acid–base balance
Phosphate	PO_4^{3-}	Part of bones and teeth, energy exchange, acid–base balance
Iron	Fe^{2+}	Red blood cell formation
Magnesium	Mg^{2+}	Necessary for enzymes
Iodide	I^-	Present in thyroid hormones

*The ions are part of the structures or play important roles in the processes listed.

There is no interaction between the two hydrogen atoms because they are too far apart.

The positively charged nucleus of each hydrogen atom begins to attract the electron of the other.

A covalent bond is formed when the electrons are shared between the nuclei because the electrons are equally attracted to each nucleus.

FIGURE 2.5 Covalent Bonding

to form a hydrogen molecule (figure 2.5). Each hydrogen atom has one electron. As the two hydrogen atoms get closer together, the positively charged nucleus of each atom begins to attract the electron of the other atom. At an optimal distance, the two nuclei mutually attract the two electrons, and each electron is shared by both nuclei. The two hydrogen atoms are now held together by a covalent bond.

When an electron pair is shared between two atoms, a **single covalent bond** results. A single covalent bond is represented by a single line between the symbols of the atoms involved (e.g., $\text{H}-\text{H}$). A **double covalent bond** results when two atoms share four electrons, two from each atom. When a carbon atom combines with two oxygen atoms to form carbon dioxide, two double covalent bonds are formed. Double covalent bonds are indicated by a double line between the atoms ($\text{O}=\text{C}=\text{O}$).

When electrons are shared equally between atoms, as in a hydrogen molecule, the bonds are called **nonpolar covalent bonds**. Atoms bound to one another by a covalent bond do not always share their electrons equally, however, because the nucleus of one atom attracts the electrons more strongly than does the nucleus of the other atom. Bonds of this type are called **polar covalent bonds** and are common in both living and nonliving matter.

Polar covalent bonds can result in polar molecules, which are electrically asymmetric. For example, oxygen atoms attract electrons more strongly than do hydrogen atoms. When covalent bonding

between an oxygen atom and two hydrogen atoms forms a water molecule, the electrons are located in the vicinity of the oxygen nucleus more than in the vicinity of the hydrogen nuclei. Because electrons have a negative charge, the oxygen side of the molecule is slightly more negative than the hydrogen side (figure 2.6).

Molecules and Compounds

A **molecule** is formed when two or more atoms chemically combine to form a structure that behaves as an independent unit. The atoms that combine to form a molecule can be of the same type, such as two hydrogen atoms combining to form a hydrogen molecule. More typically, a molecule consists of two or more different types of atoms, such as two hydrogen atoms and an oxygen atom forming water. Thus, a glass of water consists of a collection of individual water molecules positioned next to one another.

A **compound** is a substance composed of two or more *different* types of atoms that are chemically combined. Not all molecules are compounds. For example, a hydrogen molecule is not a compound because it does not consist of different types of atoms. Some compounds are molecules and some are not. Covalent compounds,

FIGURE 2.6 Polar Covalent Bonds

(a) A water molecule forms when two hydrogen atoms form covalent bonds with an oxygen atom. (b) Electron pairs (indicated by dots) are shared between the hydrogen atoms and oxygen. The dashed outline shows the expected location of the electron cloud if the electrons are shared equally. The electrons are shared unequally, as shown by the electron cloud (yellow) not coinciding with the dashed outline. Consequently, the oxygen side of the molecule has a slight negative charge (indicated by δ^-) and the hydrogen side of the molecule has a slight positive charge (indicated by δ^+).

CLINICAL FOCUS

Radioactive Isotopes and X-Rays

Protons, neutrons, and electrons are responsible for the chemical properties of atoms. They also have other properties that can be useful in a clinical setting. For example, they have been used to develop methods for examining the inside of the body. **Radioactive isotopes** are commonly used by clinicians and researchers because sensitive measuring devices can detect their radioactivity, even when they are present in very small amounts.

Radioactive isotopes have unstable nuclei that spontaneously change to form more stable nuclei. As a result, either new isotopes or new elements are produced. In this process of nuclear change, alpha particles, beta particles, and gamma rays are emitted from the nuclei of radioactive isotopes. Alpha (α) particles are positively charged helium ions (He^{2+}), which consist of two protons and two neutrons. Beta (β) particles are electrons formed as neutrons change into protons. An electron is ejected from the neutron, and the proton that is produced remains in the nucleus. Gamma (γ) rays are a form of electromagnetic radiation (high-energy photons) released from nuclei as they lose energy.

All isotopes of an element have the same atomic number, and their chemical behavior is very similar. For example, ^3H (tritium) can substitute for ^1H (hydrogen), and either ^{125}I iodine or ^{131}I iodine can substitute for ^{126}I iodine in chemical reactions.

Several procedures that are used to determine the concentration of substances such as hormones depend on the incorporation of small amounts of radioactive isotopes, such as ^{125}I iodine, into the substances being measured. Clinicians using these procedures can more accurately diagnose disorders of the thyroid gland, the adrenal gland, and the reproductive organs.

Radioactive isotopes are also used to treat cancer. Some of the particles released from isotopes have a very high energy content and can penetrate and destroy tissues. Thus, radioactive isotopes can be used to destroy tumors because rapidly growing tissues, such as tumors, are more sensitive to radiation than are healthy cells. Radiation can also be used to sterilize materials that cannot be exposed to high temperatures (e.g., some fabric and plastic items used during surgical procedures). In addition, radioactive emissions can be used to sterilize food and other items.

X-rays are electromagnetic radiations with a much shorter wavelength than visible light. When electric current is used to heat a filament to very high temperatures, energy of the electrons becomes so great that some electrons are emitted from the hot filament. When these electrons strike a positive electrode at high speeds, they release some of their energy in the form of x-rays.

X-rays do not penetrate dense material as readily as they penetrate less dense material, and x-rays can expose photographic film. Consequently, an x-ray beam can pass through a person and onto photographic film. Dense tissues of the body absorb the x-rays, and in these areas the film is underexposed and so appears white or light in color on the developed film. On the other hand, the x-rays readily pass through less dense tissue, and the film in these areas is overexposed and appears black or dark in color. In an x-ray film of the skeletal system, the dense bones are white, and the less dense soft tissues are dark, often so dark that no details can be seen. Because the dense bone material is clearly visible, x-rays can be used to determine whether bones are broken or have other abnormalities.

Soft tissues can be photographed by using low-energy x-rays. Mammograms are low-energy x-rays of the breast that can be used to detect tumors because tumors are slightly denser than normal tissue.

Radiopaque substances are dense materials that absorb x-rays. If a radiopaque liquid is given to a patient, the liquid assumes the shape of the organ into which it is placed. For example, if a barium solution is swallowed, the outline of the upper digestive tract can be photographed using x-rays to detect such abnormalities as ulcers.

in which different types of atoms are held together by covalent bonds, are molecules because the sharing of electrons results in the formation of distinct, independent units. Water is an example of a substance that is a compound and a molecule.

On the other hand, ionic compounds are not molecules because the ions are held together by the force of attraction between opposite charges. A piece of NaCl does not consist of NaCl molecules positioned next to each other. Instead, table salt is an organized array of Na^+ and Cl^- in which each charged ion is surrounded by several ions of the opposite charge (see figure 2.4b). Sodium chloride is an example of a substance that is a compound but is not a molecule.

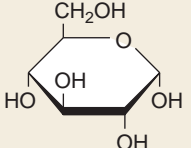

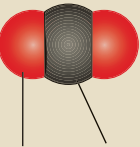

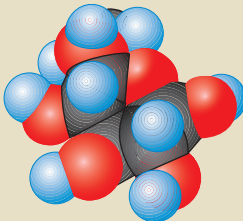

The kinds and numbers of atoms (or ions) in a molecule or compound can be represented by a formula consisting of the symbols of the atoms (or ions) plus subscripts denoting the number of each type of atom (or ion). The formula for glucose (a sugar) is

$\text{C}_6\text{H}_{12}\text{O}_6$, indicating that glucose has 6 carbon, 12 hydrogen, and 6 oxygen atoms (table 2.3).

The **molecular mass** of a molecule or compound can be determined by adding up the atomic masses of its atoms (or ions). The term *molecular mass* is used for convenience for ionic compounds, even though they are not molecules. For example, the atomic mass of sodium is 22.99 and chloride is 35.45. The molecular mass of NaCl is therefore 58.44 ($22.99 + 35.45$).

- 6 Describe how ionic bonding occurs. What is a cation and an anion?
- 7 Describe how covalent bonding occurs. What is the difference between polar and nonpolar covalent bonds?
- 8 Distinguish between a molecule and a compound. Are all molecules compounds? Are all compounds molecules?
- 9 Define molecular mass.

PREDICT 4

What is the molecular mass of a molecule of glucose? (Use table 2.1.)

Intermolecular Forces

Intermolecular forces result from the weak electrostatic attractions between the oppositely charged parts of molecules, or between ions and molecules. Intermolecular forces are much weaker than the forces producing chemical bonding.

Hydrogen Bonds

Molecules with polar covalent bonds have positive and negative “ends.” Intermolecular force results from the attraction of the positive end of one polar molecule to the negative end of another polar molecule. When hydrogen forms a covalent bond with oxygen, nitrogen, or fluorine, the resulting molecule becomes very polarized. If the positively charged hydrogen of one molecule is attracted to the negatively charged oxygen, nitrogen, or fluorine of another molecule, a **hydrogen bond** is formed. For example, the positively charged hydrogen atoms of a water molecule form hydrogen bonds with the negatively charged oxygen atoms of other water molecules (figure 2.7).

Hydrogen bonds play an important role in determining the shape of complex molecules because the hydrogen bonds between different polar parts of the molecule hold the molecule in its normal three-dimensional shape (see “Proteins,” p. 44; and “Nucleic Acids: DNA and RNA,” p. 47).

FIGURE 2.7 Hydrogen Bonds

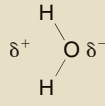

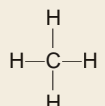

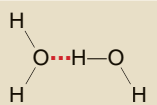

The positive hydrogen part of one water molecule forms a hydrogen bond (red dotted line) with the negative oxygen part of another water molecule. As a result, hydrogen bonds hold the water molecules together.

Table 2.4 summarizes the important characteristics of chemical bonding (ionic and covalent) and intermolecular forces (hydrogen bonds).

Solubility and Dissociation

Solubility is the ability of one substance to dissolve in another—for example, when sugar dissolves in water. Charged substances, such as sodium chloride, and polar substances, such as glucose, dissolve in water readily, whereas nonpolar substances, such as oils, do not. We all have seen how oil floats on water. Substances dissolve in water when they become surrounded by water molecules. If the positive and negative ends of the water molecules are attracted more to the charged ends of other molecules than they are to each other, the hydrogen bonds between the ends of the water molecules are broken, and the water molecules surround the other molecules, which become dissolved in the water.

When ionic compounds dissolve in water, their ions **dissociate**, or separate, from one another because the cations are attracted to the negative ends of the water molecules, and the anions are attracted to the positive ends of the water molecules. When sodium chloride dissociates in water, the sodium and chloride ions separate, and water molecules surround and isolate the ions, thereby keeping them in solution (figure 2.8).

TABLE 2.4 Comparison of Bonds	
Bond	Example
Ionic Bond A complete transfer of electrons between two atoms results in separate positively charged and negatively charged ions.	Na^+Cl^- Sodium chloride
Polar Covalent Bond An unequal sharing of electrons between two atoms results in a slight positive charge (δ^+) on one side of the molecule and slight negative charge (δ^-) on the other side of the molecule.	 Water
Nonpolar Covalent Bond An equal sharing of electrons between two atoms results in an even charge distribution among the atoms of the molecule.	 Methane
Hydrogen Bond The attraction of oppositely charged ends of one polar molecule to another polar molecule holds molecules or parts of molecules together.	 Water molecules

FIGURE 2.8 Dissociation

Sodium chloride (table salt) dissociating in water. The positively charged Na^+ are attracted to the negatively charged oxygen (red) end of the water molecule, and the negatively charged Cl^- are attracted to the positively charged hydrogen (blue) end of the water molecule.

When molecules (covalent compounds) dissolve in water, they usually remain intact, even though they are surrounded by water molecules. Thus, in a glucose solution, glucose molecules are surrounded by water molecules.

Cations and anions that dissociate in water are sometimes called **electrolytes** (ē-lek'trō-lītz) because they have the capacity to conduct an electric current, which is the flow of charged particles. An electrocardiogram (ECG) is a recording of electric currents produced by the heart. These currents can be detected by electrodes on the surface of the body because the ions in the body fluids conduct electric currents. Molecules that do not dissociate form solutions that do not conduct electricity and are called **nonelectrolytes**. Pure water is a nonelectrolyte.

- 10** Define hydrogen bond, and explain how hydrogen bonds hold polar molecules, such as water, together. How do hydrogen bonds affect the shape of a molecule?
- 11** Define solubility. How do ionic and covalent compounds typically dissolve in water?
- 12** Distinguish between electrolytes and nonelectrolytes.

CHEMICAL REACTIONS AND ENERGY

In a **chemical reaction**, atoms, ions, molecules, or compounds interact either to form or to break chemical bonds. The substances that enter into a chemical reaction are called **reactants**, and the substances that result from the chemical reaction are called **products**.

For our purposes, three important points can be made about chemical reactions. First, in some reactions, less complex reactants are combined to form a larger, more complex product. An example is the synthesis of the complex molecules of the human body from basic “building blocks” obtained from food (figure 2.9a). Second, in other reactions, a reactant can be broken down, or decomposed, into simpler, less complex products. An example is the breakdown of food molecules into basic building blocks (figure 2.9b). Third, atoms are generally associated with other atoms through chemical bonding or intermolecular forces; therefore, to synthesize new products or break down reactants, it is necessary to change the relationship between atoms.

Synthesis Reactions

When two or more reactants chemically combine to form a new and larger product, the process is called a **synthesis reaction**. An example of a synthesis reaction is the combination of two amino acids to form a dipeptide (figure 2.10a). In this synthesis reaction, water is formed as the amino acids are bound together. Synthesis reactions in which water is a product are called **dehydration reactions**. Old chemical bonds are broken and new chemical bonds are formed as the atoms rearrange as a result of a synthesis reaction.

Another example of a synthesis reaction in the body is the formation of adenosine triphosphate (ATP). In ATP, *A* stands for adenosine; *T* stands for tri-, or three; and *P* stands for phosphate group (PO_4^{3-}). Thus, ATP consists of adenosine and three phos-

FIGURE 2.9 Synthesis and Decomposition Reactions

(a) Synthesis reaction in which amino acids, the basic “building blocks” of proteins, combine to form a protein molecule. (b) Decomposition reaction in which a complex carbohydrate breaks down into smaller glucose molecules, which are the “building blocks” of carbohydrates.

phate groups (see p. 50 for the details of the structure of ATP). ATP is synthesized from adenosine diphosphate (ADP), which has two phosphate groups, and an inorganic phosphate (H_2PO_4^-), which is often symbolized as P_i .

Synthesis reactions produce the molecules characteristic of life, such as ATP, proteins, carbohydrates, lipids, and nucleic acids. All of the synthesis reactions that occur within the body are referred to collectively as **anabolism** (ā-nab'ō-lizm). The growth, maintenance, and repair of the body could not take place without anabolic reactions.

Decomposition Reactions

A **decomposition reaction** is the reverse of a synthesis reaction—a larger reactant is chemically broken down into two or more smaller products. The breakdown of a disaccharide (a type of carbohydrate) into glucose molecules (figure 2.10b) is an example. Note that this reaction requires that water be split into two parts and that each part be contributed to one of the new glucose molecules. Reactions that use water in this manner are called **hydrolysis** (hī-drol'i-sis; water dissolution) **reactions**.

The breakdown of ATP to ADP and an inorganic phosphate is another example of a decomposition reaction.

FIGURE 2.10 Synthesis (Dehydration) and Decomposition (Hydrolysis) Reactions

(a) Synthesis reaction in which two amino acids combine to form a dipeptide. This reaction is also a dehydration reaction because it results in the removal of a water molecule from the amino acids. (b) Decomposition reaction in which a disaccharide breaks apart to form glucose molecules. This reaction is also a hydrolysis reaction because it involves the splitting of a water molecule.

The decomposition reactions that occur in the body are collectively called **catabolism** (kă-tab'-ō-lizm). They include the digestion of food molecules in the intestine and within cells, the breakdown of fat stores, and the breakdown of foreign matter and microorganisms in certain blood cells that function to protect the body. All of the anabolic and catabolic reactions in the body are collectively defined as **metabolism**.

Reversible Reactions

A **reversible reaction** is a chemical reaction in which the reaction can proceed from reactants to products or from products to reactants. When the rate of product formation is equal to the rate of the reverse reaction, the reaction system is said to be at **equilibrium**. At equilibrium, the amount of reactants relative to the amount of products remains constant.

The following analogy may help clarify the concept of reversible reactions and equilibrium. Imagine a trough containing water. The trough is divided into two compartments by a partition, but the partition contains holes that allow water to move freely between the compartments. Because water can move in either direction, this is like a reversible reaction. Let the water in the left compartment be the reactant and the water in the right compartment be the product. At equilibrium, the amount of reactant relative to the amount of product in each compartment is always the same because the partition allows water to pass between the two compartments until the level of water is the same in both compartments. If additional water is added to the reactant compartment, water flows from it through the partition to the product compart-

ment until the level of water is the same in both compartments. Likewise, if additional reactants are added to a reaction system, some will form product until equilibrium is reestablished. Unlike this analogy, however, the amount of the reactants compared with the amount of products of most reversible reactions is not one to one. Depending on the specific reversible reaction, one part reactant to two parts product, two parts reactant to one part product, or many other possibilities can occur.

An important reversible reaction in the human body involves carbon dioxide and hydrogen ions. The reaction between carbon dioxide (CO_2) and water (H_2O) to form carbonic acid (H_2CO_3) is reversible. Carbonic acid then separates by a reversible reaction to form hydrogen ions (H^+) and bicarbonate ions (HCO_3^-).

If CO_2 is added to H_2O , additional H_2CO_3 forms, which in turn causes more H^+ and HCO_3^- to form. The amount of H^+ and HCO_3^- relative to CO_2 therefore remains constant. Maintaining a constant level of H^+ is necessary for proper functioning of the nervous system. This can be achieved, in part, by regulating blood CO_2 levels. For example, slowing down the respiration rate causes blood carbon dioxide levels to increase.

PREDICT 5

If the respiration rate increases, CO_2 is eliminated from the blood. What effect does this change have on blood H^+ ion levels?

Oxidation–Reduction Reactions

Chemical reactions that result from the exchange of electrons between the reactants are called oxidation–reduction reactions. When sodium and chlorine react to form sodium chloride, the sodium atom loses an electron, and the chlorine atom gains an electron. The loss of an electron by an atom is called **oxidation**, and the gain of an electron is called **reduction**. The transfer of the electron can be complete, resulting in an ionic bond, or it can be a partial transfer, resulting in a covalent bond. Because the complete or partial loss of an electron by one atom is accompanied by the gain of that electron by another atom, these reactions are called **oxidation–reduction reactions**. Synthesis and decomposition reactions can be oxidation–reduction reactions. Thus, a chemical reaction can be described in more than one way.

- 13** Define a chemical reaction and compare synthesis and decomposition reactions. How do anabolism, catabolism, and metabolism relate to synthesis and decomposition reactions?
- 14** Describe a dehydration and a hydrolysis reaction.
- 15** Describe reversible reactions. What is meant by the equilibrium condition in reversible reactions?
- 16** What is an oxidation–reduction reaction?

PREDICT 6

When hydrogen gas combines with oxygen gas to form water, is the hydrogen reduced or oxidized? Explain.

Energy

Energy, unlike matter, does not occupy space and has no mass. **Energy** is the capacity to do **work**—that is, to move matter. Energy can be subdivided into potential energy and kinetic energy. **Potential energy** is stored energy that could do work but is not doing so. **Kinetic** (ki-net'ik) **energy** is the form of energy that actually does work and moves matter. A ball held at arm's length above the floor has potential energy. No energy is expended as long as the ball does not move. If the ball is released and falls toward the floor, however, it has kinetic energy.

According to the conservation of energy principle, the total energy of the universe is constant. Therefore, energy is neither created nor destroyed. Potential energy, however, can be converted into kinetic energy, and kinetic energy can be converted into potential energy. For example, the potential energy in the ball is converted into kinetic energy as the ball falls toward the floor. Conversely, the kinetic energy required to raise the ball from the floor is converted into potential energy.

Potential and kinetic energy can be found in many different forms. **Mechanical energy** is energy resulting from the position or movement of objects. Many of the activities of the human body, such as moving a limb, breathing, and circulating blood, involve mechanical energy. Other forms of energy are chemical energy, heat energy, electric energy, and electromagnetic (radiant) energy.

Chemical Energy

The **chemical energy** of a substance is a form of stored (potential) energy within its chemical bonds. In any chemical reaction, the

potential energy contained in the chemical bonds of the reactants can be compared with the potential energy in the chemical bonds of the products. If the potential energy in the chemical bonds of the reactants is less than that of the products, then energy must be supplied for the reaction to occur. An example is the synthesis of ATP from ADP.

For simplicity, the H_2O is often not shown in this reaction, and P_i is used to represent inorganic phosphate (H_2PO_4^-). For this reaction to occur, bonds in H_2PO_4^- are broken and bonds are formed in ATP and H_2O . As a result of the breaking of existing bonds, the formation of new bonds, and the input of energy, these products have more potential energy than the reactants (figure 2.11a).

If the potential energy in the chemical bonds of the reactants is greater than that of the products, energy is released by the reaction. For example, the chemical bonds of food molecules contain more potential energy than the waste products that are produced when food molecules are decomposed. The energy released from the chemical bonds of food molecules is used by living systems to synthesize ATP. Once ATP is produced, the breakdown of ATP to ADP results in the release of energy.

For this reaction to occur, the bonds in ATP and H_2O are broken and bonds in H_2PO_4^- are formed. As a result of breaking the existing bonds and forming new bonds, these products have less potential energy than the reactants, and energy is released (figure 2.11b). Note that the energy released does not come from breaking the phosphate bond of ATP because breaking a chemical bond requires the input of energy. It is commonly stated, however, that the breakdown of ATP results in the release of energy, which is true when the overall reaction is considered. The energy released when ATP is broken down can be used to synthesize other molecules; to do work, such as muscle contraction; or to produce heat.

Heat Energy

Heat energy is the energy that flows between objects that are at different temperatures. Temperature is a measure of how hot or cold a substance is relative to another substance. Heat is always transferred from a hotter object to a cooler object, such as from a hot stove top to a finger.

All other forms of energy can be converted into heat energy. For example, when a moving object comes to rest, its kinetic energy is converted into heat energy by friction. Some of the potential energy of chemical bonds is released as heat energy during chemical reactions. Human body temperature is maintained by heat produced as a by-product of chemical reactions.

- 17** How is energy different from matter? How are potential and kinetic energy different from each other?

FIGURE 2.11 Energy and Chemical Reactions

In each figure, the upper shelf represents a higher energy level, and the lower shelf represents a lower energy level. (a) Reaction in which the input of energy is required for the synthesis of ATP. (b) Reaction in which energy is released as a result of the breakdown of ATP.

18 Define mechanical energy, chemical energy, and heat energy. How is chemical energy converted to mechanical energy and heat energy in the body?

19 Use ATP and ADP to illustrate the release or input of energy in chemical reactions.

PREDICT 7

Energy from the breakdown of ATP provides the kinetic energy for muscle movement. Why does body temperature increase during exercise?

Speed of Chemical Reactions

Molecules are constantly in motion and therefore have kinetic energy. A chemical reaction occurs only when molecules with sufficient kinetic energy collide with each other. As two molecules move closer together, the negatively charged electron cloud of one molecule repels the negatively charged electron cloud of the other molecule. If the molecules have sufficient kinetic energy, they overcome this repulsion and come together. The nuclei in some atoms attract the electrons of other atoms, resulting in the breaking and formation of new chemical bonds. The **activation energy** is the minimum energy that the reactants must have to start a chemical reaction (figure 2.12a). Even reactions that result in a release of energy must overcome the activation energy barrier for the reaction to proceed. For example, heat in the form of a spark is required to start the reaction between oxygen and gasoline vapor.

Once some oxygen molecules react with gasoline, the energy released can start additional reactions.

Given any population of molecules, some of them have more kinetic energy and move about faster than others. Even so, at normal body temperatures, most of the chemical reactions necessary for life proceed too slowly to support life because few molecules have enough energy to start a chemical reaction. **Catalysts** (kat'ă-listz) are substances that increase the rate of chemical reactions without being permanently changed or depleted. **Enzymes** (en'zīms), which are discussed in greater detail on p. 47, are protein catalysts. Enzymes increase the rate of chemical reactions by lowering the activation energy necessary for the reaction to begin (figure 2.12b). As a result, more molecules have sufficient energy to undergo chemical reactions. With an enzyme, the rate of a chemical reaction can take place more than a million times faster than without the enzyme.

Temperature can also affect the speed of chemical reactions. As temperature increases, reactants have more kinetic energy, move at faster speeds, and collide with one another more frequently and with greater force, thereby increasing the likelihood of a chemical reaction. When a person has a fever of only a few degrees, reactions occur throughout the body at an accelerated rate, resulting in increased activity in the organ systems, such as increased heart and respiratory rates. When body temperature drops, various metabolic processes slow. In cold weather, the fingers are less agile largely because of the reduced rate of chemical reactions in cold muscle tissue.

FIGURE 2.12 Activation Energy and Enzymes

(a) Activation energy is needed to change ATP to ADP. The upper shelf represents a higher energy level, and the lower shelf represents a lower energy level. The “wall” extending above the upper shelf represents the activation energy. Even though energy is given up moving from the upper to the lower shelf, the activation energy “wall” must be overcome before the reaction can proceed. (b) The enzyme lowers the activation energy, making it easier for the reaction to proceed.

Within limits, the greater the concentration of the reactants, the greater the rate at which a given chemical reaction proceeds. This occurs because, as the concentration of reactants increases, they are more likely to come into contact with one another. For example, the normal concentration of oxygen inside cells enables oxygen to come into contact with other molecules and produce the chemical reactions necessary for life. If the oxygen concentration decreases, the rate of chemical reactions decreases. A decrease in oxygen in cells can impair cell function and even result in death.

20 Define activation energy, catalysts, and enzymes. How do enzymes increase the rate of chemical reactions?

21 What effect does increasing temperature or increasing concentration of the reactants have on the rate of a chemical reaction?

INORGANIC CHEMISTRY

It was once believed that inorganic substances were those that came from nonliving sources and organic substances were those extracted from living organisms. As the science of chemistry developed, however, it became apparent that organic substances can be manufactured in the laboratory. As defined currently,

inorganic chemistry generally deals with those substances that do not contain carbon, whereas **organic chemistry** is the study of carbon-containing substances. These definitions have a few exceptions. For example, carbon monoxide (CO), carbon dioxide (CO_2), and bicarbonate ion (HCO_3^-) are classified as inorganic molecules.

Water

A molecule of **water** is composed of one atom of oxygen joined to two atoms of hydrogen by covalent bonds. Water molecules are polar, with a partial positive charge associated with the hydrogen atoms and a partial negative charge associated with the oxygen atom. Hydrogen bonds form between the positively charged hydrogen atoms of one water molecule and the negatively charged oxygen atoms of another water molecule. These hydrogen bonds organize the water molecules into a lattice, which holds the water molecules together (see figures 2.6 and 2.7).

Water accounts for approximately 50% of the weight of a young adult female and 60% of a young adult male. Females have a lower percentage of water than males because they typically have more body fat, which is relatively free of water. Plasma, the liquid portion of blood, is 92% water. Water has physical and chemical properties well suited for its many functions in living organisms. These properties are outlined in the following sections.

Stabilizing Body Temperature

Water has a high **specific heat**, meaning that a relatively large amount of heat is required to raise its temperature; therefore, it tends to resist large temperature fluctuations. When water evaporates, it changes from a liquid to a gas, and, because heat is required for that process, the evaporation of water from the surface of the body rids the body of excess heat.

Protection

Water is an effective lubricant that provides protection against damage resulting from friction. For example, tears protect the surface of the eye from the rubbing of the eyelids. Water also forms a fluid cushion around organs that helps protect them from trauma. The cerebrospinal fluid that surrounds the brain is an example.

Chemical Reactions

Many of the chemical reactions necessary for life do not take place unless the reacting molecules are dissolved in water. For example, sodium chloride must dissociate in water into Na^+ and Cl^- before they can react with other ions. Water also directly participates in many chemical reactions. As previously mentioned, a dehydration reaction is a synthesis reaction in which water is produced, and a hydrolysis reaction is a decomposition reaction that requires a water molecule (see figure 2.10).

Mixing Medium

A **mixture** is a combination of two or more substances physically blended together, but not chemically combined. A **solution** is any mixture of liquids, gases, or solids in which the substances are uniformly distributed with no clear boundary between the substances. For example, a salt solution consists of salt dissolved in water, air is a solution containing a variety of gases, and wax is a solid solution of several fatty substances. Solutions are often described in terms of one substance dissolving in another: The **solute** (sol'üt) dissolves in the **solvent**. In a salt solution, water is the solvent and the dissolved salt is the solute. Sweat is a salt solution in which sodium chloride and other solutes are dissolved in water.

A **suspension** is a mixture containing materials that separate from each other unless they are continually, physically blended together. Blood is a suspension; red blood cells are suspended in a liquid called plasma. As long as the red blood cells and plasma are mixed together as they pass through blood vessels, the red blood cells remain suspended in the plasma. If the blood is allowed to sit in a container, however, the red blood cells and plasma separate from each other.

A **colloid** (kol'oyd) is a mixture in which a dispersed (solute-like) substance is distributed throughout a dispersing (solventlike) substance. The dispersed particles are larger than a simple molecule but small enough that they remain dispersed and do not settle out. Proteins, which are large molecules, and water form colloids. For instance, the plasma portion of blood and the liquid interior of cells are colloids containing many important proteins.

In living organisms, the complex fluids inside and outside cells consist of solutions, suspensions, and colloids. Blood is an example of all of these mixtures. It is a solution containing dis-

solved nutrients, such as sugar; a suspension holding red blood cells; and a colloid containing proteins.

Water's ability to mix with other substances enables it to act as a medium for transport, moving substances from one part of the body to another. Body fluids, such as plasma, transport nutrients, gases, waste products, and a variety of molecules involved in regulating body functions.

Solution Concentrations

The concentration of solute particles dissolved in solvents can be expressed in several ways. One common way is to indicate the percent of solute by weight per volume of solution. A 10% solution of sodium chloride can be made by dissolving 10 g of sodium chloride into enough water to make 100 mL of solution.

Physiologists often determine concentrations in **osmoles** (os'mölz), which express the number of particles in a solution. A particle can be an atom, an ion, or a molecule. An osmole (Osm) is Avogadro's number of particles of a substance in 1 kilogram (kg) of water. The **osmolality** (os-mō-lal'i-tē) of a solution is a reflection of the number, not the type, of particles in a solution. For example, a 1 Osm glucose solution and a 1 Osm NaCl solution both contain Avogadro's number of particles per kg water. The glucose solution has 1.0 Osm of glucose molecules, whereas the NaCl solution has 0.5 Osm of Na^+ and 0.5 Osm of Cl^- because NaCl dissociates into Na^+ and Cl^- in water.

Because the concentration of particles in body fluids is so low, the measurement **milliosmole** (mOsm), 1/1000 of an osmole, is used. Most body fluids have a concentration of about 300 mOsm and contain many different ions and molecules. The concentration of body fluids is important because it influences the movement of water into or out of cells (see chapter 3). Appendix C contains more information on calculating concentrations.

- 22 Define inorganic and organic chemistry.
- 23 List four functions that water performs in living organisms and give an example of each.
- 24 Describe solutions, suspensions, and colloids, and give an example of each. Define solvent and solute.
- 25 How is the osmolality of a solution determined? What is a milliosmole?

Acids and Bases

Many molecules and compounds are classified as acids or bases. For most purposes, an **acid** is defined as a proton donor. A hydrogen ion (H^+) is a proton because it results from the loss of an electron from a hydrogen atom, which consists of a proton and an electron. Therefore, a molecule or compound that releases H^+ is an acid. Hydrochloric acid (HCl) forms hydrogen ions (H^+) and chloride ions (Cl^-) in solution and therefore is an acid.

A **base** is defined as a proton acceptor, and any substance that binds to (accepts) H^+ ions is a base. Many bases function as proton acceptors by releasing hydroxide ions (OH^-) when they

dissociate. The base sodium hydroxide (NaOH) dissociates to form Na^+ and OH^- .

The OH^- are proton acceptors that combine with H^+ to form water.

Acids and bases are classified as strong or weak. Strong acids or bases dissociate almost completely when dissolved in water. Consequently, they release almost all of their H^+ or OH^- . The more completely the acid or base dissociates, the stronger it is. For example, HCl is a strong acid because it completely dissociates in water.

Weak acids or bases only partially dissociate in water. Consequently, they release only some of their H^+ or OH^- . For example, when acetic acid (CH_3COOH) is dissolved in water, some of it dissociates, but some of it remains in the undissociated form. An equilibrium is established between the ions and the undissociated weak acid.

For a given weak acid or base, the amount of the dissociated ions relative to the weak acid or base is a constant.

The pH Scale

The **pH scale** is a means of referring to the H^+ concentration in a solution (figure 2.13). Pure water is defined as a **neutral solution** and has a pH of 7. A neutral solution has equal concentrations of H^+ and OH^- . Solutions with a pH less than 7 are **acidic** and have a greater concentration of H^+ than OH^- . **Alkaline** (al'kālīn), or **basic**, solutions have a pH greater than 7 and have fewer H^+ than OH^- .

A change in the pH of a solution by 1 pH unit represents a 10-fold change in the H^+ concentration. For example, a solution of pH 6 has a H^+ concentration 10 times greater than a solution of pH 7 and 100 times greater than a solution of pH 8. As the pH value becomes smaller, the solution has more H^+ and is more acidic; as the pH value becomes larger, the solution has fewer H^+ and is more basic. Appendix D considers pH in greater detail.

Acidosis and Alkalosis

The normal pH range for human blood is 7.35 to 7.45. **Acidosis** results if blood pH drops below 7.35, in which case the nervous system becomes depressed and the individual can become disoriented and possibly comatose. **Alkalosis** results if blood pH rises above 7.45. Then the nervous system becomes overexcitable, and the individual can be extremely nervous or have convulsions. Both acidosis and alkalosis can be fatal.

FIGURE 2.13 The pH Scale

A pH of 7 is considered neutral. Values less than 7 are acidic (the lower the number, the more acidic). Values greater than 7 are basic (the higher the number, the more basic). Representative fluids and their approximate pH values are listed.

Salts

A **salt** is a compound consisting of a cation other than a H^+ and an anion other than a OH^- . Salts are formed by the interaction of an acid and a base in which the H^+ of the acid are replaced by the positive ions of the base. For example, in a solution when hydrochloric acid (HCl) reacts with the base sodium hydroxide (NaOH), the salt sodium chloride (NaCl) is formed.

Typically, when salts such as sodium chloride dissociate in water, they form positively and negatively charged ions (see figure 2.8).

Buffers

The chemical behavior of many molecules changes as the pH of the solution in which they are dissolved changes. For example, many enzymes work best within narrow ranges of pH. The survival of an

organism depends on its ability to regulate body fluid pH within a narrow range. Deviations from the normal pH range for human blood are life-threatening.

One way body fluid pH is regulated involves the action of buffers, which resist changes in solution pH when either acids or bases are added. A **buffer** is a solution of a conjugate acid–base pair in which the acid component and the base component occur in similar concentrations. A conjugate base is everything that remains of an acid after the H^+ (proton) is lost. A conjugate acid is formed when an H^+ is transferred to the conjugate base. Two substances related in this way are a **conjugate acid–base pair**. For example, carbonic acid (H_2CO_3) and bicarbonate ion (HCO_3^-), formed by the dissociation of H_2CO_3 , are a conjugate acid–base pair.

In the forward reaction, H_2CO_3 loses a H^+ to produce HCO_3^- , which is a conjugate base. In the reverse reaction, a H^+ is transferred to the HCO_3^- (conjugate base) to produce H_2CO_3 , which is a conjugate acid.

For a given condition, this reversible reaction results in an equilibrium, in which the amounts of H_2CO_3 relative to the amounts of H^+ and HCO_3^- remain constant. The conjugate acid–base pair can resist changes in pH because of this equilibrium. If an acid is added to a buffer, the H^+ from the added acid can combine with the base component of the conjugate acid–base pair. As a result, the concentration of H^+ does not increase as much as it would without this reaction. If H^+ are added to a H_2CO_3 solution, many of the H^+ combine with HCO_3^- to form H_2CO_3 .

On the other hand, if a base is added to a buffered solution, the conjugate acid can release H^+ to counteract the effects of the added base. For example, if OH^- are added to a H_2CO_3 solution, the OH^- combine with H^+ to form water. As the H^+ are incorporated into water, H_2CO_3 dissociates to form H^+ and HCO_3^- , thereby maintaining the H^+ concentration (pH) within a normal range.

The greater the buffer concentration, the more effective it is in resisting a change in pH, but buffers cannot entirely prevent some change in the pH of a solution. For example, when an acid is added to a buffered solution, the pH decreases, but not to the extent it would have without the buffer. Important buffers found in living systems have bicarbonate, phosphates, amino acids, and proteins as components.

26 Define acid and base, and describe the pH scale. What is the difference between a strong acid or base and a weak acid or base?

27 Define acidosis and alkalosis, and describe the symptoms of each.

28 What is a salt? What is a buffer, and why are buffers important to organisms?

PREDICT 8

Dihydrogen phosphate ion ($H_2PO_4^-$) and monohydrogen phosphate ion (HPO_4^{2-}) form the phosphate buffer system.

Identify the conjugate acid and conjugate base in the phosphate buffer system. Explain how they function as a buffer when either H^+ or OH^- are added to the solution.

Oxygen

Oxygen (O_2) is an inorganic molecule consisting of two oxygen atoms bound together by a double covalent bond. About 21% of the gas in the atmosphere is oxygen, and it is essential for most animals. Oxygen is required by humans in the final step of a series of reactions in which energy is extracted from food molecules (see chapter 25).

Carbon Dioxide

Carbon dioxide (CO_2) consists of one carbon atom bound to two oxygen atoms. Each oxygen atom is bound to the carbon atom by a double covalent bond. Carbon dioxide is produced when organic molecules, such as glucose, are metabolized within the cells of the body (see chapter 25). Much of the energy stored in the covalent bonds of glucose is transferred to other organic molecules when glucose is broken down, and carbon dioxide is released. Once carbon dioxide is produced, it is eliminated from the cell as a metabolic by-product, transferred to the lungs by blood, and exhaled during respiration. If carbon dioxide is allowed to accumulate within cells, it becomes toxic.

29 What are the functions of oxygen and carbon dioxide in living systems?

ORGANIC CHEMISTRY

The ability of carbon to form covalent bonds with other atoms makes possible the formation of the large, diverse, complicated molecules necessary for life. A series of carbon atoms bound together by covalent bonds constitutes the “backbone” of many large molecules. Variation in the length of the carbon chains and the combination of atoms bound to the carbon backbone allows for the formation of a wide variety of molecules. For example, some protein molecules have thousands of carbon atoms bound by covalent bonds to one another or to other atoms, such as nitrogen, sulfur, hydrogen, and oxygen.

The four major groups of organic molecules essential to living organisms are carbohydrates, lipids, proteins, and nucleic acids. Each of these groups has specific structural and functional characteristics.

Carbohydrates

Carbohydrates are composed primarily of carbon, hydrogen, and oxygen atoms and range in size from small to very large. In most carbohydrates, for each carbon atom there are approximately two hydrogen atoms and one oxygen atom. Note that this ratio of hydrogen atoms to oxygen atoms is two to one, the same as in water (H_2O). They are called carbohydrates because carbon (carbo) atoms are combined with the same atoms that form water (hydrated). The large number of oxygen atoms in carbohydrates makes them relatively polar molecules. Consequently, they are soluble in polar solvents, such as water.

Carbohydrates are important parts of other organic molecules, and they can be broken down to provide the energy necessary for life. Undigested carbohydrates also provide bulk in feces, which helps maintain the normal function and health

TABLE 2.5 Role of Carbohydrates in the Body

Role	Example
Structure	Ribose forms part of RNA and ATP molecules, and deoxyribose forms part of DNA.
Energy	Monosaccharides (glucose, fructose, galactose) can be used as energy sources. Disaccharides (sucrose, lactose, maltose) and polysaccharides (starch, glycogen) must be broken down to monosaccharides before they can be used for energy. Glycogen is an important energy-storage molecule in muscles and in the liver.
Bulk	Cellulose forms bulk in the feces.

of the digestive tract. Table 2.5 summarizes the role of carbohydrates in the body.

Monosaccharides

Large carbohydrates are composed of numerous, relatively simple building blocks called **monosaccharides** (mon-ō-sak'ā-rīdz; the prefix *mono-* means one; the term *saccharide* means sugar), or simple sugars. Monosaccharides commonly contain three carbons (trioses), four carbons (tetroses), five carbons (pentoses), or six carbons (hexoses).

The monosaccharides most important to humans include both five- and six-carbon sugars. Common six-carbon sugars, such as glucose, fructose, and galactose, are **isomers** (ī'sō-merz), which are molecules that have the same number and types of atoms but differ in their three-dimensional arrangement (figure 2.14). Glucose, or blood sugar, is the major carbohydrate found in the blood and is a major nutrient for most cells of the body. Fructose and galactose are also important dietary nutrients. Important five-carbon sugars include ribose and deoxyribose (see figure 2.24), which are components of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA), respectively.

Disaccharides

Disaccharides (dī-sak'ā-rīdz; *di-* means two) are composed of two simple sugars bound together through a dehydration reaction. Glucose and fructose, for example, combine to form a disaccharide called **sucrose** (table sugar) plus a molecule of water (figure 2.15a). Several disaccharides are important to humans, including sucrose, lactose, and maltose. Lactose, or milk sugar, is glucose combined with galactose; and maltose, or malt sugar, is two glucose molecules joined together.

Polysaccharides

Polysaccharides (pol-ē-sak'ā-rīdz; *poly-* means many) consist of many monosaccharides bound together to form long chains that are either straight or branched. **Glycogen**, or animal starch, is a

FIGURE 2.14 Monosaccharides

These monosaccharides almost always form a ring-shaped molecule. They are represented as linear models to more readily illustrate the relationships between the atoms of the molecules. Fructose is a structural isomer of glucose because it has identical chemical groups bonded in a different arrangement in the molecule (*red shading*). Galactose is a stereoisomer of glucose because it has exactly the same groups bonded to each carbon atom but located in a different three-dimensional orientation (*yellow shading*).

FIGURE 2.15 Disaccharide and Polysaccharide

(a) Formation of sucrose, a disaccharide, by a dehydration reaction involving glucose and fructose (monosaccharides). (b) Glycogen is a polysaccharide formed by combining many glucose molecules. The photomicrograph shows glycogen granules in a liver cell.

polysaccharide composed of many glucose molecules (figure 2.15*b*). Because glucose can be metabolized rapidly and the resulting energy can be used by cells, glycogen is an important energy-storage molecule. A substantial amount of the glucose that is metabolized to produce energy for muscle contraction during exercise is stored in the form of glycogen in the cells of the liver and skeletal muscles.

Starch and **cellulose** are two important polysaccharides found in plants, and both are composed of long chains of glucose. Plants use starch as an energy-storage molecule in the same way that animals use glycogen, and cellulose is an important structural component of plant cell walls. When humans ingest plants, the starch can be broken down and used as an energy source. Humans, however, do not have the digestive enzymes necessary to break down cellulose. The cellulose is eliminated in the feces, where it provides bulk.

30 Name the basic building blocks of carbohydrates.

31 List the five- and six-carbon sugars that are important for humans.

32 What is an isomer?

33 What are disaccharides and polysaccharides and how are they formed?

34 Which carbohydrates are used for energy? What is the function of starch and cellulose in plants? The function of glycogen and cellulose in animals?

Lipids

Lipids are a second major group of organic molecules common to living systems. Like carbohydrates, they are composed principally of carbon, hydrogen, and oxygen, but other elements, such as phosphorus and nitrogen, are minor components of some lipids. Lipids contain a lower ratio of oxygen to carbon than do carbohydrates, which makes them less polar. Consequently, lipids can be dissolved in nonpolar organic solvents, such as alcohol or acetone, but they are relatively insoluble in water.

Lipids have many important functions in the body. They provide protection and insulation, help regulate many physiologic processes, and form plasma membranes. In addition, lipids are a major energy-storage molecule and can be broken down and used as a source of energy. Table 2.6 summarizes the many roles of lipids in the body. Several kinds of molecules, such as fats, phospholipids, steroids, and prostaglandins, are classified as lipids.

Fats are a major type of lipid. Like carbohydrates, fats are ingested and broken down by hydrolysis reactions in cells to release energy for use by those cells. Conversely, if intake exceeds need, excess chemical energy from any source can be stored in the body as fat for later use as energy is needed. Fats also provide protection by surrounding and padding organs, and under-the-skin fats act as an insulator to prevent heat loss.

TABLE 2.6 Role of Lipids in the Body

Role	Example
Protection	Fat surrounds and pads organs.
Insulation	Fat under the skin prevents heat loss. Myelin surrounds nerve cells and electrically insulates the cells from one another.
Regulation	Steroid hormones regulate many physiologic processes. For example, estrogen and testosterone are sex hormones responsible for many of the differences between males and females. Prostaglandins help regulate tissue inflammation and repair.
Vitamins	Fat-soluble vitamins perform a variety of functions. Vitamin A forms retinol, which is necessary for seeing in the dark; active vitamin D promotes calcium uptake by the small intestine; vitamin E promotes wound healing; and vitamin K is necessary for the synthesis of proteins responsible for blood clotting.
Structure	Phospholipids and cholesterol are important components of the membranes of cells.
Energy	Lipids can be stored and broken down later for energy; per unit of weight, they yield more energy than carbohydrates or proteins.

Triglycerides (trī-glis'er-idz) constitute 95% of the fats in the human body. Triglycerides, which are sometimes called **triacylglycerols** (tri-as'il-glis'er-olz), consist of two different types of building blocks: one glycerol and three fatty acids. **Glycerol** is

a three-carbon molecule with a hydroxyl group attached to each carbon atom, and **fatty acids** consist of a straight chain of carbon atoms with a carboxyl group attached at one end (figure 2.16). A **carboxyl** (kar-bok'sil) **group** (—COOH) consists of both an oxygen atom and a hydroxyl group attached to a carbon atom.

The carboxyl group is responsible for the acidic nature of the molecule because it releases hydrogen ions into solution. Glycerides can be described according to the number and kinds of fatty acids that combine with glycerol through dehydration reactions. Monoglycerides have one fatty acid, diglycerides have two fatty acids, and triglycerides have three fatty acids bound to glycerol.

Fatty acids differ from one another according to the length and the degree of saturation of their carbon chains. Most naturally occurring fatty acids contain an even number of carbon atoms, with 14- to 18-carbon chains being the most common. A fatty acid is **saturated** (figure 2.17) if it contains only single covalent bonds between the carbon atoms. Sources of saturated fats include beef, pork, whole milk, cheese, butter, eggs, coconut oil, and palm oil. The carbon chain is **unsaturated** if it has one or more double covalent bonds between carbon atoms. Because the double covalent bonds can occur anywhere along the carbon chain, many types of unsaturated fatty acids with an equal degree of unsaturation are possible. **Monounsaturated fats**, such as olive and peanut oils, have one double covalent bond between carbon atoms. **Polyunsaturated fats**, such as safflower, sunflower, corn, and fish oils, have two or more double covalent bonds between carbon atoms. Unsaturated fats are

**FIGURE 2.16** Triglyceride

Production of a triglyceride from one glycerol molecule and three fatty acid molecules. One water molecule (H₂O) is given off for each covalent bond formed between a fatty acid molecule and glycerol.

**FIGURE 2.17 Fatty Acids**

(a) Palmitic acid (saturated with no double bonds between the carbons). (b) Linolenic acid (unsaturated with three double bonds between the carbons).

the best type of fats in the diet because, unlike saturated fats, they do not contribute to the development of cardiovascular disease.

Phospholipids are similar to triglycerides, except that one of the fatty acids bound to the glycerol is replaced by a molecule containing phosphate and, usually, nitrogen (figure 2.18). They are polar at the end of the molecule to which the phosphate is bound and nonpolar at the other end. The polar end of the molecule is attracted to water and is said to be **hydrophilic** (water-loving). The nonpolar end is repelled by water and is said to be **hydrophobic** (water-fearing). Phospholipids are important structural components of the membranes of cells (see figure 3.2).

The **eicosanoids** (ī'kō-sā-noydz) are a group of important chemicals derived from fatty acids. They include **prostaglandins** (pros'tā-glan'dinz), **thromboxanes** (throm'bok-zānz), and **leukotrienes** (loo-kō-trī'ēnz). Eicosanoids are made in most

cells and are important regulatory molecules. Among their numerous effects is their role in the response of tissues to injuries. Prostaglandins have been implicated in regulating the secretion of some hormones, blood clotting, some reproductive functions, and many other processes. Many of the therapeutic effects of aspirin and other anti-inflammatory drugs result from their ability to inhibit prostaglandin synthesis.

Steroids differ in chemical structure from other lipid molecules, but their solubility characteristics are similar. All steroid molecules are composed of carbon atoms bound together into four ringlike structures (figure 2.19). Important steroid molecules include cholesterol, bile salts, estrogen, progesterone, and testosterone. Cholesterol is an important steroid because other molecules are synthesized from it. For example, bile salts, which increase fat absorption in the intestines, are derived from

**FIGURE 2.18 Phospholipids**

(a) Molecular model of a phospholipid. (b) Simplified way in which phospholipids are often depicted.

FIGURE 2.19 Steroids

Steroids are four-ringed molecules that differ from one another according to the groups attached to the rings. Cholesterol, the most common steroid, can be modified to produce other steroids.

cholesterol, as are the reproductive hormones estrogen, progesterone, and testosterone. In addition, cholesterol is an important component of plasma membranes. Although high levels of cholesterol in the blood increase the risk of cardiovascular disease, a certain amount of cholesterol is vital for normal function.

Another class of lipids is the **fat-soluble vitamins**. Their structures are not closely related to one another, but they are nonpolar molecules essential for many normal functions of the body.

35 Give four functions of fats. Name the most common type of fat in the human body. What are the basic building blocks of this type of fat?

36 What is the difference between a saturated and an unsaturated fat? Between monounsaturated and polyunsaturated fats?

37 Describe the structure of phospholipids. Which end of the molecule is hydrophilic?

38 What are the functions of eicosanoids? Give three examples of eicosanoids.

39 Why is cholesterol an important steroid?

Proteins

All **proteins** contain carbon, hydrogen, oxygen, and nitrogen bound together by covalent bonds, and most proteins contain some sulfur. In addition, some proteins contain small amounts of phosphorus, iron, and iodine. The molecular mass of proteins can be very large. For the purpose of comparison, the molecular mass of water is approximately 18, sodium chloride 58, and glucose 180, but the molecular mass of proteins ranges from approximately 1000 to several million.

Proteins regulate bodily processes, act as a transportation system in the body, provide protection, help muscles contract, and provide structure and energy. Table 2.7 summarizes the role of proteins in the body.

TABLE 2.7 Role of Proteins in the Body	
Role	Example
Regulation	Enzymes control chemical reactions. Hormones regulate many physiologic processes; for example, insulin affects glucose transport into cells.
Transport	Hemoglobin transports oxygen and carbon dioxide in the blood. Plasma proteins transport many substances in the blood. Proteins in plasma membranes control the movement of materials into and out of the cell.
Protection	Antibodies and complement protect against microorganisms and other foreign substances.
Contraction	Actin and myosin in muscle are responsible for muscle contraction.
Structure	Collagen fibers form a structural framework in many parts of the body. Keratin adds strength to skin, hair, and nails.
Energy	Proteins can be broken down for energy; per unit of weight, they yield as much energy as carbohydrates.

Protein Structure

The basic building blocks for proteins are the 20 **amino acid** (*ă-mě' nō*) molecules. Each amino acid has an amine (*ă-měn'*) group ($-\text{NH}_2$), a carboxyl group ($-\text{COOH}$), a hydrogen atom, and a side chain designated by the symbol *R* attached to the same carbon atom. The side chain can be a variety of chemical structures, and the differences in the side chains make the amino acids different from one another (figure 2.20).

Covalent bonds formed between amino acid molecules during protein synthesis are called **peptide bonds** (figure 2.21). A dipeptide is two amino acids bound together by a peptide bond, a tripeptide is three amino acids bound together by peptide bonds,

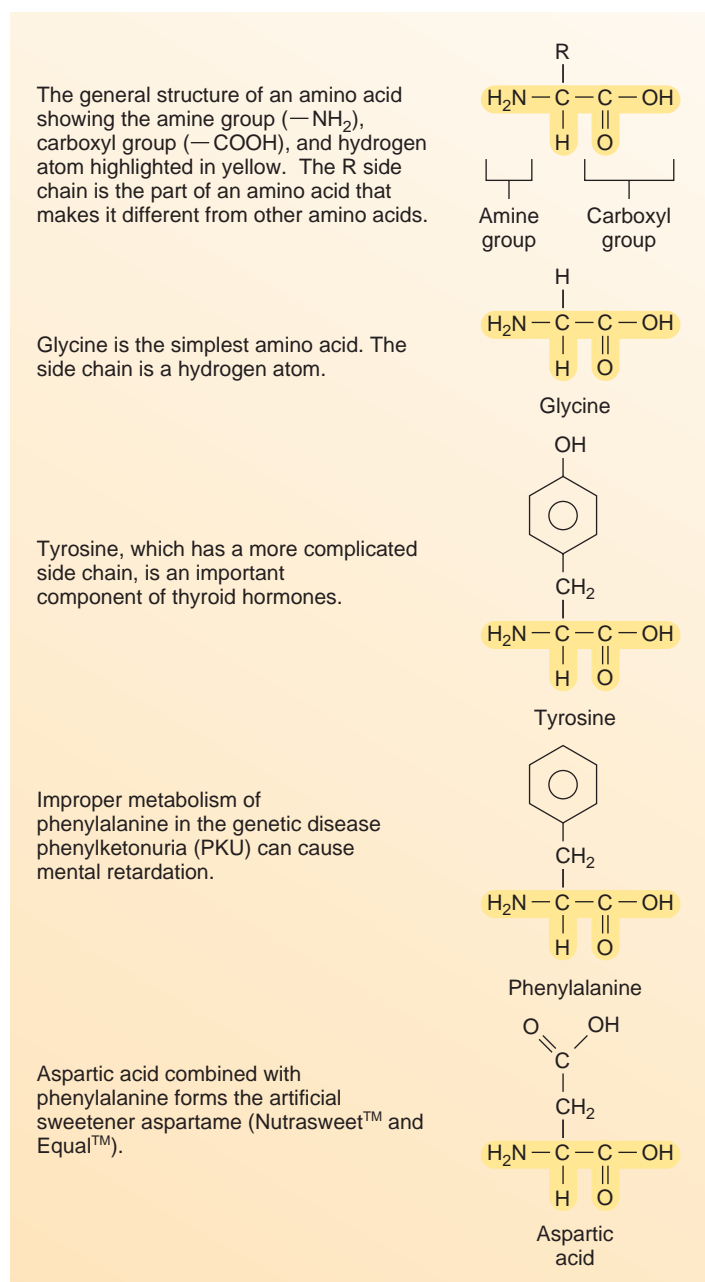

FIGURE 2.20 Amino Acids

FIGURE 2.21 Peptide Bond

A dehydration reaction between two amino acids forms a dipeptide and a water molecule. The covalent bond between the amino acids is called a peptide bond.

and a polypeptide is many amino acids bound together by peptide bonds. Proteins are polypeptides composed of hundreds of amino acids.

The **primary structure** of a protein is determined by the sequence of the amino acids bound by peptide bonds (figure 2.22a). The potential number of different protein molecules is enormous because 20 different amino acids exist, and each amino acid can be located at any position along a polypeptide chain. The characteristics of the amino acids in a protein ultimately determine the three-dimensional shape of the protein, and the shape of the protein determines its function. A change in one, or a few, amino acids in the primary structure can alter protein function, usually making the protein less or even nonfunctional.

The **secondary structure** results from the folding or bending of the polypeptide chain caused by the hydrogen bonds between amino acids (figure 2.22b). Two common shapes that result are helices (coils) and pleated (folded) sheets. If the hydrogen bonds that maintain the shape of the protein are broken, the protein becomes nonfunctional. This change in shape is called **denaturation**, and it can be caused by abnormally high temperatures or changes in the pH of body fluids. An everyday example of denaturation is the change in the proteins of egg whites when they are cooked.

The **tertiary structure** results from the folding of the helices or pleated sheets (figure 2.22c). Some amino acids are quite polar and therefore form hydrogen bonds with water. The polar portions of proteins tend to remain unfolded, maximizing their contact with water, whereas the less polar regions tend to fold into a globular shape, minimizing their contact with water. The formation of covalent bonds between sulfur atoms of one amino acid and sulfur atoms of another amino acid located at a different place in the sequence of amino acids can also contribute to the tertiary structure of proteins. The tertiary structure determines the shape of a **domain**, which is a folded sequence of 100–200 amino acids within

FIGURE 2.22 Protein Structure

a protein. The functions of proteins occur at one or more domains. Therefore, changes in the primary or secondary structure that affect the shape of the domain can change protein function.

If two or more proteins associate to form a functional unit, the individual proteins are called subunits. The **quaternary structure** is the spatial relationships between the individual subunits (figure 2.22*d*).

Enzymes

Proteins perform many roles in the body, including acting as enzymes. An **enzyme** is a protein catalyst that increases the rate at which a chemical reaction proceeds without the enzyme being permanently changed. The three-dimensional shape of enzymes is critical for their normal function because it determines the structure of the enzyme's **active site**. According to the **lock-and-key model** of enzyme action, a reaction occurs when the reactants (key) bind to the active site (lock) on the enzyme. This view of enzymes and reactants as rigid structures fitting together has been modified by the **induced fit model**, in which the enzyme is able to slightly change shape and better fit the reactants. The enzyme is like a glove that does not achieve its functional shape until the hand (reactants) moves into place.

At the active site, reactants are brought into close proximity (figure 2.23). After the reactants combine, they are released from the active site, and the enzyme is capable of catalyzing additional reactions. The activation energy required for a chemical reaction to occur is lowered by enzymes (see figure 2.12) because they

orient the reactants toward each other in such a way that it is more likely a chemical reaction will occur.

Slight changes in the structure of an enzyme can destroy the ability of the active site to function. Enzymes are very sensitive to changes in temperature or pH, which can break the hydrogen bonds within them. As a result, the relationship between amino acids changes, thereby producing a change in shape that prevents the enzyme from functioning normally.

To be functional, some enzymes require additional, nonprotein substances called **cofactors**. A cofactor can be an ion, such as magnesium or zinc, or an organic molecule. Cofactors that are organic molecules, such as certain vitamins, may be referred to as **coenzymes**. Cofactors normally form part of the enzyme's active site and are required to make the enzyme functional.

Enzymes are highly specific because their active site can bind only to certain reactants. Each enzyme catalyzes a specific chemical reaction and no others. Many different enzymes are therefore needed to catalyze the many chemical reactions of the body. Enzymes often are named by adding the suffix *-ase* to the name of the molecules on which they act. For example, an enzyme that catalyzes the breakdown of lipids is a **lipase** (lip'ās, lī'pās), and an enzyme that breaks down proteins is called a **protease** (prō'tē-ās).

Enzymes control the rate at which most chemical reactions proceed in living systems. Consequently, they control essentially all cellular activities. At the same time, the activity of enzymes themselves is regulated by several mechanisms within the cells. Some mechanisms control the enzyme concentration by influencing the rate at which the enzymes are synthesized; others alter the activity of existing enzymes. Much of what is known about the regulation of cellular activity involves knowledge of how enzyme activity is controlled.

FIGURE 2.23 Enzyme Action

The enzyme brings the two reacting molecules together. After the reaction, the unaltered enzyme can be used again.

40 What are the building blocks of proteins? Define a peptide bond.

41 What determines the primary, secondary, tertiary, and quaternary structures of proteins? Define denaturation and name two things that can cause it to occur.

42 Compare the lock-and-key model and the induced fit model of enzyme activity. Define cofactor and coenzyme.

Nucleic Acids: DNA and RNA

Deoxyribonucleic acid (DNA) is the genetic material of cells, and copies of DNA are transferred from one generation of cells to the next generation. DNA contains the information that determines the structure of proteins. **Ribonucleic acid (RNA)** is structurally related to DNA, and three types of RNA also play important roles in protein synthesis. In chapter 3, the means by which DNA and RNA direct the functions of the cell are described.

The **nucleic acids** are large molecules composed of carbon, hydrogen, oxygen, nitrogen, and phosphorus. Both DNA and RNA consist of basic building blocks called **nucleotides**. Each nucleotide is composed of a monosaccharide to which a nitrogenous organic base and a phosphate group

FIGURE 2.24 Components of Nucleotides

(a) Deoxyribose sugar, which forms nucleotides used in DNA production. (b) Ribose sugar, which forms nucleotides used in RNA production. Note that deoxyribose is ribose minus an oxygen atom. (c) Deoxyribonucleotide consisting of deoxyribose, a nitrogen base, and a phosphate group.

are attached (figure 2.24). The five-carbon monosaccharide is deoxyribose for DNA; it is ribose for RNA. The nitrogenous organic bases consist of carbon and nitrogen atoms organized into rings (figure 2.25). They are bases because the nitrogen atoms tend to take up H^+ from solution. The nitrogenous organic bases are thymine (thī'mēn, thī'min), cytosine (sī'tō-sēn), and uracil (ūr'ā-sil), which are single-ringed pyrimidines (pī-rim'i-dēnz), and adenine (ad'ē-nēn) and guanine (gwahn'ēn), which are double-ringed purines (pūr'ēnz).

DNA has two strands of nucleotides joined together to form a twisted, ladderlike structure called a double helix (figure 2.26). The uprights of the ladder are formed by covalent bonds between the deoxyribose molecules and phosphate groups of adjacent nucleotides. The rungs of the ladder are formed by the bases of the nucleotides of one upright connected to the bases of the other upright by hydrogen bonds. Each nucleotide of DNA contains one of the organic bases: adenine, thymine, cytosine, or guanine. **Complementary base pairs** are organic bases held together by hydrogen bonds. Adenine and thymine are complementary base pairs because the structure of these organic bases allows two hydrogen bonds to form between them. Cytosine and guanine are complementary base pairs because the structure of these organic bases allows three hydrogen bonds to form between them. The two strands of a DNA molecule are said to be complementary. If the sequence of bases in one DNA strand is known, the sequence of bases in the other strand can be predicted because of complementary base pairing.

The two nucleotide strands of a DNA molecule are **antiparallel**, meaning that the two strands lie side by side, but their sugar-phosphate “backbones” extend in opposite directions because of the orientation of their nucleotides (see figure 2.26). A nucleotide has a 5' end and a 3' end. The prime sign is used to indicate the carbon atoms of the deoxyribose sugar, which are numbered 1' to 5'.

The sequence of organic bases in DNA is a “code” that stores information used to determine the structures and functions of cells. A sequence of DNA bases that directs the synthesis of

FIGURE 2.25 Nitrogenous Organic Bases

The organic bases found in nucleic acids are separated into two groups. Purines are double-ringed molecules, and pyrimidines are single-ringed molecules.

proteins or RNA molecules is called a **gene** (see chapter 3 for more information on genes). Genes determine the type and sequence of amino acids found in protein molecules. Because enzymes are proteins, DNA structure determines the rate and type of chemical reactions that occur in cells by controlling enzyme structure. The information contained in DNA therefore ultimately defines all cellular activities. Other proteins, such as collagen, that are coded by DNA determine many of the structural features of humans.

RNA has a structure similar to a single strand of DNA. Like DNA, four different nucleotides make up the RNA molecule, and the organic bases are the same, except that thymine is replaced with uracil (see figure 2.25). Uracil can bind only to adenine.

43 Name two types of nucleic acids. What are their functions?

44 What are the basic building blocks of nucleic acids? What kinds of sugar and bases are found in DNA? In RNA?

45 DNA is like a twisted ladder. What forms the uprights and rungs of the ladder?

46 Name the complementary base pairs in DNA and RNA.

47 How are DNA strands complementary and antiparallel?

48 Define gene and explain how genes determine the structures and functions of cells.

1. The building blocks of nucleic acids are nucleotides, which consist of a phosphate group, a sugar, and a nitrogen base.
2. The phosphate groups connect the sugars to form two strands of nucleotides (purple columns).
3. Hydrogen bonds (dotted red lines) between the nucleotides join the two nucleotide strands together. Adenine binds to thymine and cytosine binds to guanine.
4. Deoxyribose carbon atoms are numbered. One end of a DNA strand has a 3' end because of the orientation of its nucleotides.
5. The other end of a DNA strand has a 5' end.
6. The complementary strands are antiparallel in that the 5' → 3' direction of one strand runs counter to the 5' → 3' direction of the other strand.
7. The nucleotide strands coil to form a double-stranded helix.

Cytosine (C)		Guanine (G)
Thymine (T)		Adenine (A)

FIGURE 2.26 Structure of DNA

1. Adenosine is adenine, which is one of the nitrogenous bases in DNA, combined with the sugar ribose.
2. Adenosine diphosphate (ADP) is adenosine with two phosphate groups.
3. Adenosine triphosphate (ATP) is adenosine with three phosphates.

FIGURE 2.27 Adenosine Triphosphate (ATP) Molecule

Adenosine Triphosphate

Adenosine triphosphate (ă-den'ō-sēn trī-fos'fāt) (**ATP**) is an especially important organic molecule found in all living organisms. It consists of adenosine and three phosphate groups (figure 2.27). Adenosine is the sugar ribose with the organic base adenine. The potential energy stored in the covalent bond between the second and third phosphate groups is important to living organisms because it provides the energy used in nearly all of the chemical reactions within cells.

The catabolism of glucose and other nutrient molecules results in chemical reactions that release energy. Some of that energy is used to synthesize ATP from ADP and an inorganic phosphate group (P_i):

The transfer of energy from nutrient molecules to ATP involves a series of oxidation–reduction reactions in which a high-energy electron is transferred from one molecule to the next molecule in the series. In chapter 25, the oxidation–reduction reactions of metabolism are considered in greater detail.

Once produced, ATP is used to provide energy for other chemical reactions (anabolism) or to drive cell processes, such as muscle contraction. In the process, ATP is converted back to ADP and an inorganic phosphate group.

ATP is often called the energy currency of cells because it is capable of both storing and providing energy. The concentration of ATP is maintained within a narrow range of values, and essentially all energy-requiring chemical reactions stop when there is an inadequate quantity of ATP.

Cyanide Poisoning

Cyanide compounds can be lethal to humans because they interfere with the production of ATP in mitochondria (see chapter 25). Without adequate ATP, cells die because there is inadequate energy for anabolic chemical reactions, active transport, and other energy-requiring cell processes. The heart and brain are especially susceptible to cyanide poisoning. Inhalation of smoke released by the burning of rubber and plastic by household fires is the most common cause of cyanide poisoning. Cyanide poisoning by inhalation or absorption through the skin can also occur in certain manufacturing processes, and cyanide gas was used during the Holocaust to kill people. Deliberate suicide by ingesting cyanide is rare but was made famous by the suicide capsules in spy movies. In 1982, seven people in the Chicago area died after taking Tylenol that some unknown person had laced with cyanide. Subsequent copycat tamperings occurred and led to the widespread use of tamper-proof capsules and packaging.

- 49** Describe the structure of ATP. Where does the energy to synthesize ATP come from? What is the energy stored in ATP used for?

SUMMARY

Chemistry is the study of the composition, structure, and properties of substances and the reactions they undergo. Much of the structure and function of healthy or diseased organisms can be understood at the chemical level.

Basic Chemistry (p. 24) Matter, Mass, and Weight

1. Matter is anything that occupies space.
2. Mass is the amount of matter in an object.
3. Weight results from the force exerted by earth's gravity on matter.

Elements and Atoms

1. An element is the simplest type of matter with unique chemical and physical properties.
2. An atom is the smallest particle of an element that has the chemical characteristics of that element. An element is composed of only one kind of atom.
3. Atoms consist of protons, neutrons, and electrons.
 - Protons are positively charged, electrons are negatively charged, and neutrons have no charge.
 - Protons and neutrons are found in the nucleus; electrons, which are located around the nucleus, can be represented by an electron cloud.

4. The atomic number is the unique number of protons in an atom. The mass number is the sum of the protons and the neutrons.
5. Isotopes are atoms that have the same atomic number but different mass numbers.
6. The atomic mass of an element is the average mass of its naturally occurring isotopes weighted according to their abundance.
7. A mole of a substance contains Avogadro's number (6.022×10^{23}) of atoms, ions, or molecules. The molar mass of a substance is the mass of 1 mole of the substance expressed in grams.

Electrons and Chemical Bonding

1. The chemical behavior of atoms is determined mainly by their outermost electrons. A chemical bond occurs when atoms share or transfer electrons.
2. Ions are atoms that have gained or lost electrons.
 - An atom that loses one or more electrons becomes positively charged and is called a cation. An anion is an atom that becomes negatively charged after accepting one or more electrons.
 - Ionic bonding is the attraction of the oppositely charged cation and anion to each other.
3. A covalent bond is the sharing of electron pairs between atoms. A polar covalent bond results when the sharing of electrons is unequal and can produce a polar molecule that is electrically asymmetric.

Molecules and Compounds

1. A molecule is two or more atoms chemically combined to form a structure that behaves as an independent unit. A compound is two or more *different* types of atoms chemically combined.
2. The kinds and numbers of atoms (or ions) in a molecule or compound can be represented by a formula consisting of the symbols of the atoms (or ions) plus subscripts denoting the number of each type of atom (or ion).
3. The molecular mass of a molecule or compound can be determined by adding up the atomic masses of its atoms (or ions).

Intermolecular Forces

1. A hydrogen bond is the weak attraction that occurs between the oppositely charged regions of polar molecules. Hydrogen bonds are important in determining the three-dimensional structure of large molecules.
2. Solubility is the ability of one substance to dissolve in another. Ionic substances that dissolve in water by dissociation are electrolytes. Molecules that do not dissociate are nonelectrolytes.

Chemical Reactions and Energy (p. 32)

Synthesis Reactions

1. Synthesis reactions are the chemical combination of two or more substances to form a new or larger substance.
2. Dehydration reactions are synthesis reactions in which water is produced.
3. Anabolism is the sum of all the synthesis reactions in the body.

Decomposition Reactions

1. Decomposition reactions are the chemical breakdown of a larger substance to two or more different smaller substances.
2. Hydrolysis reactions are decomposition reactions in which water is depleted.
3. All of the decomposition reactions in the body are called catabolism.

Reversible Reactions

Reversible reactions produce an equilibrium condition in which the amount of reactants relative to the amount of products remains constant.

Oxidation–Reduction Reactions

Oxidation–reduction reactions involve the complete or partial transfer of electrons between atoms.

Energy

1. Energy is the ability to do work. Potential energy is stored energy, and kinetic energy is energy resulting from movement of an object.
2. Chemical energy
 - Chemical bonds are a form of potential energy.
 - Chemical reactions in which the products contain more potential energy than the reactants require the input of energy.
 - Chemical reactions in which the products have less potential energy than the reactants release energy.
3. Heat energy
 - Heat energy is energy that flows between objects that are at different temperatures.
 - Heat energy is released in chemical reactions and is responsible for body temperature.

Speed of Chemical Reactions

1. Activation energy is the minimum energy that the reactants must have to start a chemical reaction.
2. Enzymes are specialized protein catalysts that lower the activation energy for chemical reactions. Enzymes speed up chemical reactions but are not consumed or altered in the process.
3. Increased temperature and concentration of reactants can increase the rate of chemical reactions.

Inorganic Chemistry (p. 36)

Inorganic chemistry is mostly concerned with noncarbon-containing substances but does include some carbon-containing substances, such as carbon dioxide and carbon monoxide.

Water

1. Water is a polar molecule composed of one atom of oxygen and two atoms of hydrogen.
2. Water stabilizes body temperature, protects against friction and trauma, makes chemical reactions possible, directly participates in chemical reactions (e.g., dehydration and hydrolysis reactions), and is a mixing medium (e.g., solutions, suspensions, and colloids).
3. A mixture is a combination of two or more substances physically blended together, but not chemically combined.
4. A solution is any liquid, gas, or solid in which the substances are uniformly distributed with no clear boundary between the substances.
5. A solute dissolves in the solvent.
6. A suspension is a mixture containing materials that separate from each other unless they are continually, physically blended together.
7. A colloid is a mixture in which a dispersed (solutelike) substance is distributed throughout a dispersing (solventlike) substance. Particles do not settle out of a colloid.

Solution Concentrations

1. One way to describe solution concentration is an osmole, which contains Avogadro's number (6.022×10^{23}) of particles (i.e., atoms, ions, or molecules) in 1 kilogram water.
2. A milliosmole is 1/1000 of an osmole.

Acids and Bases

1. Acids are proton (i.e., H^+) donors, and bases (e.g., OH^-) are proton acceptors.
2. A strong acid or base almost completely dissociates in water. A weak acid or base partially dissociates.
3. The pH scale is the H^+ concentration in a solution.
 - A neutral solution has an equal number of H^+ and OH^- and is assigned a pH of 7.
 - Acid solutions, in which the number of H^+ is greater than the number of OH^- , have pH values less than 7.
 - Basic, or alkaline, solutions have more OH^- than H^+ and a pH greater than 7.
4. A salt is a molecule consisting of a cation other than H^+ and an anion other than OH^- . Salts are formed when acids react with bases.
5. A buffer is a solution of a conjugate acid–base pair that resists changes in pH when acids or bases are added to the solution.

Oxygen

Oxygen is necessary in the reactions that extract energy from food molecules in living organisms.

Carbon Dioxide

During metabolism when the organic molecules are broken down, carbon dioxide and energy are released.

Organic Chemistry (p. 39)

Organic molecules contain carbon atoms bound together by covalent bonds.

Carbohydrates

1. Monosaccharides are the basic building blocks of other carbohydrates. They, especially glucose, are important sources of energy. Examples are ribose, deoxyribose, glucose, fructose, and galactose.
2. Disaccharide molecules are formed by dehydration reactions between two monosaccharides. They are broken apart into monosaccharides by hydrolysis reactions. Examples of disaccharides are sucrose, lactose, and maltose.
3. Polysaccharides are many monosaccharides bound together to form long chains. Examples include cellulose, starch, and glycogen.

Lipids

1. Triglycerides are composed of glycerol and fatty acids. One, two, or three fatty acids can attach to the glycerol molecule.
 - Fatty acids are straight chains of carbon molecules with a carboxyl group. Fatty acids can be saturated (only single covalent bonds between carbon atoms) or unsaturated (one or more double covalent bonds between carbon atoms).
 - Energy is stored in fats.
2. Phospholipids are lipids in which a fatty acid is replaced by a phosphate-containing molecule. Phospholipids are a major structural component of plasma membranes.
3. Steroids are lipids composed of four interconnected ring molecules. Examples include cholesterol, bile salts, and sex hormones.
4. Other lipids include fat-soluble vitamins, prostaglandins, thromboxanes, and leukotrienes.

Proteins

1. The building blocks of protein are amino acids, which are joined by peptide bonds.
2. The number, kind, and arrangement of amino acids determine the primary structure of a protein. Hydrogen bonds between amino acids determine secondary structure, and hydrogen bonds between amino acids and water determine tertiary structure. Interactions between different protein subunits determine quaternary structure.
3. Enzymes are protein catalysts that speed up chemical reactions by lowering their activation energy.
4. The active sites of enzymes bind only to specific reactants.
5. Cofactors are ions or organic molecules, such as vitamins, that are required for some enzymes to function.

Nucleic Acids: DNA and RNA

1. The basic unit of nucleic acids is the nucleotide, which is a monosaccharide with an attached phosphate and organic base.
2. DNA nucleotides contain the monosaccharide deoxyribose and the organic base adenine, thymine, guanine, or cytosine. DNA occurs as a double strand of joined nucleotides. Each strand is complementary and antiparallel to the other strand.
3. A gene is a sequence of DNA nucleotides that determines the structure of a protein or RNA.
4. RNA nucleotides are composed of the monosaccharide ribose. The organic bases are the same as for DNA, except that thymine is replaced with uracil.

Adenosine Triphosphate

ATP stores energy derived from catabolism. The energy is released from ATP and is used in anabolism and other cell processes.

REVIEW AND COMPREHENSION

1. The smallest particle of an element that still has the chemical characteristics of that element is a (an)
 - a. electron.
 - b. molecule.
 - c. neutron.
 - d. proton.
 - e. atom.
2. The number of electrons in an atom is equal to the
 - a. atomic number.
 - b. mass number.
 - c. number of neutrons.
 - d. isotope number.
 - e. molecular mass.
3. ^{12}C and ^{14}C are
 - a. atoms of different elements.
 - b. isotopes.
 - c. atoms with different atomic numbers.
 - d. atoms with different numbers of protons.
 - e. compounds.

4. A cation is a (an)
 - a. uncharged atom.
 - b. positively charged atom.
 - c. negatively charged atom.
 - d. atom that has gained an electron.
 - e. both c and d.
5. A polar covalent bond between two atoms occurs when
 - a. one atom attracts shared electrons more strongly than another atom.
 - b. atoms attract electrons equally.
 - c. an electron from one atom is completely transferred to another atom.
 - d. the molecule becomes ionized.
 - e. a hydrogen atom is shared between two different atoms.
6. Table salt (NaCl) is
 - a. an atom.
 - b. organic.
 - c. a molecule.
 - d. a compound.
 - e. a cation.
7. The weak attractive force between two water molecules forms a (an)
 - a. covalent bond.
 - b. hydrogen bond.
 - c. ionic bond.
 - d. compound.
 - e. isotope.
8. Electrolytes are
 - a. nonpolar molecules.
 - b. covalent compounds.
 - c. substances that usually don't dissolve in water.
 - d. found in solutions that do not conduct electricity.
 - e. cations and anions that dissociate in water.
9. In a decomposition reaction,
 - a. anabolism occurs.
 - b. proteins are formed from amino acids.
 - c. large molecules are broken down to form small molecules.
 - d. a dehydration reaction may occur.
 - e. all of the above.
10. Oxidation–reduction reactions
 - a. can be synthesis or decomposition reactions.
 - b. have one reactant gaining electrons.
 - c. have one reactant losing electrons.
 - d. can create ionic or covalent bonds.
 - e. all of the above.
11. Potential energy
 - a. is energy caused by movement of an object.
 - b. is the form of energy that is actually doing work.
 - c. includes energy within chemical bonds.
 - d. can never be converted to kinetic energy.
 - e. all of the above.
12. Which of these descriptions of heat energy is *not* correct?
 - a. Heat energy flows between objects that are at different temperatures.
 - b. Heat energy can be produced from all other forms of energy.
 - c. Heat energy can be released during chemical reactions.
 - d. Heat energy must be added to break apart ATP molecules.
 - e. Heat energy is always transferred from a hotter object to a cooler object.
13. A *decrease* in the speed of a chemical reaction occurs if
 - a. the activation energy requirement is increased.
 - b. catalysts are increased.
 - c. temperature increases.
 - d. the concentration of the reactants increases.
 - e. all of the above.
14. Which of these statements concerning enzymes is correct?
 - a. Enzymes increase the rate of reactions but are permanently changed as a result.
 - b. Enzymes are proteins that function as catalysts.
 - c. Enzymes increase the activation energy requirement for a reaction to occur.
 - d. Enzymes usually can only double the rate of a chemical reaction.
 - e. Enzymes increase the kinetic energy of the reactants.
15. Water
 - a. is composed of two oxygen atoms and one hydrogen atom.
 - b. has a low specific heat.
 - c. is composed of polar molecules into which ionic substances dissociate.
 - d. is produced in a hydrolysis reaction.
 - e. is a very small organic molecule.
16. When sugar is dissolved in water, the water is called the
 - a. solute.
 - b. solution.
 - c. solvent.
17. Which of these is an example of a suspension?
 - a. sweat
 - b. water and proteins inside cells
 - c. sugar dissolved in water
 - d. red blood cells in plasma
18. A solution with a pH of 5 is _____ and contains _____ H^+ than a neutral solution.
 - a. a base, more
 - b. a base, less
 - c. an acid, more
 - d. an acid, less
 - e. neutral, the same number of
19. A buffer
 - a. slows down chemical reactions.
 - b. speeds up chemical reactions.
 - c. increases the pH of a solution.
 - d. maintains a relatively constant pH.
 - e. works by forming salts.
20. A conjugate acid–base pair
 - a. acts as a buffer.
 - b. can combine with H^+ in a solution.
 - c. can release H^+ to combine with OH^- .
 - d. describes carbonic acid (H_2CO_3) and bicarbonate ion (HCO_3^-).
 - e. all of the above.
21. Carbon dioxide
 - a. consists of two oxygen atoms ionically bonded to carbon.
 - b. becomes toxic if allowed to accumulate within cells.
 - c. is mostly eliminated by the kidneys.
 - d. is combined with fats to produce glucose during metabolism within cells.
 - e. is taken into cells during metabolism.
22. Which of these is a carbohydrate?
 - a. glycogen
 - b. prostaglandin
 - c. steroid
 - d. DNA
 - e. triglyceride
23. The polysaccharide used for energy storage in the human body is
 - a. cellulose.
 - b. glycogen.
 - c. lactose.
 - d. sucrose.
 - e. starch.
24. The basic units or building blocks of triglycerides are
 - a. simple sugars (monosaccharides).
 - b. double sugars (disaccharides).
 - c. amino acids.
 - d. glycerol and fatty acids.
 - e. nucleotides.

25. A _____ fatty acid has one double covalent bond between carbon atoms.
 a. cholesterol c. phospholipid e. saturated
 b. monounsaturated d. polyunsaturated
26. A peptide bond joins together
 a. amino acids. d. disaccharides.
 b. fatty acids and glycerol. e. nucleotides.
 c. monosaccharides.
27. The _____ structure of a protein results from the folding of the helices or pleated sheets.
 a. primary c. tertiary
 b. secondary d. quaternary
28. According to the lock-and-key model of enzyme action,
 a. reactants must first be heated.
 b. enzyme shape is not important.
 c. each enzyme can catalyze many types of reactions.
 d. reactants must bind to an active site on the enzyme.
 e. enzymes control only a small number of reactions in the cell.
29. DNA molecules
 a. contain genes.
 b. contain a single strand of nucleotides.
 c. contain the nucleotide uracil.
 d. have three different types that have roles in protein synthesis.
 e. contain up to 100 organic bases.
30. ATP
 a. is formed by the addition of a phosphate group to ADP.
 b. is formed with energy released during catabolism reactions.
 c. provides the energy for anabolism reactions.
 d. contains three phosphate groups.
 e. all of the above.

Answers in Appendix E

CRITICAL THINKING

- Iron has an atomic number of 26 and a mass number of 56. How many protons, neutrons, and electrons are in an atom of iron? If an atom of iron lost three electrons, what would the charge of the resulting ion be? Write the correct symbol for this ion.
- Which of the following pairs of terms applies to the reaction that results in the formation of fatty acids and glycerol from a triglyceride molecule?
 a. Decomposition or synthesis reaction
 b. Anabolism or catabolism
 c. Dehydration or hydrolysis reaction
- A mixture of chemicals is warmed slightly. As a consequence, although no more heat is added, the solution becomes very hot. Explain what has occurred to make the solution so hot.
- Two solutions, when mixed together at room temperature, produce a chemical reaction. When the solutions are boiled and allowed to cool to room temperature before mixing, however, no chemical reaction takes place. Explain.
- In terms of the potential energy in food, explain why eating food is necessary for increasing muscle mass.
- Solution A has a pH of 2, and solution B has a pH of 8. If equal amounts of solutions A and B are mixed, is the resulting solution acidic or basic?
- Given a buffered solution that is based on the following equilibrium,

$$\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$$
 what happens to the pH of the solution if NaHCO_3 is added?
- An enzyme, E, catalyzes the following reaction:

$$\text{A} + \text{B} \xrightarrow{\text{E}} \text{C}$$
 The product, C, however, binds to the active site of the enzyme in a reversible fashion and keeps the enzyme from functioning. What happens if A and B are continually added to a solution that contains a fixed amount of the enzyme?
- Given the materials commonly found in a kitchen, explain how one can distinguish between a protein and a lipid.
- A student is given two unlabeled substances: one a typical phospholipid and one a typical protein. She is asked to determine which substance is the protein and which is the phospholipid. The available techniques allow her to determine the elements in each sample. How can she identify each substance?

Cell Biology and Genetics

3

The cell is the basic structural and functional unit of all living organisms. The characteristic functions of cells include cell metabolism and energy use; synthesis of molecules, such as proteins and nucleic acids; communication between cells; reproduction; and inheritance. Cells are like very complex but minute factories that are always active, carrying out the functions of life. These microscopic factories are so small that an average-sized cell is only one-fifth the size of the smallest dot you can make on a sheet of paper with a sharp pencil. Each human body is made up of trillions of cells. If each cell were the size of a standard brick, the colossal human statue made from those bricks would be 6 miles high!

All the cells of an individual originate from a single fertilized cell. During development, cell division and specialization give rise to a wide variety of cell types, such as nerve, muscle, bone, fat, and blood cells. Each cell type has important characteristics that are critical to the normal function of the body as a whole. One of the important reasons for maintaining homeostasis is to keep the trillions of cells that form the body functioning normally.

This chapter outlines *functions of the cell* (p. 56), *how we see cells* (p. 58), the composition of the *plasma membrane* (p. 58), *membrane lipids* (p. 58), and *membrane proteins* (p. 58). It addresses *movement through the plasma membrane* (p. 64) and *endocytosis and exocytosis* (p. 71). The chapter then addresses the *cytoplasm* (p. 76) and *organelles* (p. 77). It presents *genes and gene expression* (p. 86), the *cell life cycle* (p. 91), and *genetics* (p. 93).

Colorized scanning electron micrograph (SEM) of a dividing cell. Cell division is one of the major features of organisms and is the basis of growth and repair of tissues and organs.

FUNCTIONS OF THE CELL

Because cells are the basic units of all living things, they are the smallest parts of an organism, such as a human, that have the characteristics of life. Although cells may have quite different structures and functions, they share several characteristics (figure 3.1; table 3.1). The **plasma** (plaz'mă), or **cell membrane** forms the outer boundary of the cell, through which the cell interacts with its external environment. The **nucleus** (noo'klē-ūs) is usually located centrally; it directs cell activities, most of which take place in the **cytoplasm** (sī'tō-plazm), located between the plasma membrane and the nucleus. Within cells, specialized structures called **organelles** (or'gā-nelz) perform specific functions.

The characteristic functions of the cell include the following:

1. **Cell metabolism and energy use.** The chemical reactions that occur within cells are referred to as metabolic reactions and collectively as cell metabolism. The energy released from some metabolic reactions provides the energy necessary for cellular activities, such as the synthesis of molecules and muscle contraction. During some metabolic reactions, energy is released as heat, which helps maintain body temperature.

2. **Synthesis of molecules.** Cells synthesize various types of molecules, including proteins, nucleic acids, and lipids. The molecules synthesized by the various cells of the body differ. Therefore, the structural and functional characteristics of cells are determined by the types of molecules they produce.
3. **Communication.** Cells produce and respond to chemical and electrical signals that allow them to communicate with one another. For example, nerve cells produce chemical signals by which they communicate with muscle cells, and muscle cells respond by contracting or relaxing.
4. **Reproduction and inheritance.** Most cells contain a complete copy of all the genetic information of the individual. This genetic information ultimately determines the structural and functional characteristics of the cell. During the growth of an individual, cells divide to produce new cells, each containing the same genetic information. Specialized cells of the body, called gametes, are responsible for transmitting genetic information to the next generation.

1 What are the characteristic functions of the cell?

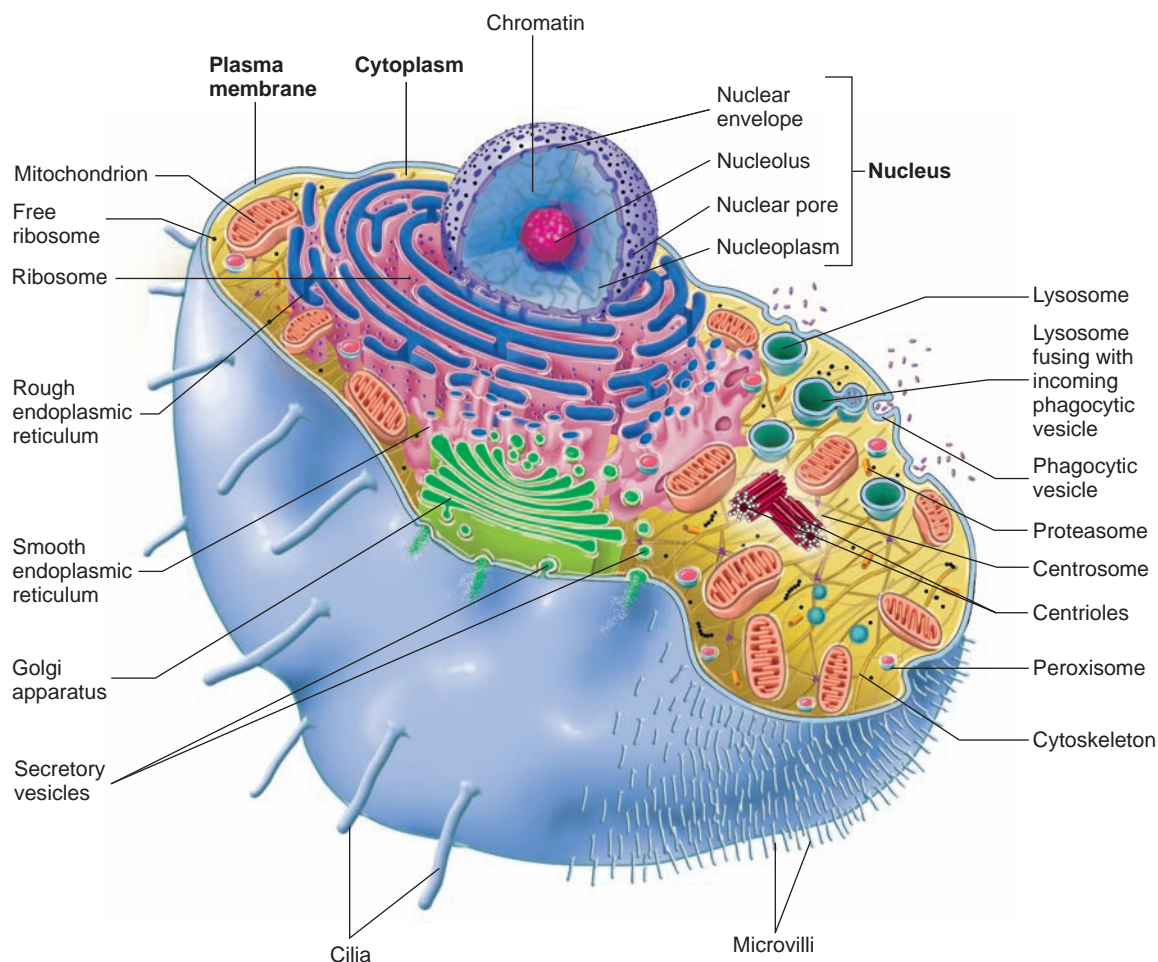

FIGURE 3.1 Cell

A generalized human cell showing the plasma membrane, nucleus, and cytoplasm with its organelles. Although no single cell contains all these organelles, many cells contain a large number of them.

TABLE 3.1 Summary of Cell Parts and Functions

Cell Parts	Structure	Function
Plasma Membrane	Lipid bilayer composed of phospholipids and cholesterol with proteins that extend across or are embedded in either surface of the lipid bilayer	Outer boundary of cells that controls entry and exit of substances; receptor molecules function in intercellular communication; marker molecules enable cells to recognize one another
Cytoplasm: Cytosol		
Fluid part	Water with dissolved ions and molecules; colloid with suspended proteins	Contains enzymes that catalyze decomposition and synthesis reactions; ATP is produced in glycolysis reactions
Cytoskeleton		
Microtubules	Hollow cylinders composed of the protein tubulin; 25 nm in diameter	Support the cytoplasm and form centrioles, spindle fibers, cilia, and flagella; responsible for movement of structures in the cell
Actin filaments	Small fibrils of the protein actin; 8 nm in diameter	Provide structural support to cells, support microvilli, responsible for cell movements
Intermediate filaments	Protein fibers; 10 nm in diameter	Provide structural support to cells
Cytoplasmic inclusions	Aggregates of molecules manufactured or ingested by the cell; may be membrane-bound	Function depends on the molecules: energy storage (lipids, glycogen), oxygen transport (hemoglobin), skin color (melanin), and others
Organelles		
Nucleus		
Nuclear envelope	Double membrane enclosing the nucleus; the outer membrane is continuous with the endoplasmic reticulum; nuclear pores extend through the nuclear envelope	Separates nucleus from cytoplasm and regulates movement of materials into and out of the nucleus
Chromatin	Dispersed, thin strands of DNA, histones, and other proteins; condenses to form chromosomes during cell division	DNA regulates protein (e.g., enzyme) synthesis and therefore the chemical reactions of the cell; DNA is the genetic, or hereditary, material
Nucleolus	One or more dense bodies consisting of ribosomal RNA and proteins	Assembly site of large and small ribosomal subunits
Cytoplasmic Organelles		
Ribosome	Ribosomal RNA and proteins form large and small subunits; attached to endoplasmic reticulum or free ribosomes are distributed throughout the cytoplasm	Site of protein synthesis
Rough endoplasmic reticulum	Membranous tubules and flattened sacs with attached ribosomes	Protein synthesis and transport to Golgi apparatus
Smooth endoplasmic reticulum	Membranous tubules and flattened sacs with no attached ribosomes	Manufactures lipids and carbohydrates; detoxifies harmful chemicals; stores calcium
Golgi apparatus	Flattened membrane sacs stacked on each other	Modifies, packages, and distributes proteins and lipids for secretion or internal use
Secretory vesicle	Membrane-bound sac pinched off Golgi apparatus	Carries proteins and lipids to cell surface for secretion
Lysosome	Membrane-bound vesicle pinched off Golgi apparatus	Contains digestive enzymes
Peroxisome	Membrane-bound vesicle	One site of lipid and amino acid degradation; breaks down hydrogen peroxide
Proteasomes	Tubelike protein complexes in the cytoplasm	Break down proteins in the cytoplasm
Mitochondria	Spherical, rod-shaped, or threadlike structures; enclosed by double membrane; inner membrane forms projections called cristae	Major site of ATP synthesis when oxygen is available
Centrioles	Pair of cylindrical organelles in the centrosome, consisting of triplets of parallel microtubules	Centers for microtubule formation; determine cell polarity during cell division; form the basal bodies of cilia and flagella
Spindle fibers	Microtubules extending from the centrosome to chromosomes and other parts of the cell (i.e., aster fibers)	Assist in the separation of chromosomes during cell division
Cilia	Extensions of the plasma membrane containing doublets of parallel microtubules; 10 μm in length	Move materials over the surface of cells
Flagellum	Extension of the plasma membrane containing doublets of parallel microtubules; 55 μm in length	In humans, responsible for movement of spermatozoa
Microvilli	Extension of the plasma membrane containing microfilaments	Increase surface area of the plasma membrane for absorption and secretion; modified to form sensory receptors

HOW WE SEE CELLS

Most cells are too small to be seen with the unaided eye. As a result, it is necessary to use microscopes to study them. **Light microscopes** allow us to visualize general features of cells. **Electron microscopes**, however, must be used to study the fine structure of cells. A **scanning electron microscope (SEM)** allows us to see features of the cell surface and the surfaces of internal structures. A **transmission electron microscope (TEM)** allows us to see “through” parts of the cell and thus to discover other aspects of cell structure. A more detailed description of microscopes and their use can be found on p. 112.

- 2** Which cell features can be seen with light and electron microscopes?

PLASMA MEMBRANE

The plasma membrane is the outermost component of a cell. It functions as a boundary separating the substances inside the cell, which are **intracellular**, from substances outside the cell, which are **extracellular**. Sometimes extracellular substances are referred to as **intercellular**, meaning between cells. The plasma membrane encloses and supports the cell contents. It attaches cells to the extracellular environment or to other cells. The cells’ ability to recognize and communicate with each other takes place through the plasma membrane. In addition, the plasma membrane determines what moves into and out of cells. As a result, the intracellular contents of cells is different from the extracellular environment.

The regulation of ion movement by cells results in a charge difference across the plasma membrane called the **membrane potential**. The outside of the plasma membrane is positively charged, compared with the inside, because there are more positively charged ions immediately on the outside of the plasma membrane and more negatively charged ions and proteins inside. The membrane potential, an important feature of a living cell’s normal function, will be considered in greater detail in chapters 9 and 11.

The plasma membrane consists of 45%–50% lipids, 45%–50% proteins, and 4%–8% carbohydrates (figure 3.2). The carbohydrates combine with lipids to form glycolipids and with proteins to form glycoproteins. The **glycocalyx** (glī-kō-kā’liks) is the collection of glycolipids, glycoproteins, and carbohydrates on the outer surface of the plasma membrane. The glycocalyx also contains molecules absorbed from the extracellular environment, so there is often no precise boundary where the plasma membrane ends and the extracellular environment begins.

- 3** Define intracellular, extracellular, and intercellular.
4 What is the membrane potential? Is the outside of the plasma membrane positively or negatively charged, compared with the inside?
5 What is the glycocalyx? What types of molecules are found in the glycocalyx?

MEMBRANE LIPIDS

The predominant lipids of the plasma membrane are phospholipids and cholesterol. **Phospholipids** readily assemble to form a **lipid bilayer**, a double layer of phospholipid molecules, because they have a polar (charged) head and a nonpolar (uncharged) tail (see chapter 2). The polar **hydrophilic** (water-loving) heads are exposed to water inside and outside the cell, whereas the nonpolar **hydrophobic** (water-fearing) tails face one another in the interior of the plasma membrane (see figure 3.2). The modern concept of the plasma membrane, the **fluid-mosaic model**, suggests that the plasma membrane is neither rigid nor static in structure but is highly flexible and can change its shape and composition through time. The lipid bilayer functions as a liquid in which other molecules, such as proteins, are suspended. The fluid nature of the lipid bilayer has several important consequences. It provides an important means of distributing molecules within the plasma membrane. In addition, slight damage to the membrane can be repaired because the phospholipids tend to reassemble around damaged sites and close them. The fluid nature of the lipid bilayer also enables membranes to fuse with one another.

Cholesterol is the other major lipid in the plasma membrane (see chapter 2). It is interspersed among the phospholipids and accounts for about one-third of the total lipids in the plasma membrane. The hydrophilic OH group of cholesterol extends between the phospholipid heads to the hydrophilic surface of the membrane, whereas the hydrophobic part of the cholesterol molecule lies within the hydrophobic region of the phospholipids. The amount of cholesterol in a particular plasma membrane is a major factor in determining the fluid nature of the membrane. Cholesterol limits the movement of phospholipids, providing stability to the plasma membrane.

- 6** How do hydrophilic heads and hydrophobic tails of phospholipid molecules result in a plasma membrane?
7 What is the function of cholesterol in plasma membranes?

MEMBRANE PROTEINS

The basic structure of the plasma membrane and some of its functions are determined by its lipids, but many functions of the plasma membrane are determined by its proteins. Some protein molecules, called **integral**, or **intrinsic, proteins**, penetrate deeply into the lipid bilayer, in many cases extending from one surface to the other (figure 3.3), whereas other proteins, called **peripheral**, or **extrinsic, proteins**, are attached to either the inner or outer surfaces of the lipid bilayer. Integral proteins consist of regions made up of amino acids with hydrophobic R groups and other regions of amino acids with hydrophilic R groups (see chapter 2). The hydrophobic regions are located within the hydrophobic part of the membrane, and the hydrophilic regions are located at the inner or outer surface of the membrane or line channels through the membrane. Some

FIGURE 3.2 Plasma Membrane

(a) Fluid-mosaic model of the plasma membrane. The membrane is composed of a bilayer of phospholipids and cholesterol with proteins “floating” in the membrane. The nonpolar hydrophobic region of each phospholipid molecule is directed toward the center of the membrane and the polar hydrophilic region is directed toward the water environment either outside or inside the cell. (b) Colorized transmission electron micrograph of plasma membranes of two adjacent cells. Proteins at either surface of the lipid bilayer stain more readily than the lipid bilayer does and give each membrane the appearance of consisting of three parts: the two yellow, outer parts are proteins and the phospholipid heads, and the red, central part is the phospholipid tails and cholesterol.

peripheral proteins may be bound to integral proteins, whereas others are bound to the polar heads of the phospholipid molecules. Membrane proteins can function as marker molecules, attachment proteins, transport proteins, receptor proteins, or enzymes (table 3.2). The ability of membrane proteins to function depends on their three-dimensional shapes and their chemical characteristics.

Marker Molecules

Marker molecules are cell surface molecules that allow cells to identify one another or other molecules. They are mostly **glycoproteins** (proteins with attached carbohydrates) or **glycolipids** (lipids with

attached carbohydrates). The protein portions of glycoproteins may be either integral or peripheral proteins (figure 3.4). Examples include recognition of an oocyte by a sperm cell and the ability of the immune system to distinguish between self-cells and foreign cells, such as bacteria or donor cells in an organ transplant. Intercellular communication and recognition are important because cells are not isolated entities; they must work together to ensure normal body functions.

Attachment Proteins

Integral proteins may function as **attachment proteins**, which allow cells to attach to other cells or to extracellular molecules

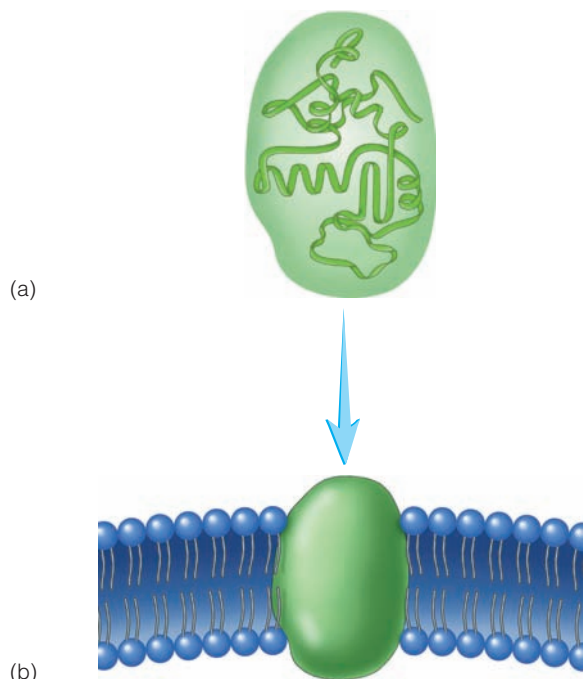

FIGURE 3.3 Proteins in the Plasma Membrane

(a) Proteins are commonly depicted as ribbons (see chapter 2). The space occupied by the protein ribbon can be enclosed by a three-dimensional, shaded region. (b) The shaded region can be depicted as a three-dimensional integral protein inserted into the plasma membrane.

TABLE 3.2 Functions of Membrane Proteins	
Membrane Proteins	Protein Function
Marker molecules	Allow cells to identify one another or other molecules
Attachment proteins	Anchor cells to other cells (cadherins) or to extracellular molecules (integrins)
Transport proteins	
Channel proteins	Form passageways through the plasma membrane, allowing specific ions or molecules to enter or exit the cell; may be gated or nongated
Carrier proteins (transporters)	Move ions or molecules across the membrane; binding of specific chemical to carrier proteins causes changes in the shape of the carrier proteins; the carrier proteins then move the specific chemical across the membrane
ATP-powered pumps	Move specific ions or molecules across the membrane; require ATP molecules to function
Receptor proteins	Function as binding sites for chemical signals in the extracellular fluid; binding of chemical signals to receptors triggers cellular responses
Enzymes	Catalyze chemical reactions either inside or outside cells

FIGURE 3.4 Cell Surface Marker

Glycoproteins that extend to the cell surface allow cells to identify one another or other molecules.

(figure 3.5). Many attachment proteins also attach to intracellular molecules. **Cadherins** are proteins that attach cells to other cells. **Integrins** are proteins that attach cells to extracellular molecules. Integrins function in pairs of integral proteins, which interact with both intracellular and extracellular molecules. Because of the interaction with intracellular molecules, integrins also function in cellular communication.

Transport Proteins

Transport proteins are integral proteins that allow ions or molecules to move from one side of the plasma membrane to the other. Transport proteins include channel proteins, carrier proteins, and ATP-powered pumps.

Channel Proteins

Channel proteins are one or more integral proteins arranged so that they form a tiny channel through the plasma membrane (figure 3.6). The hydrophobic regions of the proteins face outward

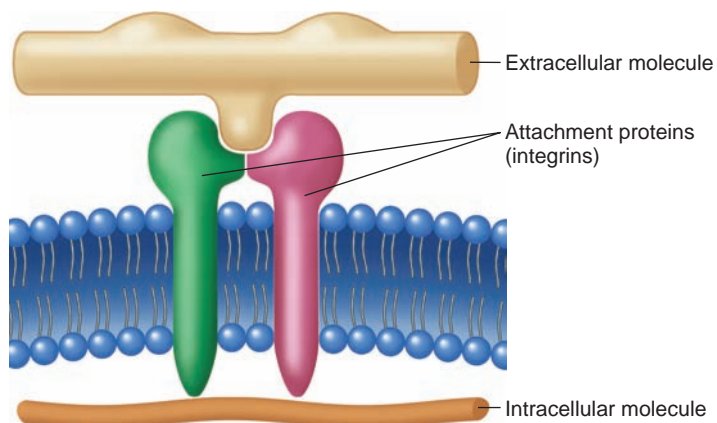

FIGURE 3.5 Attachment Proteins

Proteins (integrins) in the plasma membrane attach to extracellular molecules.

FIGURE 3.6 Channel Protein

toward the hydrophobic part of the plasma membrane, and the hydrophilic regions of the protein face inward and line the channel. Ions or small molecules of the right size, charge, and shape can pass through the channel. The charges in the hydrophilic part of the channel proteins determine which types of ions can pass through the channel.

Some channel proteins, called **nongated ion channels**, are always open and are responsible for the permeability of the plasma membrane to ions when the plasma membrane is at rest. Other channels, called **gated ion channels**, can be open or closed. Some gated ion channels open or close in response to **chemical signals**, or **ligands** (lig'andz, li'gandz), which are small molecules that bind to the proteins or glycoproteins. These are called **ligand-gated ion channels**. Other gated ion channels open or close when there is a change in charge across the plasma membrane. These are called **voltage-gated ion channels**.

Carrier Proteins

Carrier proteins, or **transporters**, are integral membrane proteins that move ions or molecules from one side of the plasma membrane to the other. The carrier proteins have specific binding sites to which ions or molecules attach on one side of the plasma membrane. The carrier proteins change shape to move the bound ions or molecules to the other side of the plasma membrane, where they are released (figure 3.7). The carrier protein then resumes its original shape and is available to transport more molecules.

Movement of ions or molecules by carrier proteins can be classified as uniport, symport, or antiport. **Uniport** is the movement of one specific ion or molecule across the membrane. **Symport** is the movement of two different ions or molecules in the same direction across the plasma membrane, whereas **antiport** is the movement of two different ions or molecules in opposite directions across the plasma membrane. Transport proteins involved in these types of movement are called **uniporters**, **symporters**, and **antiporters**, respectively.

ATP-Powered Pumps

ATP-powered pumps are transport proteins that move specific ions and molecules from one side of the plasma membrane to the other. Unlike carrier proteins, however, the movement of ions or molecules across the membrane is fueled by the breakdown of adenosine triphosphate (ATP). Recall from chapter 2 that energy stored in ATP molecules is used to power many cellular activities. ATP-powered pumps have binding sites, to which specific ions or molecules can bind, as well as a binding site for ATP. The breakdown of ATP to adenosine diphosphate (ADP) releases energy, changing the shape of the protein, which moves the ion or molecule across the membrane (figure 3.8).

Receptor Proteins

Receptor proteins (figure 3.9) are proteins or glycoproteins in the plasma membrane with an exposed **receptor site** on the outer cell surface, which can attach to specific chemical signals. Many receptors and the chemical signals they bind are part of an intercellular communication system that coordinates cell activities. One cell can release a chemical signal that diffuses to another cell and binds to its receptor. The binding acts as a signal that triggers a response. The same chemical signal would have no effect on other cells that lacked the specific receptor molecule.

1. A molecule enters the carrier protein from one side of the plasma membrane.

2. The carrier protein briefly binds the transported molecule.

3. The carrier protein changes shape and releases the transported molecule on the other side of the plasma membrane. The carrier protein then changes back to its original shape (go to step 1).

PROCESS FIGURE 3.7 Carrier Protein

Receptors Linked to Channel Proteins

Some membrane-bound receptors also help form ligand-gated ion channels. The ion channels are composed of proteins that span the plasma membrane. Parts of one or more of the channel proteins form receptors on the cell surface. When chemical signals, or ligands, bind to these receptors, the combination alters the three-dimensional structure of the proteins of the ion channels, causing

1. ATP and ion bind to the ATP-powered pump.

2. The ATP breaks down to adenosine diphosphate (ADP) and a phosphate (P) and releases energy, which powers the shape change in the ATP-powered pump. As a result, the ion moves across the membrane.

3. The ion and phosphate are released from the ATP-powered pump. The pump resumes its original shape (go to step 1).

PROCESS FIGURE 3.8 ATP-Powered Pump

FIGURE 3.9 Receptor Protein

A protein in the plasma membrane with an exposed receptor site, which can attach to specific chemical signals.

the channels either to open or to close. The result is a change in the permeability of the plasma membrane to the specific ions passing through the ion channels (figure 3.10). For example, acetylcholine released from nerve cells is a chemical signal that combines with membrane-bound receptors of skeletal muscle cells. The combination of acetylcholine molecules with the receptor sites opens Na^+ channels in the plasma membrane. Consequently, the Na^+ diffuse into the skeletal muscle cells and trigger events that cause them to contract.

Cystic Fibrosis

Cystic fibrosis is a genetic disorder that affects chloride ion channels. There are three types of cystic fibrosis. In about 70% of cases, a defective channel protein is produced that fails to reach the plasma membrane from its site of production inside the cell. In the remaining cases, the channel protein is incorporated into the plasma membrane but does not function normally. In some cases, the channel protein fails to bind ATP. In others, ATP binds to the channel protein, but the channel does not open. Failure of these ion channels to function results in the affected cells producing thick, viscous secretions. Although cystic fibrosis affects many cell types, its most profound effects are in the pancreas and in the lungs. In the pancreas, the thick secretions block the release of digestive enzymes, resulting in an inability to digest certain types of food and sometimes leading to serious cases of pancreatitis (inflammation of the pancreas). In the lungs, the thick secretions block airways and make breathing difficult. A more detailed description of cystic fibrosis and its consequences can be found in chapter 23.

Receptors Linked to G Protein Complexes

Some membrane-bound receptor molecules function by altering the activity of a **G protein complex** located on the inner surface of the plasma membrane (figure 3.11), which acts as an intermediate between a receptor and other cellular proteins. The G protein complex consists of three proteins, called alpha (α), beta (β), and gamma (γ) proteins. The G protein complex will only associate with a receptor that has a chemical signal bound to it. In its unassociated state, the α subunit of the G protein complex has guanosine diphosphate (GDP) attached to it (figure 3.11, step 1). When a chemical signal binds to the receptor, the receptor becomes associated with the G protein complex. The α subunit releases the GDP and attaches to guanosine triphosphate (GTP) (figure 3.11, step 2). The G protein complex separates from the receptor and the α subunit separates from the β and γ subunits (figure 3.11, step 3). The activated α subunit can stimulate a cell response in at least three ways: (1) by means of intracellular chemical signals, (2) by the opening of ion channels in the plasma membrane, and (3) by the activation of enzymes associated with the plasma membrane.

1. The Na^+ channel has receptor sites for the chemical signal, acetylcholine. When the receptor sites are not occupied by acetylcholine, the Na^+ channel remains closed.

2. When two acetylcholine molecules bind to their receptor sites on the Na^+ channel, the channel opens to allow Na^+ to diffuse through the channel into the cell.

PROCESS FIGURE 3.10 Receptors Linked to a Channel Protein

Drugs and Receptors

Drugs with structures similar to specific chemical signals may compete with those chemical signals for their receptor sites. Depending on the exact characteristics of a drug, it may either bind to a receptor site and activate the receptor or bind to a receptor site and inhibit the action of the receptor. For example, some drugs compete with the chemical signal epinephrine for its receptor sites. Some of these drugs activate epinephrine receptors; others inhibit them.

Enzymes

Some membrane proteins function as **enzymes**, which can catalyze chemical reactions on either the inner or the outer surface of the plasma membrane. For example, some enzymes on the surface

1. A G protein complex will only associate with a receptor that has a chemical signal bound to it. In its unassociated state, the α subunit of the G protein complex has guanosine diphosphate (GDP) attached to it.

2. When a chemical signal binds to the receptor, the receptor becomes associated with the G protein complex. GDP is released from the α subunit and a guanosine triphosphate (GTP) is attached to it.

3. The G protein complex separates from the receptor and the α subunit separates from the other subunits. The α subunit stimulates a cell response.

PROCESS FIGURE 3.11 Receptor Linked to a G Protein Complex

of cells in the small intestine break the peptide bonds of dipeptides to form two single amino acids (figure 3.12). Some membrane-associated enzymes are always active. Others are activated by membrane-bound receptors or G protein complexes.

FIGURE 3.12 Enzyme in the Plasma Membrane

This enzyme in the plasma membrane breaks the peptide bond of a dipeptide to produce two amino acids.

- 8 Describe the difference between integral and peripheral proteins in the plasma membrane. Define glycolipid and glycoprotein.
- 9 List two functions of marker molecules.
- 10 Describe and give the function of cadherins and integrins.
- 11 What are the three classes of transport proteins?
- 12 Define nongated ion channels, ligand-gated ion channels, and voltage-gated ion channels.
- 13 Describe how carrier proteins and ATP-powered pumps move ions or molecules across the plasma membrane.
- 14 Define uniport, symport, and antiport.
- 15 To what part of a receptor molecule does a chemical signal attach? Explain how a chemical signal can bind to a receptor in the plasma membrane and cause a change in membrane permeability.
- 16 Describe how receptors alter the activity of G protein complexes. List three ways in which activated α subunits can stimulate a cell response.
- 17 Give an example of the action of an enzyme in the plasma membrane.

MOVEMENT THROUGH THE PLASMA MEMBRANE

The plasma membrane separates extracellular material from intracellular material and is **selectively permeable**—that is, it allows only certain substances to pass through it. The intracellular material has a different composition than the extracellular material, and the cell's survival depends on the maintenance of these differences. Enzymes, other proteins, glycogen, and potassium ions are found in higher concentrations intracellularly; sodium, calcium, and chloride ions are found in greater concentrations extracellularly.

In addition, nutrients must continually enter the cell, and waste products must exit, but the volume of the cell remains unchanged. Because of the plasma membrane's permeability characteristics and its ability to transport molecules selectively, the cell is able to maintain homeostasis. Rupture of the membrane, alteration of its permeability characteristics, or inhibition of transport processes can disrupt the normal concentration differences across the plasma membrane and lead to cell death.

Molecules and ions can pass through the plasma membrane in four ways:

1. *Directly through the phospholipid membrane.* Molecules that are soluble in lipids, such as oxygen, carbon dioxide, and steroids, pass through the plasma membrane readily by dissolving in the lipid bilayer. The phospholipid bilayer acts as a barrier to most substances that are not lipid-soluble, but some small, nonlipid-soluble molecules, such as carbon dioxide and urea, can diffuse between the phospholipid molecules of the plasma membrane.
2. *Membrane channels.* There are several types of protein channels through the plasma membrane. Each channel type allows only certain molecules to pass through it. The size, shape, and charge of molecules determine whether they can pass through a given channel. For example, sodium ions pass through sodium channels, and potassium and chloride ions pass through potassium and chloride channels, respectively. Rapid movement of water across the cell membrane also occurs through membrane channels.
3. *Transport proteins.* Large polar molecules that are not lipid-soluble, such as glucose and amino acids, cannot pass through the plasma membrane in significant amounts unless they are moved across by transport proteins. Substances that are moved across the plasma membrane by transport proteins are said to be transported by **mediated processes**. Specific molecules bind to specific transport proteins that carry them across the plasma membrane. Transport proteins

that move glucose across the plasma membrane do not move amino acids, and transport proteins that move amino acids across the plasma membrane do not move glucose.

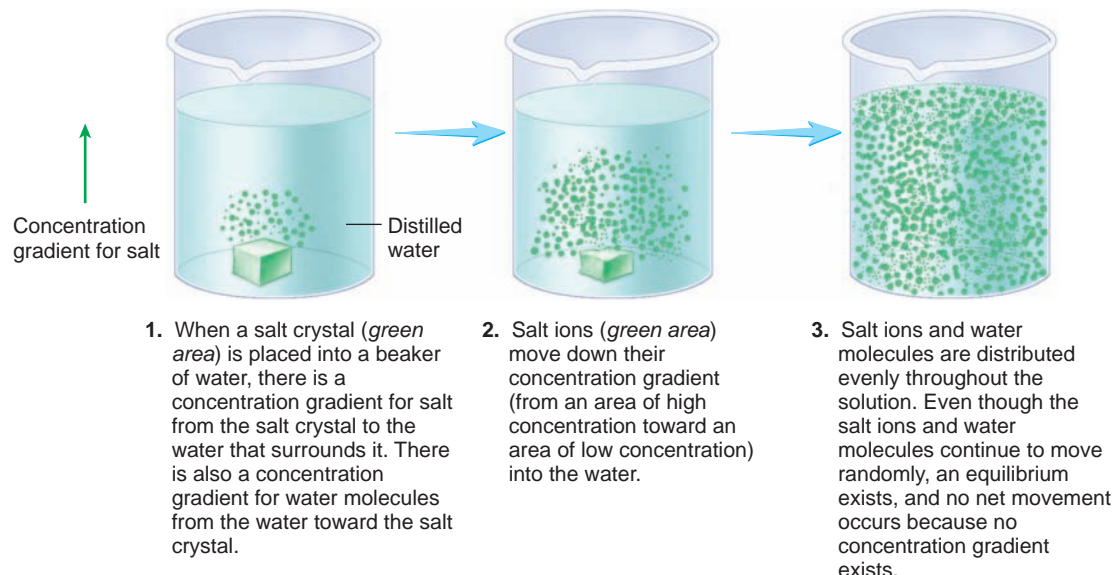

4. *Vesicles.* Large nonlipid-soluble molecules, small pieces of matter, and even whole cells can be transported across the plasma membrane in a **vesicle**, which is a small sac surrounded by a membrane. Because of the fluid nature of membranes, the vesicle and the plasma membrane can fuse, allowing the contents of the vesicle to cross the plasma membrane.

18 List four ways that substances move across the plasma membrane.

Diffusion

A solution consists of one or more substances called **solute**s dissolved in the predominant liquid or gas, which is called the **solvent**. **Diffusion** is the movement of solutes from an area of higher solute concentration to an area of lower solute concentration (figure 3.13). Diffusion is a product of the constant random motion of all atoms, molecules, or ions in a solution. Because there are more solute particles in an area of higher concentration than in an area of lower concentration and because the particles move randomly, the chances are greater that solute particles will move from the higher to the lower concentration than in the opposite direction. Thus, the overall, or net, movement is from the area of higher solute concentration to that of lower solute concentration. At equilibrium, the net movement of solutes stops, although the random molecular motion continues, and the movement of solutes in any one direction is balanced by an equal movement in the opposite direction. The movement and distribution of smoke or perfume throughout a room without air currents and of a dye throughout a beaker of still water are examples of diffusion.

A concentration difference occurs when the concentration of a solute is greater at one point than at another point in a solvent. The concentration difference between two points, divided by the distance

1. When a salt crystal (*green area*) is placed into a beaker of water, there is a concentration gradient for salt from the salt crystal to the water that surrounds it. There is also a concentration gradient for water molecules from the water toward the salt crystal.
2. Salt ions (*green area*) move down their concentration gradient (from an area of high concentration toward an area of low concentration) into the water.
3. Salt ions and water molecules are distributed evenly throughout the solution. Even though the salt ions and water molecules continue to move randomly, an equilibrium exists, and no net movement occurs because no concentration gradient exists.

between the two points, is called the **concentration**, or **density, gradient**. Solutes diffuse down their concentration gradients (from a higher to a lower solute concentration) until an equilibrium is achieved. The greater the concentration gradient, the greater the rate of diffusion of a solute down that gradient. Increasing the concentration difference or decreasing the distance between the two points increases the concentration gradient, whereas decreasing the concentration difference or increasing the distance between the two points decreases the concentration gradient.

The rate of diffusion is influenced by the magnitude of the concentration gradient, the temperature of the solution, the size of the diffusing molecules, and the viscosity of the solvent. The greater the concentration gradient, the greater the number of solute particles moving from a higher to a lower solute concentration. As the temperature of a solution increases, the speed at which all molecules move increases, resulting in a greater diffusion rate. Small molecules diffuse through a solution more readily than do large ones. **Viscosity** is a measure of how easily a liquid flows; thick solutions, such as syrup, are more viscous than water. Diffusion occurs more slowly in viscous solvents than in thin, watery solvents.

Diffusion of molecules is an important means by which substances move between the extracellular and intracellular fluids in the body. Substances that can diffuse through either the lipid bilayer or the membrane channels can pass through the plasma membrane (figure 3.14). Some nutrients enter and some waste products leave the cell by diffusion, and maintenance of the appropriate intracellular concentration of these substances depends to a large degree on diffusion. For example, if the extracellular concentration of oxygen is reduced, inadequate oxygen diffuses into the cell, and normal cell function cannot occur. Some lipid-soluble

1. Certain, specific non-lipid-soluble molecules or ions diffuse through membrane channels.
2. Other non-lipid-soluble molecules or ions, for which membrane channels are not present in the cell, cannot enter the cell.
3. Lipid-soluble molecules diffuse directly through the plasma membrane.

PROCESS FIGURE 3.14 Diffusion Through the Plasma Membrane

FIGURE 3.15 Intracellular Receptor

A small, lipid-soluble chemical signal diffuses through the plasma membrane and combines with the receptor site of an intracellular receptor.

chemical signals can diffuse through the plasma membrane and attach to receptors inside the cell (figure 3.15).

- 19 **Define solute, solvent, and concentration gradient. Do solutes diffuse with (down) or against their concentration gradient?**
- 20 **How is the rate of diffusion affected by an increased concentration gradient? By increased temperature of a solution? By increased viscosity of the solvent?**

PREDICT 1

Urea is a toxic waste produced inside cells. It diffuses from the cells into the blood and is eliminated from the body by the kidneys. What would happen to the intracellular and extracellular concentration of urea if the kidneys stopped functioning?

Osmosis

Osmosis (os-mō'sis) is the diffusion of water (solvent) across a selectively permeable membrane, such as a plasma membrane. A selectively permeable membrane is a membrane that allows water but not all the solutes dissolved in the water to diffuse through the membrane. **Aquaporins**, or water channel proteins, increase membrane permeability to water in some cell types, such as kidney cells. Water diffuses from a solution with proportionately more water, across a selectively permeable membrane, and into a solution with proportionately less water. Because solution concentrations are defined in terms of solute concentrations, not in terms of water content (see chapter 2), water diffuses from the less concentrated solution (fewer solutes, more water) into the more concentrated solution (more solutes, less water). Osmosis is important to cells because large volume changes caused by water movement disrupt normal cell function.

Osmotic pressure is the force required to prevent the movement of water by osmosis across a selectively permeable membrane.

The osmotic pressure of a solution can be determined by placing the solution into a tube that is closed at one end by a selectively permeable membrane (figure 3.16). The tube is then immersed in distilled water. Water molecules move by osmosis through the membrane into the tube, forcing the solution to move up the tube. As the solution rises into the tube, its weight produces hydrostatic pressure, which moves water out of the tube back into the distilled water surrounding the tube. At equilibrium, net movement of water stops, which means the movement of water into the tube by

osmosis is equal to the movement of water out of the tube caused by hydrostatic pressure. The osmotic pressure of the solution in the tube is equal to the hydrostatic pressure that prevents net movement of water into the tube.

The osmotic pressure of a solution provides information about the tendency for water to move by osmosis across a selectively permeable membrane. Because water moves from less concentrated solutions (fewer solutes, more water) into more concentrated solutions (more solutes, less water), the

PROCESS FIGURE 3.16 Osmosis

greater the concentration of a solution (the less water it has), the greater the tendency for water to move into the solution, and the greater the osmotic pressure to prevent that movement. Thus, the greater the concentration of a solution, the greater the osmotic pressure of the solution, and the greater the tendency for water to move into the solution.

PREDICT 2

Given the demonstration in figure 3.16, what would happen to osmotic pressure if the membrane were not selectively permeable but instead allowed all solutes and water to pass through?

Three terms describe the osmotic pressure of solutions. Solutions with the same concentration of solute particles (see chapter 2) have the same osmotic pressure and are referred to as **isosmotic** (ī'sos-mot'ik). The solutions are still isosmotic even if the types of solute particles in the two solutions differ from each other. If one solution has a greater concentration of solute particles, and therefore a greater osmotic pressure than another solution, the first solution is said to be **hyperosmotic** (hī'per-oz-mot'ik) compared with the more dilute solution. The more dilute solution, with the lower osmotic pressure, is **hyposmotic** (hī-pos-mot'ik) compared with the more concentrated solution.

Three additional terms describe the tendency of cells to shrink or swell when placed into a solution. If a cell is placed into a solution in which it neither shrinks nor swells, the solution is said to be **isotonic** (ī-sō-ton'ik). In an isotonic solution, the shape of the cell remains constant, maintaining its internal tension or tone, a condition called **tonicity** (tō-nis'i-tē). If a cell is placed into

a solution and water moves out of the cell by osmosis, causing the cell to shrink, the solution is called **hypertonic** (hī-per-ton'ik). If a cell is placed into a solution and water moves into the cell by osmosis, causing the cell to swell, the solution is called **hypotonic** (hī-pō-ton'ik; figure 3.17a).

An isotonic solution may be isosmotic to the cytoplasm. Because isosmotic solutions have the same concentration of solutes and water as the cytoplasm of the cell, no net movement of water occurs, and the cell neither swells nor shrinks (figure 3.17b). Hypertonic solutions can be hyperosmotic and have a greater concentration of solute molecules and a lower concentration of water than the cytoplasm of the cell. Therefore, water moves by osmosis from the cell into the hypertonic solution, causing the cell to shrink, a process called **crenation** (krē-nā'shūn) in red blood cells (figure 3.17c). Hypotonic solutions can be hyposmotic and have a smaller concentration of solute molecules and a greater concentration of water than the cytoplasm of the cell. Therefore, water moves by osmosis into the cell, causing it to swell. If the cell swells enough, it can rupture, a process called **lysis** (lī'sis; see figure 3.17a). Solutions injected into the circulatory system or the tissues must be isotonic because shrinkage or swelling of cells disrupts their normal function and can lead to cell death.

The *-osmotic* terms refer to the concentration of the solutions, and the *-tonic* terms refer to the tendency of cells to swell or shrink. These terms should not be used interchangeably. Not all isosmotic solutions are isotonic. For example, it is possible to prepare a solution of glycerol and a solution of mannitol that are isosmotic to the cytoplasm of the cell. Because the solutions are isosmotic, they have the same concentration of solutes and

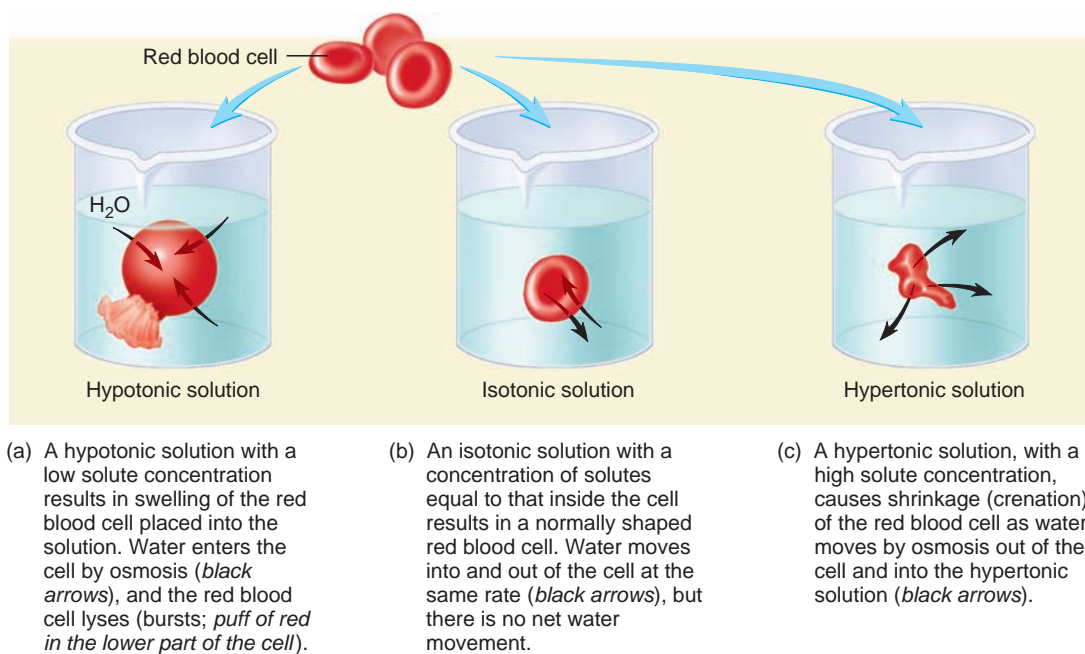

FIGURE 3.17 Effects of Hypotonic, Isotonic, and Hypertonic Solutions on Red Blood Cells

water as the cytoplasm. Glycerol, however, can diffuse across the plasma membrane, but mannitol cannot. When glycerol diffuses into the cell, the solute concentration of the cytoplasm increases, and its water concentration decreases. Therefore, water moves by osmosis into the cell, causing it to swell, and the glycerol solution is both isosmotic and hypotonic. In contrast, mannitol cannot enter the cell, and the isosmotic mannitol solution is also isotonic.

21 Define osmosis and osmotic pressure. As the concentration of a solution increases, what happens to its osmotic pressure and to the tendency for water to move into it?

22 Compare isosmotic, hyperosmotic, and hyposmotic solutions with isotonic, hypertonic, and hypotonic solutions. What type of solution causes crenation of a cell? What type of solution causes lysis of a cell?

Filtration

Filtration results when a partition containing small holes is placed in a stream of moving liquid. The partition works as a minute sieve. Particles small enough to pass through the holes move through the partition with the liquid, but particles larger than the holes are prevented from moving beyond the partition. In contrast to diffusion, filtration depends on a pressure difference on either side of the partition. The liquid moves from the side of the partition with the greater pressure to the side with the lower pressure.

Filtration occurs in the kidneys as a step in urine formation. Blood pressure moves fluid from the blood through a partition, or filtration membrane. Water, ions, and small molecules pass through the partition, whereas most proteins and blood cells remain in the blood.

23 Define filtration and give an example of where it occurs in the body.

Mediated Transport

Many essential molecules, such as amino acids and glucose, cannot enter the cell by diffusion, and many products, such as proteins, cannot exit the cell by diffusion. **Mediated transport** is the process by which transport proteins mediate, or assist in, the movement of large, water-soluble molecules or electrically charged molecules or ions across the plasma membrane. All three types of transport proteins—carrier proteins (transporters), ATP-powered pumps, and channel proteins (ion channels)—are involved in mediated transport.

Mediated transport has three characteristics: specificity, competition, and saturation. **Specificity** means that each transport protein binds to and transports only a single type of molecule or ion (figure 3.18a). For example, the transport protein that moves glucose does not move amino acids or ions. The chemical structure of the binding site determines the specificity of the transport protein (see figure 3.7). **Competition** is the result of similar molecules binding to the transport protein. Although

(a) Specificity. Only molecules that are the right shape to bind to the binding site are transported.

(b) Competition. Similarly shaped molecules can compete for the same binding site.

FIGURE 3.18 Mediated Transport: Specificity and Competition

the binding sites of transport proteins exhibit specificity, closely related substances, in which regions of two different molecules have the same shape, may bind to the same binding site. The substance in the greater concentration or the substance that binds to the binding site more readily is moved across the plasma membrane at the greater rate (figure 3.18b). **Saturation** means that the rate of movement of molecules across the membrane is limited by the number of available transport proteins. As the concentration of a transported substance increases, more transport proteins have their binding sites occupied. The rate at which the substance is moved across the plasma membrane increases; however, once the concentration of the substance is increased so that all the binding sites are occupied, the rate of movement remains constant, even though the concentration of the substance increases further (figure 3.19).

Ion channels often are thought of as simple tubes, with or without gates, through which ions pass. Many ion channels, however, appear to be more complex than once thought. It now appears that ions briefly bind to specific sites inside channels, and that there is a change in the shape of those channels as ions are transported through them. The size and charge within a channel determine the channel's specificity. For example, Na^+ channels do not transport K^+ and vice versa. In addition, similar ions moving into and binding within an ion channel are in competition with each other. Furthermore, the number of ions moving into an ion

PROCESS FIGURE 3.19 Saturation of a Transport Protein

channel can exceed the capacity of the channel, thus saturating the channel. Therefore, ion channels exhibit specificity, competition, and saturation.

Three kinds of mediated transport exist: facilitated diffusion, active transport, and secondary active transport.

Facilitated Diffusion

Facilitated diffusion is a carrier-mediated or channel-mediated process that moves substances into or out of cells from a higher to a lower concentration (figure 3.20). Facilitated diffusion does not require metabolic energy to transport substances across the plasma membrane. The rate at which molecules or ions are transported is directly proportional to their concentration gradient up to the point of saturation, when all the carrier proteins or channels are occupied. Then the rate of transport remains constant at its maximum rate.

PREDICT 3

The transport of glucose into and out of most cells, such as muscle and fat cells, occurs by facilitated diffusion. Once glucose enters a cell, it is rapidly converted to other molecules, such as glucose-6-phosphate or glycogen. What effect does this conversion have on the cell's ability to acquire glucose? Explain.

Active Transport

Active transport is a mediated transport process that requires energy provided by ATP (figure 3.21). Movement of the transported substance to the opposite side of the membrane and its subsequent release from the ATP-powered pump are fueled by the breakdown of ATP. The maximum rate at which active transport proceeds depends on the number of ATP-powered pumps in the plasma membrane and the availability of adequate ATP. Active-transport processes are important because they can move

PROCESS FIGURE 3.20 Facilitated Diffusion

substances against their concentration gradients—that is, from lower concentrations to higher concentrations. Consequently, they can accumulate substances on one side of the plasma membrane at concentrations many times greater than those on the other side. Active transport can also move substances from higher to lower concentrations.

Some active-transport mechanisms exchange one substance for another. For example, the **sodium–potassium ($\text{Na}^+ - \text{K}^+$) pump** moves Na^+ out of cells and K^+ into cells (see figure 3.21). The result is a higher concentration of Na^+ outside the cell and a higher concentration of K^+ inside the cell. Because ATP is broken down during the transport of Na^+ and K^+ , the pump is also called **sodium–potassium ATP-ase**. The $\text{Na}^+ - \text{K}^+$ pump is very important to a number of cell functions. These are discussed in chapters 9 and 11.

Secondary Active Transport

Secondary active transport involves the active transport of an ion, such as sodium, out of a cell, establishing a concentration gradient, with a higher concentration of the ions outside the cell. The tendency

for the ions to move back into the cell, down their concentration gradient, provides the energy necessary to move a different ion or some other molecule into the cell. For example, glucose is moved from the lumen of the intestine into epithelial cells by secondary active transport (figure 3.22). This process requires two transport proteins: (1) a $\text{Na}^+ - \text{K}^+$ pump actively moves Na^+ out of the cell, and (2) a carrier protein facilitates the movement of Na^+ and glucose into the cell. Both Na^+ and glucose are necessary for the carrier protein to function.

The movement of Na^+ down their concentration gradient provides the energy to move glucose molecules into the cell against their concentration gradient. Thus, glucose can accumulate at concentrations higher inside the cell than outside. Because the movement of glucose molecules against their concentration gradient results from the formation of a concentration gradient of Na^+ by an active-transport mechanism, the process is called secondary active transport.

- 24** What is mediated transport? What types of molecules are moved through the plasma membrane by mediated transport?
- 25** Describe specificity, competition, and saturation as characteristics of mediated transport mechanisms.
- 26** Contrast facilitated diffusion and active transport in relation to energy expenditure and movement of substances with or against their concentration gradients.
- 27** What is secondary active transport?

PREDICT 4

In cardiac (heart) muscle cells, the force of contraction increases as the intracellular Ca^{2+} concentration increases. Intracellular Ca^{2+} concentration is regulated in part by secondary active transport involving a $\text{Na}^+ - \text{Ca}^{2+}$ antiporter. The movement of Na^+ down their concentration gradient into the cell provides the energy to transport Ca^{2+} out of the cell against their concentration gradient. Digitalis, a drug often used to treat congestive heart failure, slows the active transport of Na^+ out of the cell by the $\text{Na}^+ - \text{K}^+$ pump, thereby increasing intracellular Na^+ concentration. Should the heart beat more or less forcefully when exposed to this drug? Explain.

ENDOCYTOSIS AND EXOCYTOSIS

Endocytosis (en'dō-sī-tō'sis), or the internalization of substances, includes both phagocytosis and pinocytosis and refers to the uptake of material through the plasma membrane by the formation of a vesicle. A **vesicle** is a membrane-bound sac found within the cytoplasm of a cell. A portion of the plasma membrane wraps around a particle or droplet and fuses so that the particle or droplet is surrounded by a membrane. That portion of the membrane then “pinches off” so that the particle or droplet, surrounded by a membrane, is within the cytoplasm of the cell, and the plasma membrane is left intact.

Phagocytosis (fāg-ō-sī-tō'sis) literally means cell-eating (figure 3.23) and applies to endocytosis when solid particles are ingested and phagocytic vesicles are formed. White blood cells and some other cell types phagocytize bacteria, cell debris, and foreign

1. Three sodium ions (Na^+) and adenosine triphosphate (ATP) bind to the Na^+-K^+ pump.

2. The ATP breaks down to adenosine diphosphate (ADP) and a phosphate (P) and releases energy. That energy is used to power a shape change in the Na^+-K^+ pump. Phosphate remains bound to the Na^+-K^+ -ATP binding site.

3. The Na^+-K^+ pump changes shape, and the Na^+ are transported across the membrane.

4. The Na^+ diffuse away from the Na^+-K^+ pump.

5. Two potassium ions (K^+) bind to the Na^+-K^+ pump.

6. The phosphate is released from the Na^+-K^+ pump binding site.

7. The Na^+-K^+ pump resumes its original shape, transporting K^+ across the membrane, and the K^+ diffuse away from the pump. The Na^+-K^+ pump can again bind to Na^+ and ATP.

PROCESS FIGURE 3.21 Sodium–Potassium Pump

particles. Phagocytosis is therefore important in the elimination of harmful substances from the body.

Pinocytosis (pin'ō-sī-tō'sis) means cell-drinking and is distinguished from phagocytosis in that smaller vesicles are formed, and they contain molecules dissolved in liquid rather than particles (figure 3.24). Pinocytosis often forms vesicles near the tips of deep invaginations of the plasma membrane. It is a common transport

phenomenon in a variety of cell types and occurs in certain cells of the kidneys, epithelial cells of the intestines, cells of the liver, and cells that line capillaries.

Endocytosis can exhibit specificity. For example, cells that phagocytize bacteria and necrotic tissue do not phagocytize healthy cells. The plasma membrane may contain specific receptor molecules that recognize certain substances and allow them to be

1. A $\text{Na}^+\text{-K}^+$ pump maintains a concentration of Na^+ that is higher outside the cell than inside.
2. Sodium ions move back into the cell through a transport protein that also moves glucose. The concentration gradient for Na^+ provides energy required to move glucose against its concentration gradient.

PROCESS FIGURE 3.22 Secondary Active Transport (Symport) of Na^+ and Glucose

transported into the cell by phagocytosis or pinocytosis. This is called **receptor-mediated endocytosis**, and the receptor sites combine only with certain molecules (figure 3.25). This mechanism increases the rate at which specific substances are taken up by the cells. Cholesterol and growth factors are examples of molecules that can be taken into a cell by receptor-mediated endocytosis. Both phagocytosis and pinocytosis require energy in the form of ATP and therefore are active processes. Because they involve the bulk movement of material into the cell, however, phagocytosis and pinocytosis do not exhibit the degree of specificity or saturation that active transport exhibits.

(b)

FIGURE 3.23 Endocytosis

(a) Phagocytosis. (b) Scanning electron micrograph of phagocytosis of red blood cells.

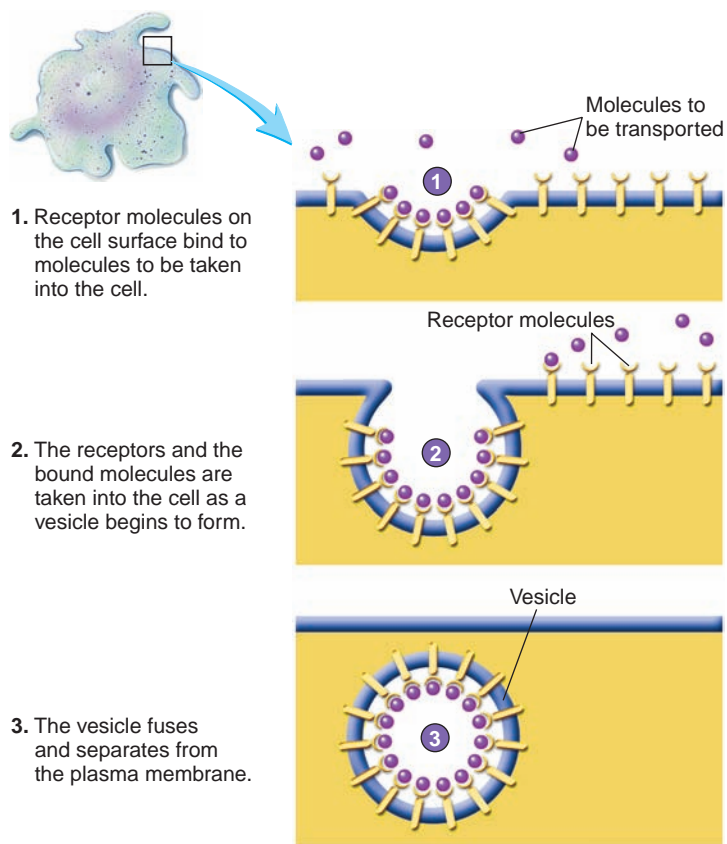

FIGURE 3.24 Pinocytosis

Pinocytosis is much like phagocytosis, except that the cell processes and therefore the vesicles formed are much smaller and the material inside the vesicle is liquid rather than particulate. Pinocytotic vesicles form on the internal side of a capillary, are transported across the cell, and open by exocytosis outside the capillary.

PROCESS FIGURE 3.25 Receptor-Mediated Endocytosis

PROCESS FIGURE 3.26 Exocytosis

(a) Diagram of exocytosis. (b) Transmission electron micrograph of exocytosis.

Hypercholesterolemia

Hypercholesterolemia is a common genetic disorder affecting 1 in every 500 adults in the United States. It consists of a reduction in or absence of low-density lipoprotein (LDL) receptors on cell surfaces. This interferes with receptor-mediated endocytosis of LDL cholesterol. As a result of inadequate cholesterol uptake, cholesterol synthesis within these cells is not regulated, and too much cholesterol is produced. The excess cholesterol accumulates in blood vessels, resulting in atherosclerosis. Atherosclerosis can result in heart attacks or strokes. A more detailed description of hypercholesterolemia can be found in chapter 24.

In some cells, secretions accumulate within vesicles. These secretory vesicles then move to the plasma membrane, where the membrane of the vesicle fuses with the plasma membrane and the content of the vesicle is expelled from the cell. This process is called **exocytosis** (ek'sō-sī-tō'sis; figure 3.26). Secretion of digestive enzymes by the pancreas and secretion of mucus by the salivary glands are examples of exocytosis.

Table 3.3 summarizes and compares the mechanisms by which different kinds of molecules are transported across the plasma membrane.

28 Define endocytosis and vesicle. How do phagocytosis and pinocytosis differ from each other?

29 What is receptor-mediated endocytosis?

30 Describe and give examples of exocytosis.

TABLE 3.3 Comparison of Membrane Transport Mechanisms

Transport Mechanism	Description	Substances Transported	Example
Diffusion	Random movement of molecules results in net movement from areas of higher to lower concentration.	Lipid-soluble molecules dissolve in the lipid bilayer and diffuse through it; ions and small molecules diffuse through membrane channels.	Oxygen, carbon dioxide, and lipids, such as steroid hormones, dissolve in the lipid bilayer; Cl^- and urea move through membrane channels.
Osmosis	Water diffuses across a selectively permeable membrane.	Water diffuses through the lipid bilayer.	Water moves from the intestines into the blood.
Filtration	Liquid moves through a partition that allows some, but not all, of the substances in the liquid to pass through it; movement is due to a pressure difference across the partition.	Liquid and substances pass through holes in the partition.	Filtration in the kidneys allows removal of everything from the blood except proteins and blood cells.
Facilitated diffusion	Carrier proteins combine with substances and move them across the plasma membrane; no ATP is used; substances are always moved from areas of higher to lower concentration; it exhibits the characteristics of specificity, saturation, and competition.	Some substances too large to pass through membrane channels and too polar to dissolve in the lipid bilayer are transported.	Glucose moves by facilitated diffusion into muscle cells and fat cells.
Active transport	ATP-powered pumps combine with substances and move them across the plasma membrane; ATP is used; substances can be moved from areas of lower to higher concentration; it exhibits the characteristics of specificity, saturation, and competition.	Substances too large to pass through channels and too polar to dissolve in the lipid bilayer are transported; substances that are accumulated in concentrations higher on one side of the membrane than on the other are transported.	Ions, such as Na^+ , K^+ , and Ca^{2+} , are actively transported.
Secondary active transport	Ions are moved across the plasma membrane by active transport, which establishes an ion concentration gradient; ATP is required; ions then move back down their concentration gradient by facilitated diffusion, and another ion or molecule moves with the diffusion ion (symport) or in the opposite direction (antiport).	Some sugars, amino acids, and ions are transported.	There is a concentration gradient for Na^+ into intestinal epithelial cells. This gradient provides the energy for the symport of glucose. As Na^+ enter the cell, down their concentration gradient, glucose also enters the cell. In many cells, H^+ are moved in the opposite direction of Na^+ (antiport).
Endocytosis	The plasma membrane forms a vesicle around the substances to be transported, and the vesicle is taken into the cell; this requires ATP; in receptor-mediated endocytosis, specific substances are ingested.	Phagocytosis takes in cells and solid particles; pinocytosis takes in molecules dissolved in liquid.	Immune system cells called phagocytes ingest bacteria and cellular debris; most cells take in substances through pinocytosis.
Exocytosis	Materials manufactured by the cell are packaged in secretory vesicles that fuse with the plasma membrane and release their contents to the outside of the cell; this requires ATP.	Proteins and other water-soluble molecules are transported out of cells.	Digestive enzymes, hormones, neurotransmitters, and glandular secretions are transported, and cell waste products are eliminated.

CYTOPLASM

Cytoplasm, the cellular material outside the nucleus but inside the plasma membrane, is about half cytosol and half organelles.

Cytosol

Cytosol (sī'tō-sol) consists of a fluid portion, a cytoskeleton, and cytoplasmic inclusions. The fluid portion of cytosol is a solution with dissolved ions and molecules and a colloid with suspended molecules, especially proteins. Many of these proteins are enzymes that catalyze the breakdown of molecules for energy or the synthesis of sugars, fatty acids, nucleotides, amino acids, and other molecules.

Cytoskeleton

The **cytoskeleton** supports the cell and holds the nucleus and other organelles in place. It is also responsible for cell movements, such as changes in cell shape and the movement of cell organelles. The cytoskeleton consists of three groups of proteins: microtubules, actin filaments, and intermediate filaments (figure 3.27).

Microtubules are hollow tubules composed primarily of protein units called **tubulin**. The microtubules are about 25 nanometers (nm) in diameter, with walls about 5 nm thick. Microtubules vary in length but are normally several micrometers (μm) long. Microtubules play a variety of roles within cells. They help provide

support and structure to the cytoplasm of the cell, much like an internal scaffolding. They are involved in the process of cell division and in the transport of intracellular materials, and they form essential components of certain cell organelles, such as centrioles, spindle fibers, cilia, and flagella.

Actin filaments, or **microfilaments**, are small fibrils about 8 nm in diameter that form bundles, sheets, or networks in the cytoplasm of cells. These filaments have a spiderweb-like appearance within the cell. Actin filaments provide structure to the cytoplasm and mechanical support for microvilli. Actin filaments support the plasma membrane and define the shape of the cell. Changes in cell shape involve the breakdown and reconstruction of actin filaments. These changes in shape allow some cells to move about. Muscle cells contain a large number of highly organized actin filaments, which are responsible for the muscle's contractile capabilities (see chapter 9).

Intermediate filaments are protein fibers about 10 nm in diameter. They provide mechanical strength to cells. For example, intermediate filaments support the extensions of nerve cells, which have a very small diameter but can be a meter in length.

Cytoplasmic Inclusions

The cytosol also contains **cytoplasmic inclusions**, which are aggregates of chemicals either produced by the cell or taken in by the cell.

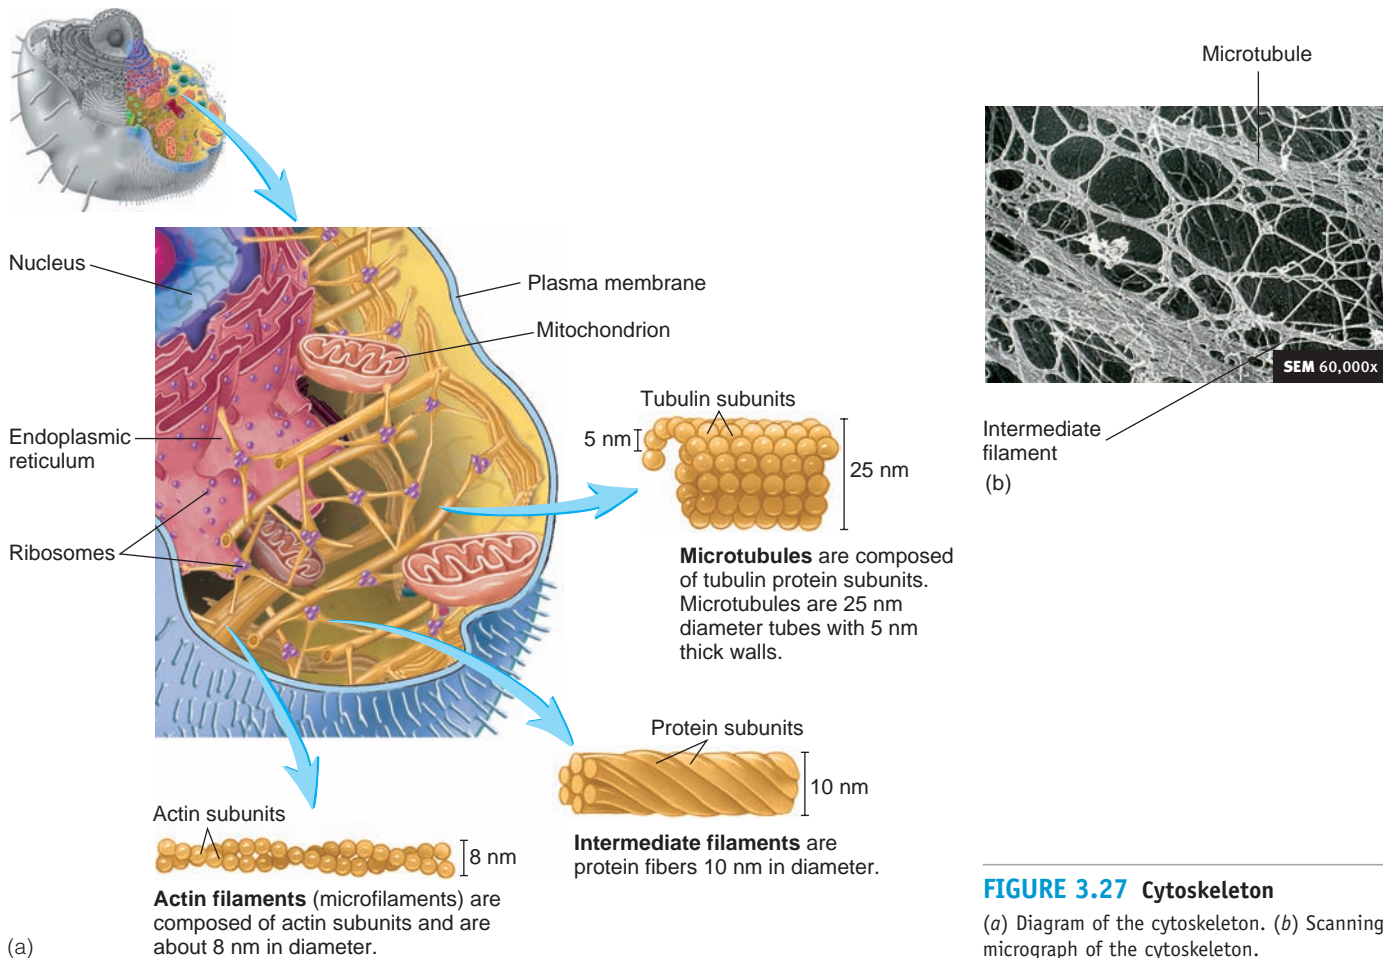

FIGURE 3.27 Cytoskeleton

(a) Diagram of the cytoskeleton. (b) Scanning electron micrograph of the cytoskeleton.

For example, lipid droplets or glycogen granules store energy-rich molecules; hemoglobin in red blood cells transports oxygen; melanin is a pigment that colors the skin, hair, and eyes; and **lipochromes** (lip'ō-krōmz) are pigments that increase in amount with age. Dust, minerals, and dyes can also accumulate in the cytoplasm.

- 31** Define cytoplasm and cytosol.
32 What are the two general functions of the cytoskeleton?
33 Describe and list the functions of microtubules, actin filaments, and intermediate filaments.
34 Define and give examples of cytoplasmic inclusions. What are lipochromes?

THE NUCLEUS AND CYTOPLASMIC ORGANELLES

Organelles are structures within cells that are specialized for particular functions, such as manufacturing proteins or producing ATP. Organelles can be thought of as individual workstations within the cell, each responsible for performing specific tasks. Most, but not all, organelles have membranes that are similar to the plasma membrane. The membranes separate the interior of the organelles from the cytoplasm, creating subcellular compartments with their own enzymes that are capable of carrying out unique

chemical reactions. The nucleus is the largest organelle of the cell. The remaining organelles are referred to as cytoplasmic organelles (see table 3.1).

The number and type of cytoplasmic organelles within each cell are related to the specific structure and function of the cell. Cells secreting large amounts of protein contain well-developed organelles that synthesize and secrete protein, whereas cells actively transporting substances, such as sodium ions, across their plasma membrane contain highly developed organelles that produce ATP. The following sections describe the structure and main functions of the nucleus and major cytoplasmic organelles found in cells.

Nucleus

The **nucleus** is a large, membrane-bound structure usually located near the center of the cell. It may be spherical, elongated, or lobed, depending on the cell type. All cells of the body have a nucleus at some point in their life cycle (see p. 91), although some cells, such as red blood cells, lose their nuclei as they develop. Other cells, such as skeletal muscle cells and certain bone cells, called osteoclasts, contain more than one nucleus.

The nucleus consists of **nucleoplasm** surrounded by a **nuclear envelope** (figure 3.28) composed of two membranes separated by a space. At many points on the surface of the nuclear envelope, the inner and outer membranes fuse to form porelike structures

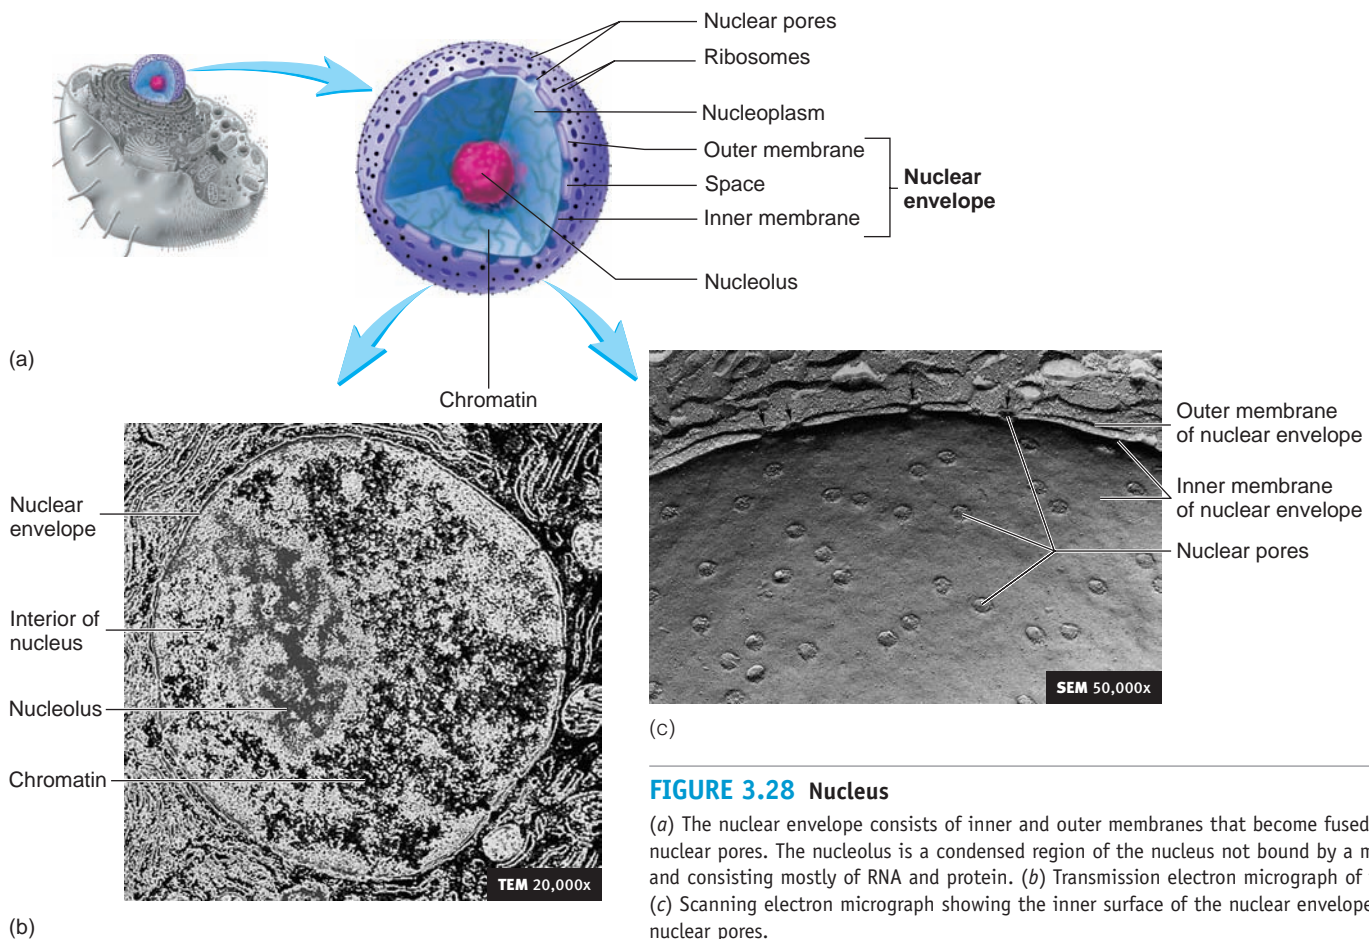

FIGURE 3.28 Nucleus

(a) The nuclear envelope consists of inner and outer membranes that become fused at the nuclear pores. The nucleolus is a condensed region of the nucleus not bound by a membrane and consisting mostly of RNA and protein. (b) Transmission electron micrograph of the nucleus. (c) Scanning electron micrograph showing the inner surface of the nuclear envelope and the nuclear pores.

FIGURE 3.29 Chromosome Structure

(a) DNA is associated with globular histone proteins and other DNA-binding proteins. DNA molecules and bound proteins are called chromatin. During cell division, the chromatin condenses so that individual structures, called chromosomes, become visible. (b) Transmission electron micrograph of chromatin.

called **nuclear pores**. Molecules move between the nucleus and the cytoplasm through these nuclear pores.

Deoxyribonucleic acid (DNA) is mostly found within the nucleus (see figure 2.26), although small amounts of DNA are also found within mitochondria (see p. 83). Nuclear DNA and associated proteins are organized into discrete structures called **chromosomes** (krō'mō-sōmz; colored bodies; figure 3.29). The proteins include **histones** (his'tōnz), which are important for the structural organization of DNA, and other proteins that regulate DNA function. During most of the life cycle of a cell, the chromosomes are dispersed throughout the nucleus as delicate filaments referred to as **chromatin** (krō'ma-tin; colored material; see figures 3.28 and 3.29). During cell division (see p. •••), the dispersed chromatin becomes densely coiled, forming compact chromosomes. At the beginning of cell division, each chromosome consists of two **chromatids** (krō'ma-tids), which are attached at a single point called the **centromere** (sen'trō-mēr). The **kinetochore** (ki-nē'tō-kōr, ki-net'ō-kōr), a protein structure within the centromere, provides a point of attachment for microtubules during cell division.

DNA determines the structural and functional characteristics of the cell by specifying the structure of proteins. Proteins form

many structural components of the cell and all the enzymes, which regulate most chemical reactions in the cell. DNA establishes the structure of proteins by specifying the sequence of their amino acids (see figure 2.22). DNA is a large molecule that does not leave the nucleus but functions by means of an intermediate, **ribonucleic acid (RNA)**, which can leave the nucleus through nuclear pores. DNA determines the structure of messenger RNA (mRNA), ribosomal RNA (rRNA), and transfer RNA (tRNA) (all described in more detail on p. 86). A sequence of nucleotides in a DNA molecule that specifies the structure of a protein or RNA molecule is called a **gene**.

Because mRNA synthesis occurs within the nucleus, cells without nuclei accomplish protein synthesis only as long as the mRNA produced before the nucleus degenerates remains functional. The nuclei of developing red blood cells are expelled from the cells before the red blood cells enter the blood, where they survive without a nucleus for about 120 days. In comparison, many cells with nuclei, such as nerve and skeletal muscle cells, survive as long as the person survives.

A **nucleolus** (noo-klē'ō-lūs) is a somewhat rounded, dense region within the nucleus that lacks a surrounding membrane (figure 3.30). Usually, one nucleolus exists per nucleus, but

1. Ribosomal proteins, produced in the cytoplasm, are transported through nuclear pores into the nucleolus.
2. rRNA, most of which is produced in the nucleolus, is assembled with ribosomal proteins to form small and large ribosomal subunits.
3. The small and large ribosomal subunits leave the nucleolus and the nucleus through nuclear pores.
4. The small and large subunits, now in the cytoplasm, combine with each other and with mRNA during protein synthesis.

PROCESS FIGURE 3.30 Production of Ribosomes

several nucleoli may also be seen in the nuclei of rapidly dividing cells. The nucleolus incorporates portions of 10 chromosomes (5 pairs), called **nucleolar organizer regions**. These regions contain DNA from which rRNA is produced. Within the nucleolus, the subunits of ribosomes are manufactured (see the section “Ribosomes” below).

- 35 **Define organelles.**
- 36 **Describe the structure of the nucleus and nuclear envelope. What is the function of the nuclear pores?**
- 37 **What molecules are found in chromatin? When does chromatin become a chromosome?**
- 38 **List the types of RNA whose structure is determined by DNA. How can DNA control the structural and functional characteristics of the cell without leaving the nucleus?**
- 39 **Describe the nucleolus. Define and give the function of the nucleolar organizer regions.**

Ribosomes

Ribosomes (rī'bō-sōms) are the sites of protein synthesis. Each ribosome is composed of a large subunit and a smaller one. The ribosomal subunits, which consist of **ribosomal RNA (rRNA)** and proteins, are produced separately in the nucleolus of the nucleus. The ribosomal subunits then move through the nuclear pores

into the cytoplasm, where the ribosomal subunits assemble with mRNA to form the functional ribosome during protein synthesis (see figure 3.30). Ribosomes can be found free in the cytoplasm or associated with an intracellular membrane complex called the endoplasmic reticulum. **Free ribosomes** primarily synthesize proteins used inside the cell, whereas ribosomes attached to the endoplasmic reticulum usually produce proteins that are secreted from the cell.

- 40 **What kinds of molecules combine to form ribosomes? Where are ribosomal subunits formed and assembled?**
- 41 **Compare the functions of free ribosomes and ribosomes attached to the endoplasmic reticulum.**

Endoplasmic Reticulum

The outer membrane of the nuclear envelope is continuous with a series of membranes distributed throughout the cytoplasm of the cell (see figure 3.1), collectively referred to as the **endoplasmic reticulum** (en'dō-plas'mik re-tik'ū-lūm; network inside the cytoplasm; figure 3.31). The endoplasmic reticulum consists of broad, flattened, interconnecting sacs and tubules. The interior spaces of those sacs and tubules are called **cisternae** (sis-ter'nē) and are isolated from the rest of the cytoplasm.

The **rough endoplasmic reticulum** is called “rough” because it has ribosomes attached to it. The ribosomes of the rough

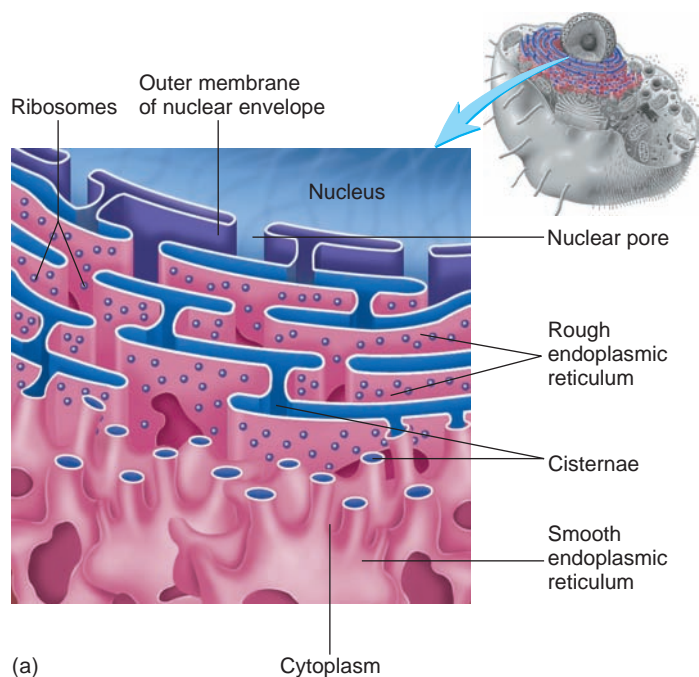

FIGURE 3.31 Endoplasmic Reticulum

(a) The endoplasmic reticulum is continuous with the nuclear envelope and occurs either as rough endoplasmic reticulum (with ribosomes) or as smooth endoplasmic reticulum (without ribosomes). (b) Transmission electron micrograph of the rough endoplasmic reticulum.

endoplasmic reticulum are sites where proteins are produced and modified for secretion and for internal use. The amount and configuration of the endoplasmic reticulum within the cytoplasm depend on the cell type and function. Cells with abundant rough endoplasmic reticulum synthesize large amounts of protein that are secreted for use outside the cell.

Smooth endoplasmic reticulum, which is endoplasmic reticulum without attached ribosomes, manufactures lipids, such as phospholipids, cholesterol, steroid hormones, and carbohydrates. Many phospholipids produced in the smooth endoplasmic reticulum help form vesicles within the cell and contribute to the plasma membrane. Cells that synthesize large amounts of lipid contain dense accumulations of smooth endoplasmic reticulum. Enzymes required for lipid synthesis are associated with the membranes of the smooth endoplasmic reticulum. Smooth endoplasmic reticulum also participates in the detoxification processes by which enzymes act on chemicals and drugs to change their structure and reduce their toxicity. The smooth endoplasmic reticulum of skeletal muscle stores calcium ions that function in muscle contraction.

Golgi Apparatus

The **Golgi** (gōl'jē) **apparatus** (figure 3.32) is composed of flattened, membranous sacs, containing cisternae, that are stacked on each other, like dinner plates. The Golgi apparatus can be thought of as a packaging and distribution center because it modifies, packages, and distributes proteins and lipids manufactured by the rough and smooth endoplasmic reticula (figure 3.33). Proteins produced at the ribosomes of the rough endoplasmic reticulum enter the endoplasmic reticulum and then are surrounded by a **vesicle** (ves'i-kl), or little sac, that forms from the membrane

of the endoplasmic reticulum. This vesicle, called a **transport vesicle**, moves to the Golgi apparatus, fuses with its membrane, and releases the protein into its cisterna. The Golgi apparatus concentrates and, in some cases, chemically modifies the proteins by synthesizing and attaching carbohydrate molecules to the proteins to form glycoproteins or by attaching lipids to proteins to form lipoproteins. The proteins are then packaged into vesicles that pinch off from the margins of the Golgi apparatus and are distributed to various locations. Some vesicles carry proteins to the plasma membrane, where the proteins are secreted from the cell by exocytosis; other vesicles contain proteins that become part of the plasma membrane; and still other vesicles contain enzymes that are used within the cell.

The Golgi apparatus is most highly developed in cells that secrete large amounts of protein or glycoproteins, such as cells in the salivary glands and the pancreas.

42 *How is the endoplasmic reticulum related to the nuclear envelope? How are the cisternae of the endoplasmic reticulum related to the rest of the cytoplasm?*

43 *What are the functions of smooth endoplasmic reticulum?*

44 *Describe the structure and function of the Golgi apparatus.*

45 *Describe the production of a protein at the endoplasmic reticulum and its distribution to the Golgi apparatus. Name three ways in which proteins are distributed from the Golgi apparatus.*

Secretory Vesicles

The membrane-bound **secretory vesicles** (see figure 3.32) that pinch off from the Golgi apparatus move to the surface of the cell, their membranes fuse with the plasma membrane, and the

FIGURE 3.32 Golgi Apparatus

1. Some proteins are produced at ribosomes on the surface of the rough endoplasmic reticulum and are transferred into the cisterna as they are produced.
2. The proteins are surrounded by a vesicle that forms from the membrane of the endoplasmic reticulum.
3. This transport vesicle moves from the endoplasmic reticulum to the Golgi apparatus, fuses with its membrane, and releases the proteins into its cisterna.
4. The Golgi apparatus concentrates and, in some cases, modifies the proteins into glycoproteins or lipoproteins.
5. The proteins are packaged into vesicles that form from the membrane of the Golgi apparatus.
6. Some vesicles, such as lysosomes, contain enzymes that are used within the cell.
7. Secretory vesicles carry proteins to the plasma membrane, where the proteins are secreted from the cell by exocytosis.
8. Some vesicles contain proteins that become part of the plasma membrane.

PROCESS FIGURE 3.33 Function of the Golgi Apparatus

contents of the vesicle are released to the exterior by exocytosis. The membranes of the vesicles are then incorporated into the plasma membrane.

Secretory vesicles accumulate in some cells, but their contents frequently are not released to the exterior until the cell receives a signal. For example, secretory vesicles that contain the hormone insulin do not release it until the concentration of glucose in the blood increases and acts as a signal for the secretion of insulin from the cells.

Lysosomes

Lysosomes (lī' sō-sōmz) are membrane-bound vesicles that pinch off from the Golgi apparatus (see figure 3.33). They contain a variety of hydrolytic enzymes that function as intracellular digestion systems. Vesicles taken into the cell fuse with the lysosomes to form one vesicle and to expose the endocytized materials to hydrolytic enzymes (figure 3.34). Various enzymes within lysosomes digest nucleic acids, proteins, polysaccharides, and lipids. Certain white blood cells have large numbers of lysosomes that contain enzymes to digest phagocytized bacteria. Lysosomes also digest the organelles of the cell that are no longer functional in a process called **autophagia** (aw-tō-fā'jē-ā; self-eating). In other cells, the lysosomes move to the plasma membrane, and the enzymes are secreted by exocytosis. For example, the normal process of bone remodeling involves the breakdown of bone tissue by specialized bone cells. Enzymes responsible for that degradation are released into the extracellular fluid from lysosomes produced by those cells.

Diseases of Lysosomal Enzymes

Some diseases result from nonfunctional lysosomal enzymes.

For example, **Pompe disease** is a rare genetic disorder that results from the inability of lysosomal enzymes to break down glycogen. The glycogen accumulates in large amounts in the heart, liver, and skeletal muscles, an accumulation that often leads to heart failure. **Familial hyperlipoproteinemia** is a group of genetic disorders characterized by the accumulation of large amounts of lipids in phagocytic cells that lack the normal enzymes required to break down the lipid droplets. Symptoms include abdominal pain, enlargement of the spleen and liver, and eruption of yellow nodules in the skin filled with the affected phagocytic cells. **Mucopolysaccharidoses**, such as **Hurler syndrome**, are genetic diseases in which lysosomal enzymes are unable to break down mucopolysaccharides (glycosaminoglycans), so these molecules accumulate in the lysosomes of connective tissue cells and nerve cells. People affected by these diseases suffer mental retardation and skeletal deformities.

Peroxisomes

Peroxisomes (per-ok'si-sōmz) are membrane-bound vesicles that are smaller than lysosomes. Peroxisomes contain enzymes that break down fatty acids and amino acids. Hydrogen peroxide (H_2O_2), which can be toxic to the cell, is a by-product of that breakdown. Peroxisomes also contain the enzyme **catalase**, which breaks down hydrogen peroxide to water and oxygen. Cells that are active in detoxification, such as liver and kidney cells, have many peroxisomes.

1. A vesicle forms around material outside the cell.
2. The vesicle is pinched off from the plasma membrane and becomes a separate vesicle inside the cell.
3. A lysosome is pinched off the Golgi apparatus.
4. The lysosome fuses with the vesicle.
5. The enzymes from the lysosome mix with the material in the vesicle, and the enzymes digest the material.

PROCESS FIGURE 3.34 Action of Lysosomes

Proteasomes

Proteasomes (prō'tē-ă-sōmz) consist of large protein complexes, including several enzymes that break down and recycle proteins within the cell. Proteasomes are not surrounded by membranes. They are tunnel-like structures, similar to channel protein complexes; the inner surfaces of the tunnel have enzymatic regions that break down proteins. Smaller protein subunits close the ends of the tunnel and regulate which proteins are taken into it for digestion.

Mitochondria

Mitochondria (mī-tō-kon'drē-ă) provide energy for the cell. Consequently, they are often called the cell's power plants. Mitochondria are usually illustrated as small, rod-shaped structures (figure 3.35). In living cells, time-lapse photomicrography reveals that mitochondria constantly change shape from spherical to rod-shaped or even to long, threadlike structures. Mitochondria are the major sites of ATP production, which is the major energy source for most energy-requiring chemical reactions within the cell. Each mitochondrion has an inner and an outer membrane, separated by an intermembranous space. The outer membrane has a smooth contour, but the inner membrane has numerous infoldings called **cristae** (kris'tē; sing. *crista*) that project like shelves into the interior of the mitochondria.

A complex series of mitochondrial enzymes forms two major enzyme systems that are responsible for oxidative metabolism and most ATP synthesis (see chapter 25). The enzymes of the citric acid (or Krebs) cycle are found in the **matrix**, which is the substance located in the space formed by the inner membrane. The enzymes of the electron-transport chain are embedded within the inner membrane. Cells with a greater energy requirement have more mitochondria with more cristae than do cells with lower energy requirements. Within the cytoplasm of a cell, the mitochondria are more numerous in areas in which ATP is used. For example, mitochondria are numerous in cells that perform active transport and are packed near the membrane where active transport occurs.

Increases in the number of mitochondria result from the division of preexisting mitochondria. When muscles enlarge as a result of exercise, the number of mitochondria within the muscle cells increases to provide the additional ATP required for muscle contraction.

The information for making some mitochondrial proteins is stored in DNA contained within the mitochondria themselves, and those proteins are synthesized on ribosomes within the mitochondria. The structure of many other mitochondrial proteins is determined by nuclear DNA, however, and these proteins are synthesized on ribosomes within the cytoplasm and then transported into the mitochondria. Both the mitochondrial DNA and

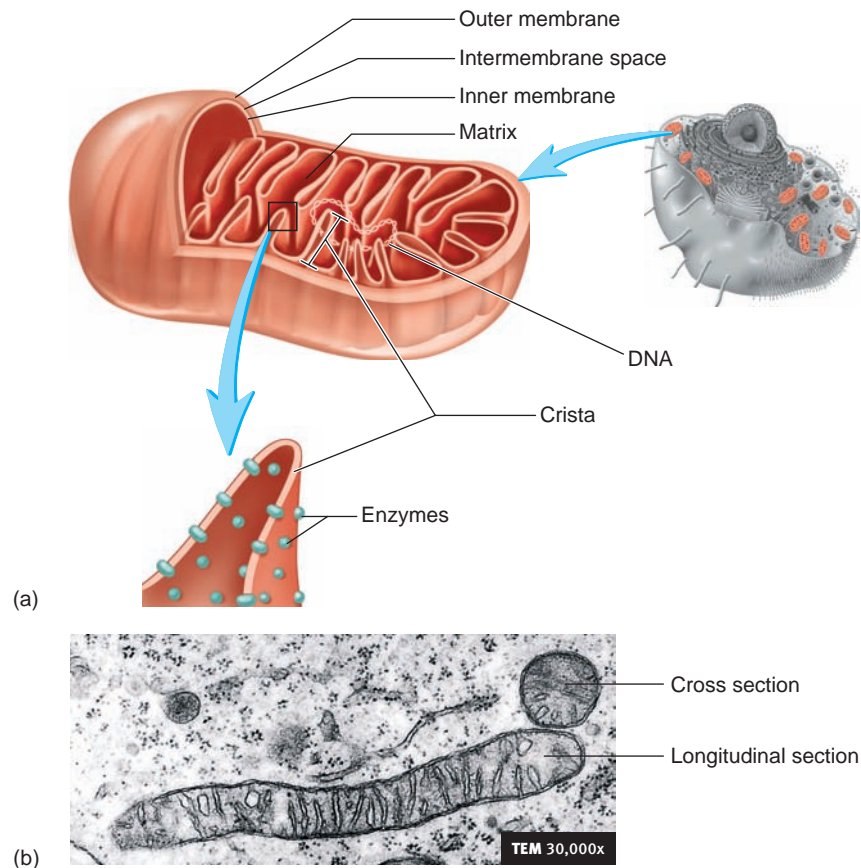

FIGURE 3.35 Mitochondrion

(a) Typical mitochondrion structure. (b) Transmission electron micrograph of mitochondria in longitudinal and cross section.

mitochondrial ribosomes are very different from those within the nucleus and cytoplasm of the cell, respectively. Mitochondrial DNA is a closed circle of about 16,500 base pairs (bp) coding for 37 genes, compared with the open strands of nuclear DNA, which is composed of 3 billion bp coding for 30,000 genes. In addition, unlike nuclear DNA, mitochondrial DNA does not have associated histone proteins.

Mitochondrial Diseases

Mitochondria play a major role in the synthesis of ATP. Each mitochondrion contains a single DNA molecule with at least 37 genes, 13 of which code for proteins that are important for ATP synthesis. The other 24 genes are important for the expression of mitochondrial genes. Therefore, mutations, or changes, in mitochondrial genes can lead to disruptions in normal ATP synthesis, reducing the amount of ATP produced by the cells. Disorders that result from such mutations are collectively called **mitochondrial diseases**. The effects of these diseases are most obvious in tissues that require large amounts of ATP, particularly nervous and muscle tissues. As a consequence, the common symptoms of mitochondrial diseases are loss of neurological function and defects in muscular activity. For example, **Leber hereditary optic neuropathy** results in sudden vision loss due to optic nerve degeneration. Mutations associated with this disorder have been found in the genes that function in ATP synthesis, especially in the cells of the optic nerve. Because of their high energy demands, the cells of the optic nerve are damaged or die because of the lack of ATP.

In humans, mitochondria are passed only from the mother to her offspring because the mitochondria of sperm cells do not enter the oocyte during fertilization (see chapter 29). Therefore, mitochondrial diseases, involving the mitochondrial genes, show a pattern of maternal inheritance in which a mother afflicted with a mitochondrial disease passes it to all of her offspring, but a father suffering from the same disorder passes it to none of his offspring.

PREDICT 5

Describe the structural characteristics of cells that are highly specialized to do the following: (a) synthesize and secrete proteins, (b) actively transport substances into the cell, (c) synthesize lipids, and (d) phagocytize foreign substances.

Centrioles and Spindle Fibers

The **centrosome** (sen'trō-sōm), a specialized zone of cytoplasm close to the nucleus, is the center of microtubule formation. It contains two **centrioles** (sen'trē-ōlz). Each centriole is a small, cylindrical organelle about 0.3–0.5 μm in length and 0.15 μm in diameter, and the two centrioles are normally oriented perpendicular to each other within the centrosome (see figure 3.1). The wall of the centriole is composed of nine evenly spaced, longitudinally oriented, parallel units, or triplets. Each unit consists of three parallel microtubules joined together (figure 3.36).

Microtubules appear to influence the distribution of actin and intermediate filaments. Through its control of microtubule formation, the centrosome is closely involved in determining cell shape and movement. The microtubules extending from the centrosomes are very dynamic—constantly growing and shrinking.

Before cell division, the two centrioles double in number, the centrosome divides into two, and one centrosome, containing two

(a)

(b)

FIGURE 3.36 Centriole

(a) Structure of a centriole, which comprises nine triplets of microtubules. Each triplet contains one complete microtubule fused to two incomplete microtubules. (b) Transmission electron micrograph of a pair of centrioles, which are normally located together near the nucleus. One is shown in cross section and one in longitudinal section.

centrioles, moves to each end of the cell. Microtubules called **spindle fibers** extend out in all directions from the centrosome. These microtubules grow and shrink even more rapidly than those of nondividing cells. If the extended end of a spindle fiber comes in contact with a kinetochore, a specialized region in the centromere of each chromosome, the spindle fiber attaches to the kinetochore and stops growing or shrinking. Eventually, spindle fibers from each centrosome bind to the kinetochores of all the chromosomes. During cell division, the microtubules facilitate the movement of chromosomes toward the two centrosomes (see “Cell Division,” p. 92).

Cilia and Flagella

Cilia (sil'ē-ă) are structures that project from the surface of cells and are capable of movement. They vary in number from one to thousands per cell. Cilia are cylindrical in shape, about 10 μm in length and 0.2 μm in diameter, and the shaft of each cilium is enclosed by the plasma membrane. Two centrally located microtubules and nine peripheral pairs of fused microtubules, the so-called 9 + 2 arrangement, extend from the base to the tip of each cilium (figure 3.37). Movement of the microtubules past each other, a process that requires energy from ATP, is responsible for movement of the cilia. **Dynein arms**, proteins connecting adjacent

FIGURE 3.37 Cilia and Flagella

(a) Ciliary and flagellar structures. The shaft is composed of nine microtubule doublets around its periphery and two in the center. Dynein arms are proteins that connect one pair of microtubules to another pair. Dynein arm movement, which requires ATP, causes the microtubules to slide past each other, resulting in bending or movement of the cilium or flagellum. A basal body attaches the cilium or flagellum to the plasma membrane. (b) Transmission electron micrograph through a cilium. (c) Transmission electron micrograph through the basal body of a cilium.

FIGURE 3.38 Ciliary Movement

(a) Power and (b) recovery strokes.

pairs of microtubules, push the microtubules past each other. A **basal body** (a modified centriole) is located in the cytoplasm at the base of the cilium. Cilia are numerous on surface cells that line the respiratory tract and the female reproductive tract. In these regions, cilia move in a coordinated fashion, with a power stroke in one direction and a recovery stroke in the opposite direction (figure 3.38). Their motion moves materials over the surface of the cells. For example, cilia in the trachea move mucus embedded with dust particles upward and away from the lungs. This action helps keep the lungs clear of debris.

Flagella (flă-jel'ă) have a structure similar to cilia but are longer (45 μm). Sperm cells are the only human cells to possess flagella and usually only one flagellum exists per cell. Furthermore, whereas cilia move small particles across the cell surface, flagella move the entire cell. For example, each sperm cell is propelled by a single flagellum. In contrast to cilia, which have a power stroke and a recovery stroke, flagella move in a wavelike fashion.

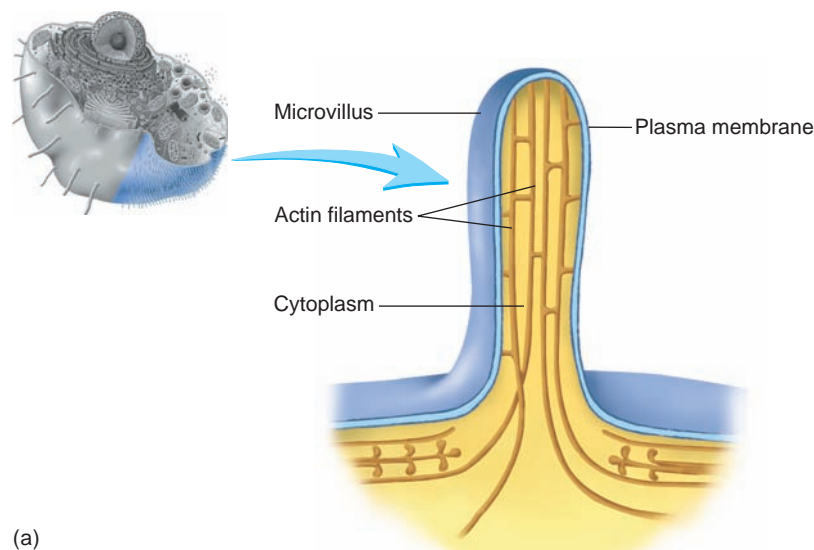

FIGURE 3.39 Microvillus

(a) A microvillus is a tiny, tubular extension of the cell; it contains cytoplasm and some actin filaments (microfilaments). (b) Transmission electron micrograph of microvilli.

Microvilli

Microvilli (mī-krō-vil'ī; figure 3.39) are cylindrically shaped extensions of the plasma membrane about 0.5–1.0 μm in length and 90 nm in diameter. Normally, many microvilli are on each cell, and they function to increase the cell surface area. A student looking at photographs may confuse microvilli with cilia. Microvilli, however, are only one-tenth to one-twentieth the size of cilia. Individual microvilli can usually be seen only with an electron microscope, whereas cilia can be seen with a light microscope. Microvilli do not move, and they are supported with actin filaments, not microtubules. Microvilli are found in the intestine, kidney, and other areas in which absorption is an important function. In certain locations of the body, microvilli are highly modified to function as sensory receptors. For example, elongated microvilli in hair cells of the inner ear respond to sound.

GENES AND GENE EXPRESSION

Heredity is the genetic transmission of characteristics, or traits, from parents to their offspring. **Genes** are the functional units of heredity. Each gene is a segment of a DNA molecule. DNA molecules, along with their associated proteins, form the chromosomes.

The sequence of nucleotides in a DNA molecule is a method of storing information that is based on a triplet code. Three

consecutive nucleotides, called **triplets**, form the words of the triplet code. Just as the sequence of letters “seedogrun” can be deciphered to mean “see dog run,” a sequence of bases, such as “CATGAGTAG,” has meaning, which is used to construct other DNA molecules, RNA molecules, or proteins. A molecular definition of a gene is all the triplets necessary to make a functional RNA molecule or protein.

Most chromosomes contain thousands of genes. There are two major types of genes: structural and regulatory. **Structural genes** are those DNA sequences that determine specific amino acid sequences in proteins, such as enzymes; hormones; or structural proteins, such as collagen. **Regulatory genes** are segments of DNA involved in controlling which structural genes are expressed in a given tissue. By determining the structure of proteins and by regulating which proteins are produced by cells, genes are responsible for the characteristics of cells, and therefore the inherited characteristics, or traits, of the entire organism.

The production of proteins from the information stored in DNA is called **gene expression** (figure 3.40). Gene expression

involves two steps, transcription and translation, which can be illustrated with an analogy. Suppose a cook wants a cake recipe that is found only in a reference book in the library. Because the book cannot be checked out, the cook makes a copy, or **transcription**, of the recipe. Later in the kitchen, the information contained in the copied recipe is used to make the cake. The changing of something from one form to another (from recipe to cake) is called **translation**. In this analogy, DNA is the reference book that contains many recipes (genes) for making different proteins. DNA, however, is too large a molecule to pass through the nuclear envelope to go to the cytoplasm (the kitchen), where the proteins are synthesized. Just as the reference book stays in the library, DNA remains in the nucleus. Therefore, through transcription, the cell makes a copy of the gene (the recipe) necessary to make a particular protein (the cake). The copy, which is called mRNA, travels from the nucleus to ribosomes (the kitchen) in the cytoplasm, where the information in the copy is used to construct a protein (i.e., translation). Of course, to turn a recipe into a cake, ingredients are needed. The ingredients necessary to synthesize a

1. DNA contains the information necessary to produce proteins.
2. Transcription of one DNA strand results in mRNA, which is a complementary copy of the information in the DNA strand needed to make a protein.
3. The mRNA leaves the nucleus and goes to a ribosome.
4. Amino acids, the building blocks of proteins, are carried to the ribosome by tRNAs.
5. In the process of translation, the information contained in mRNA is used to determine the number, kinds, and arrangement of amino acids in the polypeptide chain.

PROCESS FIGURE 3.40 Overview of Gene Expression

protein are amino acids. Specialized transport molecules, called **transfer RNA (tRNA)**, carry the amino acids to the ribosomes (see figure 3.40).

In summary, gene expression involves transcription, making a copy of a small part of the stored information in DNA, and translation, converting that copied information into a protein. The details of transcription and translation are considered next.

55 *What is a gene, and how are genes responsible for the structure and function of cells?*

56 *What type of molecule is produced as a result of transcription? Of translation? Where do these events take place?*

Transcription

Transcription is the synthesis of mRNA, tRNA, and rRNA based on the nucleotide sequence in DNA (figure 3.41). Transcription occurs when a section of a DNA molecule unwinds and its complementary strands separate. One of the DNA strands serves as the template strand for the process of transcription. Nucleotides that form RNA align with the DNA nucleotides in the template strand by complementary base pairing. An adenine aligns with a thymine of DNA, cytosine aligns with a guanine of DNA, and guanine aligns with a cytosine of DNA. Instead of thymine, uracil of RNA (see figure 2.25), aligns with adenine of DNA. Thus, the sequence of bases that aligns with the TCGA sequence of DNA is AGCU. This pairing relationship between nucleotides ensures that the information in DNA is transcribed correctly into RNA.

PREDICT 6

Given the following sequence of nucleotides of a DNA molecule, write the sequence of mRNA that is transcribed from it. What is the nucleotide sequence of the complementary strand of the DNA molecule? How does it differ from the nucleotide sequence of RNA?

DNA nucleotide sequence: CGTACGCCGAGACGTC AAC

RNA polymerase is an enzyme that synthesizes the complementary RNA molecule from DNA. RNA polymerase attaches to a DNA nucleotide sequence called a **promoter**. RNA polymerase, however, does not attach to the promoter by itself. It must first associate with other proteins called **transcription factors** in order to interact with the DNA. The attachment of RNA polymerase to the promoter causes a portion of the DNA molecule to unwind, exposing the nucleotide sequence for that region of the template strand. Complementary RNA nucleotides then align with the DNA nucleotides of the template strand. The RNA nucleotides are combined by dehydration reactions, catalyzed by RNA polymerase, to form mRNA. Only a small portion of the DNA molecule unwinds at any one time. As complementary nucleotides are added to the mRNA, RNA polymerase moves along the DNA unwinding the next portion, while the previously unwound section of DNA strands winds back together. When RNA polymerase encounters a DNA nucleotide sequence called the **terminator**, it detaches from the DNA releasing the newly formed mRNA.

1. The strands of the DNA molecule separate from each other. One DNA strand serves as a template for mRNA synthesis.
2. Nucleotides that will form mRNA pair with DNA nucleotides according to the base-pair combinations shown in the key at the top of the figure. Thus, the sequence of nucleotides in the template DNA strand (*purple*) determines the sequence of nucleotides in mRNA (*gray*). RNA polymerase (the enzyme is not shown) joins the nucleotides of mRNA together.
3. As nucleotides are added, an mRNA molecule is formed.

PROCESS FIGURE 3.41 Formation of mRNA by Transcription of DNA

The region of a DNA molecule between the promoter and terminator is a gene. The structure of a gene is more complex than just the nucleotides that code for a protein; some regions that are transcribed to form mRNA do not code for parts of a protein. The DNA sequence of a gene contains a protein-coding region and flanking untranslated regions. During transcription, the sequence of nucleotides in DNA between the promoter and the terminator serve as a template to make an RNA molecule called **pre-mRNA** (figure 3.42). The untranslated regions are

FIGURE 3.42 Posttranscriptional Change in mRNA

The two DNA strands separate, and one strand is transcribed to produce a pre-mRNA strand. An intron is cleaved from between two exons and is discarded. The exons are spliced together by spliceosomes (not shown) to make the functional mRNA. Also, a 7-methyl guanosine cap and a poly-A tail are added to the mRNA.

transcribed into pre-mRNA but do not code for parts of a protein. Instead, these regions function in the regulation of translation. The protein-coding region of RNA contains sections, called **exons**, that code for parts of a protein and sections, called **introns**, that do not code for parts of a protein.

Before pre-mRNA leaves the nucleus, it undergoes several modifications called **posttranscriptional processing**, which produces the functional mRNA that is used in translation to produce a protein or part of a protein (see figure 3.42). A **7-methyl guanosine cap** is added to one end of mRNA and a series of adenine nucleotides, called a **poly-A tail**, is added to the other end. These modifications to the ends of the mRNA ensure that mRNA travels from the nucleus to the cytoplasm and interacts with ribosomes during translation. The introns are removed from the pre-mRNA and the exons are spliced together by enzymes called **spliceosomes**. The functional mRNA consists only of exons.

In a process called **alternative splicing**, various combinations of exons are incorporated into mRNA. Which exons, and how

many exons, are used to make mRNA can vary between cells of different tissues, resulting in different mRNAs transcribed from the same gene. Alternative splicing allows a single gene to produce more than one specific protein; however, the various proteins usually have similar functions in different tissues.

Thalassemia

Hemoglobin is an oxygen-carrying protein molecule composed of four polypeptides. **Thalassemia** is a group of genetic disorders in which one or more of the polypeptides of hemoglobin is produced in decreased amounts as the result of defective post-transcriptional processing. The decreased amount of hemoglobin in the blood causes anemia, which reduces the oxygen-carrying capacity of the blood.

Genetic Code

The information contained in mRNA, called the **genetic code**, is carried in sets of three nucleotide units called **codons**. A codon specifies an amino acid during translation. For example, the codon GAU specifies the amino acid aspartic acid, and the codon CGA specifies arginine. Although there are only 20 different amino acids commonly found in proteins, 64 possible codons exist. Therefore, an amino acid can have more than one codon. The codons for arginine include CGA, CGG, CGU, and CGC. Furthermore, some codons act as signals during translation. AUG, which specifies methionine, also acts as a **start codon**, which signals the beginning of translation. UAA, UGA, and UAG act as **stop codons**, which signal the end of translation. Unlike the start codon, those codons do not specify amino acids. Therefore, the protein-coding region of an mRNA begins at the start codon and ends at a stop codon.

Translation

The synthesis of a protein at the ribosome in response to the codons of mRNA is called translation (figure 3.43). In addition to mRNA, translation requires ribosomes and tRNA. Ribosomes consist of **ribosomal RNA (rRNA)** and proteins. Like mRNA, tRNA and rRNA are produced in the nucleus by transcription.

The function of tRNA is to match a specific amino acid to a specific codon of mRNA. To do this, one end of each kind of tRNA combines with a specific amino acid. Another part of the tRNA called the **anticodon** consists of three nucleotides and is complementary to a particular codon of mRNA. On the basis of the pairing relationships between nucleotides, the anticodon can combine only with its matched codon. For example, the tRNA that binds to aspartic acid has the anticodon CUA, which combines with the codon GAU of mRNA. Therefore the codon GAU codes for aspartic acid.

Ribosomes align the codons of the mRNA with the anticodons of tRNA and then enzymatically join the amino acids of adjacent tRNA molecules. The mRNA moves through the ribosome one codon at a time. With each move, a new tRNA enters the ribosome and the amino acid is linked to the growing chain, forming a polypeptide. The step-by-step process of gene expression at the ribosome is described in detail in figure 3.43.

1. To start protein synthesis, a ribosome binds to mRNA. The ribosome also has two binding sites for tRNA, one of which is occupied by a tRNA with its amino acid. Note that the first codon to associate with a tRNA is AUG, the start codon, which codes for methionine. The codon of mRNA and the anticodon of tRNA are aligned and joined. The other tRNA binding site is open.

2. By occupying the open tRNA binding site, the next tRNA is properly aligned with mRNA and with the other tRNA.

3. An enzyme within the ribosome catalyzes a synthesis reaction to form a peptide bond between the amino acids. Note that the amino acids are now associated with only one of the tRNAs.

4. The ribosome shifts position by three nucleotides. The tRNA without the amino acid is released from the ribosome, and the tRNA with the amino acid takes its position. A tRNA binding site is left open by the shift. Additional amino acids can be added by repeating steps 2 through 4.

5. Eventually, a stop codon in the mRNA, such as UAA, ends the process of translation. At this point, the mRNA and polypeptide chain are released from the ribosome.

6. Multiple ribosomes attach to a single mRNA to form a polyribosome. As the ribosomes move down the mRNA, proteins attached to the ribosomes lengthen and eventually detach from the mRNA.

PROCESS FIGURE 3.43 Translation of mRNA to Produce a Protein

Many proteins are longer when first made than they are in their final, functional state. These proteins are called **proproteins**, and the extra piece of the molecule is cleaved off by enzymes to make the proprotein into a functional protein. Many proteins are enzymes, and the proproteins of those enzymes are called **proenzymes**. If many proenzymes were made within cells as functional enzymes, they could digest the cell that made them. Instead, they are made as proenzymes and are not converted to active enzymes until they reach a protected region of the body, such as inside the small intestine, where they are functional. Many proteins have side chains, such as polysaccharides, added to them following translation. Some proteins are composed of two or more amino acid chains that are joined after each chain is produced on separate ribosomes. These various modifications to proteins are referred to as **posttranslational processing**.

After the initial part of mRNA is used by a ribosome, another ribosome can attach to the mRNA and begin to make a protein. The resulting cluster of ribosomes attached to the mRNA is called a **polyribosome** (see figure 3.43). Each ribosome in a polyribosome produces an identical protein, and polyribosomes are an efficient way to use a single mRNA molecule to produce many copies of the same protein.

Regulation of Gene Expression

Most of the cells in the body have the same DNA. The transcription of mRNA in cells is regulated, however, so that all portions of all DNA molecules are not continually transcribed. The proteins associated with DNA in the nucleus play a role in regulating the transcription. As cells differentiate and become specialized by function during development, part of the DNA becomes non-functional and is not transcribed, whereas other segments of DNA remain very active. For example, in most cells the DNA coding for hemoglobin is nonfunctional, and little if any hemoglobin is synthesized. In developing red blood cells, however, the DNA coding for hemoglobin is functional, and hemoglobin synthesis occurs rapidly.

Gene expression in a single cell is not normally constant, but it occurs more rapidly at some times than others. Regulatory molecules that interact with the nuclear proteins can either increase or decrease the transcription rate of specific DNA segments. For example, triiodothyronine (T₃), a hormone released by cells of the thyroid gland, enters cells, such as skeletal muscle cells; interacts with specific nuclear proteins; and increases specific types of mRNA transcription. Consequently, the production of certain proteins increases. As a result, an increase in the number of mitochondria and an increase in metabolism occur in these cells.

CELL LIFE CYCLE

The **cell life cycle** includes the changes a cell undergoes from the time it is formed until it divides to produce two new cells. The life cycle of a cell has two stages, an interphase and a cell division stage (figure 3.44).

Interphase

Interphase is the phase between cell divisions; 90% or more of the life cycle of a typical cell is spent in interphase. During this time, the cell carries out the metabolic activities necessary for life and performs its specialized functions—for example, secreting digestive enzymes. In addition, the cell prepares to divide. This preparation includes an increase in cell size, because many cell

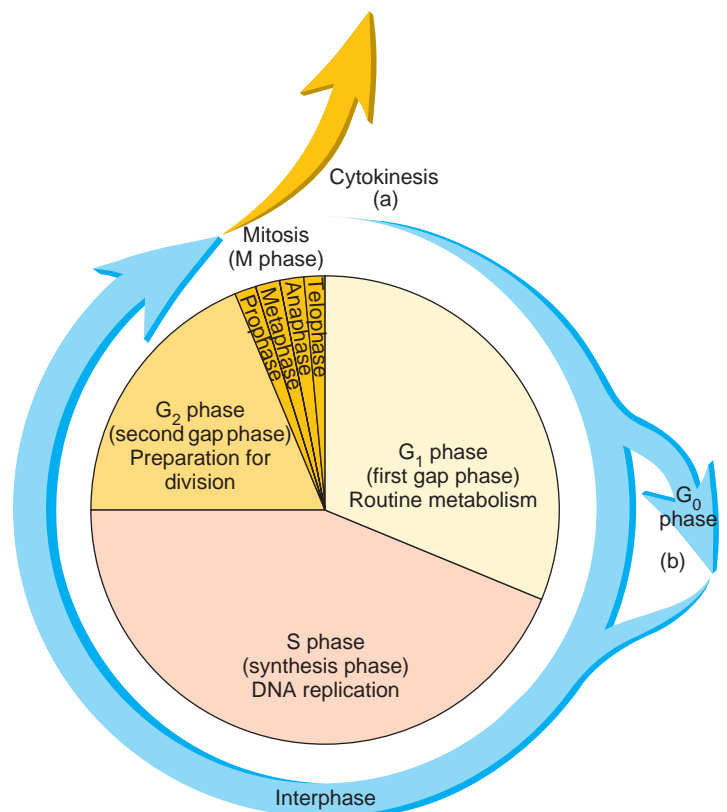

FIGURE 3.44 Cell Cycle

The cell cycle is divided into interphase and cell division. Interphase is divided into G₁, S, and G₂ subphases. During G₁, the cell carries out routine metabolic activities. During the S phase, DNA is replicated. During the G₂ phase, the cell prepares for division. Cell division includes mitosis and cytokinesis. (a) Following mitosis, two cells are formed by the process of cytokinesis. Each new cell begins a new cell cycle. (b) Many cells exit the cell cycle and enter the G₀ phase, where they remain until stimulated to divide, at which point they reenter the cell cycle.

components double in quantity, and a replication of the cell's DNA. The centrioles within the centrosome are also duplicated. Consequently, when the cell divides, each new cell receives the organelles and DNA necessary for continued functioning.

Interphase can be divided into three subphases, called G_1 , S, and G_2 . During G_1 (the first *gap* phase), the cell carries out routine metabolic activities. During the S phase (the *synthesis* phase), the DNA is replicated (new DNA is synthesized). During the G_2 phase (the second *gap* phase), the cell prepares for cell division. Many cells in the body do not divide for days, months, or even years. These “resting” cells exit the cell cycle and enter what is called the G_0 phase, in which they remain unless stimulated to divide.

DNA Replication

DNA **replication** is the process by which two new strands of DNA are made, using the two existing strands as templates. During interphase, DNA and its associated proteins appear as dispersed chromatin threads within the nucleus. When DNA replication begins, the two strands of each DNA molecule separate from each other for some distance (figure 3.45). Each strand then functions as a template, or pattern, for the production of a new, complementary strand of DNA, which is formed as complementary nucleotides pair with the existing nucleotides of each strand of the separated DNA molecule. The production of the new nucleotide strands is catalyzed by DNA **polymerase**, an enzyme that adds new nucleotides to the 3' end of the growing strands. Because of the antiparallel orientation of the two DNA strands, the strands are formed differently. One strand, called the **leading strand**, is formed as a continuous strand, whereas the other strand, called the **lagging strand**, is formed in short segments called *Okazaki fragments*. The Okazaki fragments are then spliced by **DNA ligase**. As a result of DNA replication, two identical DNA molecules are produced. Each of the two new DNA molecules has one strand of nucleotides derived from the original DNA molecule and one newly synthesized strand.

PREDICT 7

Suppose a molecule of DNA separates, forming strands 1 and 2. Part of the nucleotide sequence in strand 1 is ATGCTA. From this template, what would be the sequence of nucleotides in the DNA replicated from strand 1 and strand 2?

Cell Division

New cells necessary for growth and tissue repair are produced by cell division. A parent cell divides to form two daughter cells, each of which has the same amount and type of DNA as the parent cell. Because DNA determines cell structure and function, the daughter cells tend to have the same structure and perform the same functions as the parent cell. During development and cell differentiation, however, the functions of daughter cells may differ from each other and from that of the parent cell.

Cell division involves two major events: the division of the nucleus to form two new nuclei and the division of the cytoplasm to form two new cells. Each of the new cells contains one of the newly formed nuclei. The division of the nucleus occurs by mitosis, and the division of the cytoplasm is called cytokinesis.

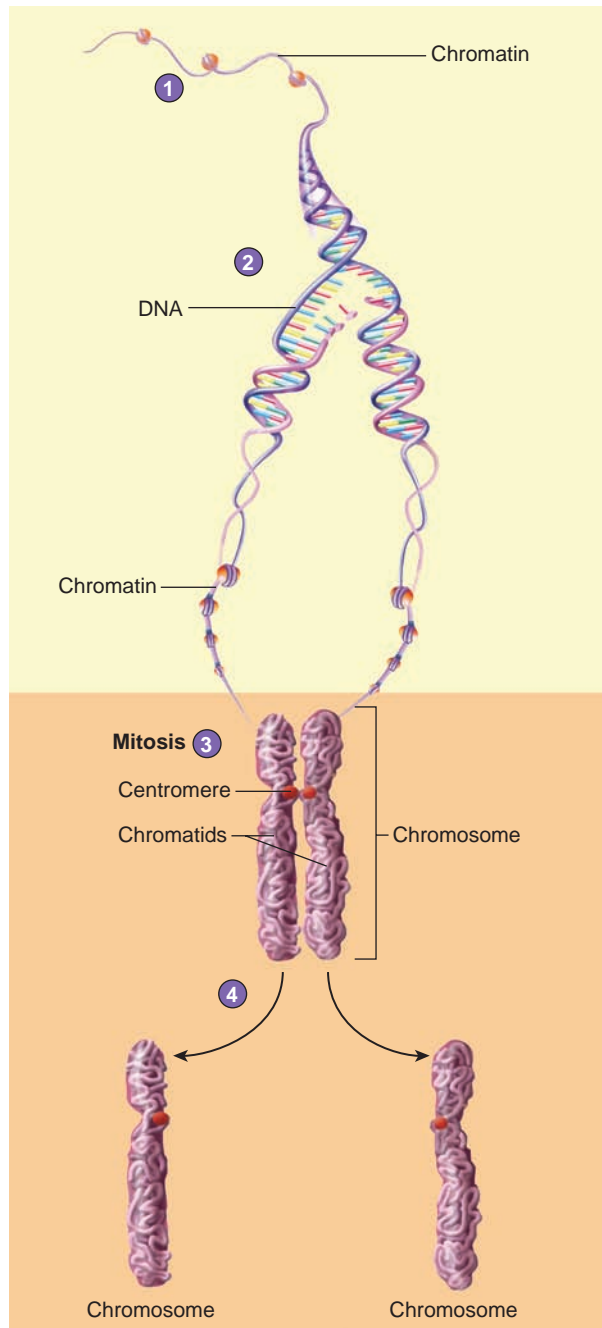

1. The strands of the DNA molecule separate from each other.
2. Each old strand (*dark purple*) functions as a template on which a new, complementary strand (*light purple*) is formed. The base-pairing relationship between nucleotides determines the sequence of nucleotides in the newly formed strands.
3. Two identical DNA molecules are produced.

PROCESS FIGURE 3.45 Replication of DNA

Replication of DNA during the S phase of interphase produces two identical molecules of DNA.

Mitosis

Mitosis (mī-tō'sis) is the division of the nucleus into two nuclei, each of which has the same amount and type of DNA as the original nucleus. The DNA, which was replicated during interphase, is dispersed as chromatin. During mitosis, the chromatin becomes very densely coiled to form compact chromosomes. These chromosomes are discrete bodies easily seen with a light microscope after staining the nuclei of dividing cells. Because the DNA has been replicated, each chromosome consists of two chromatids, which are attached at a single point called the centromere (figure 3.46; see figure 3.29). Each chromatid contains a DNA molecule. As two

1. The DNA of a chromosome is dispersed as chromatin.
2. The DNA molecule unwinds and each strand of the molecule is replicated.
3. During mitosis the chromatin from each replicated DNA strand condenses to form a chromatid. The chromatids are joined at the centromere to form a single chromosome.
4. The chromatids separate to form two new, identical chromosomes. The chromosomes will unwind to form chromatin in the nuclei of the two daughter cells.

PROCESS FIGURE 3.46 Replication of a Chromosome

daughter cells are formed, the chromatids separate, and each is now called a chromosome. Each daughter cell receives one of the chromosomes. Thus, the daughter cells receive the same complement of chromosomes and DNA and are genetically identical.

For convenience of discussion, mitosis is divided into four phases: **prophase**, **metaphase**, **anaphase**, and **telophase** (tel'ō-fāz). Although each phase represents major events, mitosis is a continuous process, and no discrete jumps occur from one phase to another. Learning the characteristics associated with each phase is helpful, but a more important concept is that each daughter cell obtains the same number and type of chromosomes as the parent cell. The major events of mitosis are summarized in figure 3.47.

Cytokinesis

Cytokinesis (sī'tō-ki-nē'sis) is the division of the cytoplasm of the cell to produce two new cells. Cytokinesis begins in anaphase, continues through telophase, and ends in the following interphase (see figure 3.47). The first sign of cytokinesis is the formation of a **cleavage furrow**, or an indentation of the plasma membrane, which forms midway between the centrioles. A contractile ring composed primarily of actin filaments pulls the plasma membrane inward, dividing the cell into halves. Cytokinesis is complete when the membranes of the halves separate at the cleavage furrow to form two separate cells.

GENETICS

Genetics is the study of heredity—that is, those characteristics inherited by children from their parents. Although the environment can influence gene expression, people's physical characteristics and abilities are largely determined by their genetic makeup. Many of a person's abilities, susceptibility to disease, and even life span are influenced by the genes they inherit from their parents. Because many of the diseases caused by microorganisms now are preventable or treatable, diseases that have a genetic basis are receiving more attention.

An understanding of genetics is an important tool for medical professionals. Patients are asked questions about their family medical history to help diagnose many diseases. The family medical history also allows doctors to determine the probability that patients will develop certain diseases, such as heart disease or

1. **Interphase** is the time between cell divisions. DNA is found as thin threads of chromatin in the nucleus. DNA replication occurs during the S phase of interphase. Organelles, other than the nucleus, and centrioles duplicate during interphase.

2. In **prophase**, the chromatin condenses into chromosomes. Each chromosome consists of two chromatids joined at the centromere. The centrioles move to the opposite ends of the cell, and the nucleolus and the nuclear envelope disappear. Microtubules form near the centrioles and project in all directions. Some of the microtubules end blindly and are called astral fibers. Others, known as spindle fibers, project toward an invisible line called the equator and overlap with fibers from opposite centrioles.

3. In **metaphase**, the chromosomes align in the center of the cell in association with the spindle fibers. Some spindle fibers are attached to kinetochores in the centromere of each chromosome.

4. In **anaphase**, the chromatids separate, and each chromatid is then referred to as a chromosome. Thus, when the centromeres divide, the chromosome number is double, and there are two identical sets of chromosomes. The chromosomes, assisted by the spindle fibers, move toward the centrioles at each end of the cell. Separation of the chromatids signals the beginning of anaphase, and, by the time anaphase has ended, the chromosomes have reached the poles of the cell. Cytokinesis begins during anaphase as a cleavage furrow forms around the cell.

5. In **telophase**, migration of each set of chromosomes is complete. The chromosomes unravel to become less distinct chromatin threads. The nuclear envelope forms from the endoplasmic reticulum. The nucleoli form, and cytokinesis continues to form two cells.

6. Mitosis is complete, and a new interphase begins. The chromosomes have unraveled to become chromatin. Cell division has produced two daughter cells, each with DNA that is identical to the DNA of the parent cell.

PROCESS FIGURE 3.47 Mitosis and Cytokinesis

cancer, and to suggest preventive measures. Recent advances in the field of genetics have shown how genes influence health and have provided new methods for treating certain diseases.

Some genetic diseases, such as hemophilia, have a simple pattern of inheritance, usually involving one or a few genes, and it is easy to predict whether a person will develop the disease. However, other genetic diseases have a more complex pattern of inheritance involving many more genes. **Mendelian genetics**, the study of how certain genetic traits are passed from parent to offspring, has been used to determine an individual's risk of developing certain genetic diseases.

Over the past 10 years, the human genome, all of the genes in human chromosomes, has been sequenced. The results of this project have provided a wealth of information useful to the medical field. This information will allow researchers to better identify genes associated with particular diseases, to understand the biochemical relationship between genes and diseases, and to create new treatments for disease. The new, genetic approach to the diagnosis and management of diseases is known as **genomic medicine**.

Mendelian Genetics

Gregor Mendel (1822–1884) was an Austrian monk who made revolutionary discoveries about inheritance patterns in pea plants. For his discoveries, Mendel is known as the “father of genetics.” Mendel found that the transmission of traits, such as purple versus white flowers, from one generation of pea plants to another can be explained by discrete units he called “heritable factors.” He concluded that each pea plant has two heritable factors for a characteristic, such as flower color. He proposed that, during the production of **gametes**, or sex cells, each gamete receives one of these factors. Then two gametes combine to produce the next generation so that each member of the next generation of pea plants has two heritable factors. Mendel's “heritable factors” are now called genes. The genes an organism has for a given trait is called the **genotype** (jĕn'ō-tĭp). The expression of the genes as traits is called the **phenotype** (fĕ'nō-tĭp).

Environmental effects can interact with gene expression to determine the phenotype of many traits. Even genetically identical twins can have different phenotypes because of environmental effects. For example, in addition to genes, height is affected by nutrition, and skin color by exposure to the sun. Knowledge of environmental effects can be used to improve our genetic potential and to prevent harmful effects. For example, a healthy diet can promote growth or help prevent diabetes, and not smoking can reduce the risk of developing cancer.

Mendel proposed that genes can occur in dominant and recessive forms. Alternate forms of genes are now called **alleles** (ă-lĕlz'). By definition, the effects of a **dominant allele** for a trait mask the effects of the **recessive allele** for that trait. For example, in pea plants, the allele for purple flowers is dominant over the allele for white flowers. By convention, dominant alleles are indicated by uppercase letters, and recessive alleles are indicated by lowercase letters. For example, the letter *P* designates the dominant allele for purple flower color, and the letter *p*

represents the recessive allele for white flower color. A plant with the *Pp* genotype has purple flowers because purple is dominant over white.

An organism is **homozygous** (hō-mō-zĭ'gŭs) for a trait if the two alleles for the trait are identical, whereas an organism is **heterozygous** (het'er-ō-zĭ'gŭs) for a trait if the two alleles for the trait are different. The possible genotypes and phenotypes for purple flower color are

Alleles	Genotype	Phenotype
<i>PP</i>	Homozygous dominant	Purple
<i>Pp</i>	Heterozygous	Purple
<i>pp</i>	Homozygous recessive	White

Note that the recessive trait is expressed when it is not masked by the dominant trait.

The relationship between genotype and phenotype can be understood on the molecular level. For example, there is a recessive trait in humans called **albinism** (al'bĭ-nĭzm), which results in a lack of normal coloring of the skin, hair, and eyes. Several human genes produce the enzymes that are necessary for the synthesis of melanin, the pigment responsible for skin, hair, and eye color (see chapter 5). An **albino**, a person with albinism, has light blonde or white hair and light colored eyes and skin, with shades of pink, blue, and yellow (figure 3.48). The pink and blue colors result from blood seen in the eyes or through the skin. The yellow is from the natural accumulation of ingested yellow plant pigments in the skin (see “Skin Color,” chapter 5).

The normal alleles for the melanin-synthesizing enzymes produce normal, functional enzymes capable of catalyzing the steps in melanin synthesis. When normal enzymes are produced, a person has normal pigmentation. An abnormal allele for any one of the enzymes in the melanin pathway will produce a defective enzyme. The defective enzyme will block the pathway and stop the production of melanin. Type 1 albinism results from a defective enzyme that fails to initiate the synthesis of melanin from tyrosine. The normal allele of the gene for this enzyme,

FIGURE 3.48 Albinism

Photograph of an albino male with his normally pigmented father.

designated *A*, is dominant over the abnormal allele, designated *a*. The possible genotypes and phenotypes for albinism are

Alleles	Genotype	Phenotype
AA	Homozygous dominant	Normal pigmentation
<i>Aa</i>	Heterozygous	Normal pigmentation
<i>aa</i>	Homozygous recessive	Albino

A person with the genotype *AA* has the phenotype of normal pigmentation because the functional enzyme for melanin synthesis is produced by both alleles. A person with the genotype *Aa* has the phenotype of normal pigmentation. Even though the *a* allele produces an abnormal, nonfunctional enzyme for melanin synthesis, the *A* allele produces sufficient amounts of the normal enzyme so that pigmentation is normal. A person with the genotype *aa* has the phenotype of albinism because only the abnormal, nonfunctional enzyme for melanin synthesis is produced.

Not all dominant traits are the normal condition, and not all recessive traits are abnormal. In many cases, the dominant trait is abnormal. For example, a person with **polydactyly** (pol-ē-dak'ti-lē) has extra fingers or toes (figure 3.49). One allele for polydactyly, which results in extra fingers or toes, is dominant over the recessive, normal allele which results in the normal number of fingers or toes.

71 What is genetics?

72 What is the difference between genotype and phenotype?

73 Define homozygous dominant, heterozygous, and homozygous recessive.

PREDICT 8

List all the possible genotypes and phenotypes for polydactyly. Use the letters *D* and *d* for the genotypes.

FIGURE 3.49 Polydactyly

Polydactyly, having extra fingers or toes, is determined by a dominant gene.

Modern Concepts of Genetics

Although the existence of chromosomes was known in Mendel's time, the relationship between genes and chromosomes was not confirmed until T. H. Morgan was able to induce mutations (gene changes) in fruit flies in 1910. DNA was first isolated as the genetic material in 1944, and James Watson and Francis Crick resolved the structure of DNA in 1953, which led to an understanding of the genetic code and protein synthesis. The sequence of nucleotides of a human gene, specifically the gene that causes cystic fibrosis, was determined for the first time in 1989. The sequencing of 99% of the human genome was accomplished in 2003, with the completion of the Human Genome Project (see p. 102).

Chromosomes

In modern terminology, Mendel hypothesized that organisms have genes that control the expression of traits. Most genes, which are segments of DNA, occur in pairs of alleles. Chromosomes are made up of DNA and associated proteins found in the nuclei of somatic cells and gametes. **Somatic** (sō-mat'ik) **cells** are all the cells of the body except for the gametes. Examples of somatic cells are epithelial cells, muscle cells, neurons, fibroblasts, lymphocytes, and macrophages. In males, the gametes are **sperm cells**; in females, the gametes are **oocytes** (egg cells; see chapter 28).

The normal number of chromosomes in a somatic cell is called the **diploid** (dip'loid; twofold) **number**. The normal number of chromosomes in a gamete is the **haploid** (hap'loid; single) **number**. In humans, the diploid number of chromosomes is 46. Chromosomes in diploid cells are paired, so humans have 23 pairs of chromosomes. The haploid number of chromosomes is 23.

PREDICT 9

Why does it make sense that the number of chromosomes in a gamete is half the number in a somatic cell?

The 23 pairs of chromosomes are divided into autosomal and sex chromosomes. Humans have 22 pairs of **autosomal** (aw-tō-sō'māl) **chromosomes**, which are all the chromosomes but the sex chromosomes, and one pair of **sex chromosomes**, which determines the sex of the individual. Sex chromosomes are denoted as **X** or **Y chromosomes**. A normal female has two X chromosomes (XX) in each somatic cell. One X chromosome of a female is derived from her mother; the other is derived from her father. A normal male has one X chromosome and one Y chromosome (XY) in each somatic cell. The X chromosome of a male is derived from his mother; the Y chromosome is derived from his father.

Genetic traits can be classified by the type of chromosome their alleles are located on and by whether their alleles are dominant or recessive. Thus, traits can be autosomal dominant or recessive, or they can be sex-linked dominant or recessive. For example, albinism is an autosomal recessive trait.

A **karyotype** (kar'ē-ō-tīp) is a display of the chromosomes of a somatic cell during metaphase of mitosis. It is produced

FIGURE 3.50 Human Karyotype

The 23 pairs of chromosomes in humans consist of 22 pairs of autosomal chromosomes (numbered 1–22) and 1 pair of sex chromosomes. This karyotype is of a male and has an X and a Y sex chromosome. A female karyotype would have two X chromosomes.

by photographing the cell's stained chromosomes through a microscope and arranging the photographed chromosomes in pairs (figure 3.50). For convenience, the autosomal chromosomes are numbered, from largest to smallest, 1 through 22. The sex chromosomes are denoted with an X or a Y. Note that a chromosome in a karyotype is a replicated chromosome—that is, it has two chromatids (see figure 3.50). The chromatids of each chromosome are attached at the centromere so that each replicated chromosome appears as a single structure.

Chromosome pairs are called **homologous** (hō-mōl'ō-gūs) **pairs**, and each member of the pair is called a **homolog** (hōm'ō-lōg). One homolog is derived from a person's father, and the other is derived from a person's mother. A **genome** (jē'nōm, jē'nōm) consists of all the genes found in the haploid number of chromosomes from one parent. The combined genomes from both parents are responsible for all of a person's genetic traits. Each gene of the genome occupies a specific **locus**, or location, on a chromosome (figure 3.51). The locus on one chromosome may have one allele type; whereas the locus on its homolog may have another allele type.

74 How do the chromosomes in somatic cells and gametes differ from each other?

75 What are the number and type of chromosomes in the karyotype of a human somatic cell? How do the chromosomes of a male and female differ from each other?

76 What are homologous chromosomes?

FIGURE 3.51 Homologous Chromosomes

A drawing of a pair of unduplicated homologous chromosomes. For simplicity, the chromosomes are shown as compact bodies. In the unduplicated state, chromosomes are dispersed within the nucleus as chromatin.

Multiple Alleles

Mendel believed that alleles came in two forms, dominant and recessive. It is now known that alleles can exist in many forms, called **multiple alleles**. An individual has only two alleles for a given gene, one on each homologous chromosome. At the population level, however, there can be many forms of an allele.

Differences in alleles arise by mutation (see p. 100), in which the DNA nucleotide sequence is altered. Many alleles are possible in a population because any change in the nucleotide sequence of DNA, even of one base pair, potentially produces a different allele. A different form of an allele is called an **allelic variant**, a **mutated allele (gene)**, or a **polymorphism** (many forms).

Allelic variants can result in either no effect on the phenotype or minor to major phenotypic changes. Allelic variants at a locus may encode for different sequences of amino acids in proteins. Recall from chapter 2 that the sequence of amino acids in a protein affects the shape of the protein, including the protein's domain, which is the functional part of the protein. A mutated allele that causes an amino acid change in a protein that does not significantly change protein shape may not affect the phenotype. The greater the effect of an amino acid change on a protein's shape, however, the greater the effect on the protein's function, and the greater the effect on the phenotype. Millions of allelic variants have been identified. The significance of most of them is unknown.

The allelic variant present at a locus can affect a person's phenotype. For example, **phenylketonuria (PKU)** (fen'il-kē'tō-noo'rē-ă) is an autosomal recessive trait with multiple alleles. On chromosome 12 is a gene that encodes for an enzyme that converts the amino acid phenylalanine to the amino acid tyrosine. If phenylalanine is not converted to tyrosine, high levels of phenylalanine can accumulate, leading to brain cell damage. The more defective the enzyme, the greater the accumulation of phenylalanine and the greater the damage to the brain, in most cases. Over 400 disease-causing allelic variants of the

PKU gene are known. The severity of PKU depends in part on which two allelic variants are present. The less severe of the two alleles determines the severity of the disorder. Symptoms of untreated PKU can vary from profound mental retardation to nearly normal mental abilities. Thus, even though PKU is an autosomal recessive trait, the expression of the recessive condition exhibits considerable variability because of multiple alleles. Furthermore, reducing phenylalanine in the diet can prevent the development of mental retardation.

Gene Dominance

In Mendel's experiments with pea plants, each dominant allele produced enough of its protein product to cause the maximum phenotypic response in the heterozygote. Thus, the homozygous dominant and heterozygote had the same phenotype—that is, purple flowers. This is called **complete dominance**. It is now known that many other types of gene expression exist.

Complete dominance is at one end of a continuum of genetic expression. At the other end is codominance, and between them is incomplete dominance. In **codominance**, two alleles at the same locus are expressed so that separate, distinguishable phenotypes occur at the same time. ABO blood types are an example of codominance. A gene with three alleles on chromosome 9 encodes for enzymes that add sugar molecules to certain carbohydrates found on the surface of red blood cells. The carbohydrates are part of glycoproteins (see figure 3.2), called A and B antigens (see chapter 19). These carbohydrates consist of different sugars joined together. Traditionally, in designating alleles for blood type, the A and B alleles are superscripted to a capital letter “I” and the O allele is designated with the lower case letter “i.” The I^A allele encodes for an enzyme that adds a particular sugar to the ends of the carbohydrate, producing the A antigen. The I^B allele encodes for a different enzyme that adds a different sugar to the ends of the carbohydrate, producing the B antigen. The i allele encodes for no functional enzyme and therefore is recessive to A and B. The possible genotypes and phenotypes for the ABO blood group are

Genotype	Phenotype
$I^A I^A$ or $I^A i$	Type A blood (A antigen only)
$I^B I^B$ or $I^B i$	Type B blood (B antigen only)
$I^A I^B$	Type AB blood (A and B antigens)
ii	Type O blood (neither A nor B antigen)

Type A blood results from the expression of only the I^A allele, type B blood from the expression of only the I^B allele, and type O blood from the expression of neither the I^A allele nor the I^B allele. Type AB blood illustrates codominance and results from the expression of both the I^A allele and the I^B allele at the same time.

In **incomplete dominance**, the dominant allele does not completely mask the effects of the recessive allele in the heterozygote. The heterozygote produces less of the protein product than the homozygous dominant and has phenotypic characteristics intermediate between the homozygous dominant and the homozygous recessive. For example, **beta thalassemia** (thäl-ä-sē'mē-ä) is a disorder of a gene on chromosome 11. It affects the synthesis of β -globulin polypeptide chains, which are part of the hemoglobin in red blood cells. Hemoglobin is a protein that transports oxygen.

If normal amounts of the β -globulin polypeptide are produced, the β -globulin polypeptides join with other proteins to form hemoglobin. If lower than normal amounts of β -globulin polypeptide are synthesized, lower than normal amounts of hemoglobin are produced. In the homozygous dominant state, two normal alleles for β -globulin synthesis are present, normal amounts of hemoglobin are produced, and the phenotype is normal, meaning that there is normal transport of oxygen. In the homozygous recessive condition, called **major thalassemia**, two abnormal alleles are present, and much lower than normal amounts of β -globulin polypeptide chains are synthesized. The result is severe **anemia** (ä-nē'mē-ä), which is a deficiency of hemoglobin in the blood. Symptoms include pallor, weakness, fatigue, and spleen enlargement. Blood transfusions are necessary to maintain hemoglobin levels. In the heterozygous condition, called **minor thalassemia**, one normal allele and one abnormal allele are present. The production of hemoglobin is intermediate between the normal phenotype and major thalassemia, and mild anemia results.

Polygenic Traits

In some cases, one gene (usually with two alleles) determines one phenotype. In other cases, many genes determine a phenotype. These **polygenic traits** result from the interactions of many genes. Although all the genes contribute to the phenotype without being dominant or recessive to each other, each gene has its own characteristics, such as multiple alleles or incomplete dominance. Some of the genes may be more important than others for the expression of the phenotype, and the genes can be on different chromosomes. The result of all the gene interactions is a phenotype with a great amount of variability. Examples of polygenic traits are height, intelligence, eye color, and skin color.

Even though a complex combination of genes determines a polygenic trait, a defect in one of them can sometimes have a dramatic effect on phenotype. For example, even though many genes contribute to skin color, one defective gene can eliminate skin color completely, resulting in albinism.

Sex-Linked Traits

Sex-linked traits are traits affected by genes on the sex chromosomes. **X-linked traits** are on the X chromosome, and **Y-linked traits** are on the Y chromosome. Most sex-linked traits are X-linked, whereas only a few Y-linked traits exist, mainly because the Y chromosome is very small. An example of an X-linked recessive trait is **hemophilia A** (classic hemophilia), in which the ability to produce certain blood clotting factors is not present (see chapter 19). Consequently, clotting is impaired and persistent bleeding occurs either spontaneously or as a result of an injury. Traditionally, X-linked genes are designated by letters superscripted to the letter “X.” The possible genotypes and phenotypes for hemophilia A are

Genotype	Phenotype
$X^H X^H$ or $X^H X^h$	Normal female
$X^h X^h$	Hemophiliac female
$X^H Y$	Normal male
$X^h Y$	Hemophiliac male

Note that a female must have both recessive alleles (X^hX^h) to exhibit hemophilia, whereas a male, because he has only one X chromosome, has hemophilia if he has only one of the recessive alleles. For this reason, X-linked recessive traits are seen more frequently in males than in females.

- 77** Explain multiple allelism.
- 78** Distinguish among complete dominance, incomplete dominance, and codominance. Give examples of each.
- 79** What is the difference between multiple allelism and polygenic traits?
- 80** How are sex-linked traits inherited? Give an example.

Meiosis and the Transmission of Genes

Gametes are haploid cells that are derived from diploid cells. In **meiosis** (mī-ō'sīs) gametes are produced that have one homolog from each of the homologous pairs of chromosomes. Therefore

gametes have one half the number of chromosomes and one half the alleles as the original diploid cells.

Before meiosis begins, DNA replication occurs so that replicated chromosomes are formed, each consisting of two chromatids (figure 3.52). As a result of the first meiotic division, each daughter cell receives one replicated member of a homologous pair. No replication of DNA takes place between the first and second meiotic divisions. During the second meiotic division, the chromatids of each chromosome separate. As a result of the second meiotic division, each cell receives one chromatid from each chromosome. That single chromatid is now referred to as a chromosome. Each gamete now has a haploid number of chromosomes. See chapter 28 for a more detailed discussion of gamete production.

In figure 3.52, the alleles for albinism are shown on the homologous chromosomes. On one homolog, the normal, dominant allele is indicated with an uppercase *A*; on the other homolog, the abnormal allele is indicated with a lowercase *a*. Figure 3.52 illustrates how the alleles on homologous chromosomes are distributed to gametes. In this case, gametes with either an *A* or an *a* allele are produced.

1. A pair of unduplicated homologous chromosomes is shown in the nucleus of a somatic cell. For simplicity, the chromosomes are shown as compact bodies. In the unduplicated state, chromosomes are dispersed within the nucleus as chromatin.
2. The dominant (*A*) and recessive (*a*) alleles for albinism are shown on the homologous chromosomes.
3. The DNA has replicated, and each replicated chromosome consists of two chromatids (see figure 3.46).
4. Each replicated homologous chromosome has two alleles because the DNA has replicated.
5. As a result of the first meiotic division, each new nucleus has a replicated homologous chromosome.
6. DNA is not replicated between the first and second meiotic divisions. As a result of the second meiotic division, the chromatids separate and are now called chromosomes.
7. Each homologous chromosome has an allele for albinism. Two types of gametes have been produced, those carrying the *A* allele and those carrying the *a* allele.

PROCESS FIGURE 3.52 Meiosis and the Distribution of Alleles

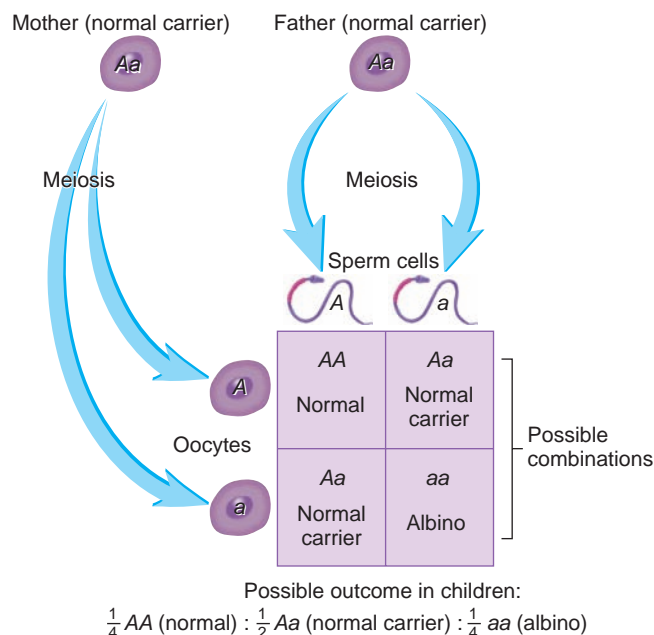

FIGURE 3.53 Inheritance of a Recessive Trait: Albinism

A represents the normal, pigmented condition, and a represents the recessive, unpigmented condition. The figure shows a Punnett square of a mating between two normal carriers.

The probability of the transmission of alleles to the next generation can be determined using a **Punnett square** if the genotypes of the parents are known (figure 3.53). The possible alleles found in the gametes of one parent form the rows of the square, and the possible alleles found in the gametes of the other parent form the columns. The body of the Punnett square shows all possible combinations of the parents' gametes. For example, suppose both parents are heterozygous (Aa) for albinism. The heterozygous parents can produce two types of gametes. One gamete has the A allele, and the other has the a allele. The probability that the child will be homozygous dominant (AA) is one out of four; heterozygous (Aa), two out of four; and homozygous recessive (aa), one out of four.

Albinism is an autosomal recessive trait. The homozygous dominant and heterozygous conditions result in normal pigmentation, whereas the homozygous recessive condition results in albinism. Both heterozygous parents have normal pigmentation, but there is a one out of four chance that any one of their children will be an albino. A **carrier** for a recessive trait is a person who is heterozygous for that trait, with one normal allele and one disorder-causing allele. The carrier does not exhibit the disorder but can pass it on to his or her children.

PREDICT 10

If a carrier for albinism mates with a homozygous normal person, what is the likelihood that any of the children will be albinos? Explain.

81 What is meiosis? How does it differ from mitosis?

82 What is a carrier?

Genetic Disorders

A **genetic disorder** is a failure of structure, function, or both as a result of abnormalities in a person's genetic makeup—that is, his or her DNA. Humans suffer from a variety of genetic disorders, some of which are highlighted throughout the remainder of this book. Genetic disorders determined by one gene are described by Mendelian characteristics—for example, as autosomal recessive. In some cases, this type of description is accurate, but, in other cases, the reality is more complex. For example, PKU is said to be autosomal recessive, but PKU has multiple alleles, which result in a spectrum of defects. As you study the genetic disorders in later chapters, keep in mind the concepts discussed in this chapter.

Genetic disorders involve either a single gene or an entire chromosome, as in the case of aneuploidy (table 3.4). Recall that a mutation is a change in a gene that usually involves a change in the number or kinds of nucleotides composing the DNA (see chapter 2). Mutations are known to occur by chance (randomly without known cause), but they can also be caused by chemicals, radiation, and viruses. Agents that cause mutations are called **mutagens** (mū'tā-jenz). In most cases, a specific cause of a mutation cannot be determined. Once a mutation has occurred, however, the abnormal trait can be passed from one generation to the next.

A mutation involving a single nucleotide change is called a point mutation. Mutations that change the sequence or number of nucleotides involve changes in chromosome structure, and therefore are called structural mutations. Structural mutations can involve deletions, the loss of part of a chromosome; duplications, the addition of a copied section of a chromosome; translocations, in which part of one chromosome becomes attached to another chromosome; and inversions, in which the DNA sequence of a section of a chromosome is reversed.

Furthermore, segregation errors that occur during meiosis result in changes in the chromosome number in the gametes. As the chromosomes separate during meiosis, the two members of a homologous pair may become "sticky" and not segregate as they normally do. As a result, one of the daughter cells receives both chromosomes and the other daughter cell receives none. This event is called **nondisjunction**. When the gametes are fertilized, the resulting zygote has either 47 chromosomes or 45 chromosomes rather than the normal 46, a condition called **aneuploidy** (an'ū-ploy-dē). Aneuploidies include monosomies, in which a chromosome is missing, or trisomies, in which an extra chromosome is present. Aneuploidies are usually lethal and is one reason for a high rate of early embryo loss. **Down syndrome**, or **trisomy 21**, is a type of aneuploidy in which three chromosomes 21 are present. A **syndrome** (sīn'drōm) is a set of signs and symptoms occurring together as the result of a single cause, such as a single mutation or one extra chromosome (a trisomy). Down syndrome is an example of an aneuploidy that is not always lethal. However, individuals with this genetic disorder exhibit physical and mental developmental problems, as well as an increased probability of developing certain cancers. These individuals also have a shortened life span.

TABLE 3.4 Genetic Disorders

Disorder	Description
Dominant Traits	
Achondroplasia	Dwarfism characterized by shortening of the upper and lower limbs
Huntington chorea	Severe degeneration of the basal nuclei and frontal cerebral cortex; characterized by purposeless movements and mental deterioration; onset is usually between 40 and 50 years of age
Hypercholesterolemia	Elevated blood cholesterol levels that contribute to atherosclerosis and cardiovascular disease
Marfan syndrome	Abnormal connective tissue, resulting in increased height, elongated digits, and weakness in the aortic wall
Neurofibromatosis	Small, pigmented lesions (café-au-lait spots) in the skin and disfiguring tumors (noncancerous) caused by the proliferation of Schwann cells along nerves
Osteogenesis imperfecta	Abnormal collagen synthesis, resulting in brittle bones that break repeatedly
Recessive Traits	
Albinism	Lack of an enzyme necessary to produce the pigment melanin; characterized by lack of skin, hair, and eye coloration
Cystic fibrosis	Impaired transport of chloride ions across plasma membranes; resulting in excessive production of thick mucus, which blocks the respiratory and gastrointestinal tract; the most common fatal genetic disorder
Phenylketonuria	Lack of the enzyme necessary to convert the amino acid phenylalanine to the amino acid tyrosine; an accumulation of phenylalanine leads to mental retardation
Severe combined immune deficiency	Inability to form the white blood cells (B cells, T cells, and phagocytes) necessary for an immune system response
Sickle-cell disease	Inability to produce normal hemoglobin; resulting in abnormally shaped red blood cells that clog capillaries or rupture
Tay-Sachs disease	Lack of the enzyme necessary to break down certain fatty substances; an accumulation of fatty substances impairs action potential propagation, resulting in deterioration of mental and physical functions and death by 3–4 years of age
Thalassemia	Decreased rate of hemoglobin synthesis; resulting in anemia, enlargement of the spleen, increased cell numbers in red bone marrow, and congestive heart failure
Sex-Linked Traits	
Duchenne muscular dystrophy	Deletion or alteration of part of the X chromosome; resulting in progressive weakness and wasting of muscles
Hemophilia	Most commonly, failure to produce blood clotting factors, caused by a recessive gene; resulting in prolonged bleeding
Red-green color blindness	Most commonly, deficiency in functional green-sensitive cones, caused by a recessive gene; inability to distinguish between red and green colors
Chromosomal Disorders	
Down syndrome	Caused by having three chromosomes 21; resulting in mental retardation, short stature, and poor muscle tone
Klinefelter syndrome	Caused by two or more X chromosomes in a male (XXY); resulting in small testes, sterility, and development of femalelike breasts
Turner syndrome	Caused by having only one X chromosome; resulting in immature uterus, lack of ovaries, and short stature

Sex Chromosome Abnormalities

A wide range of sex chromosome abnormalities exist. The presence of a Y chromosome makes a person genetically a male, and the absence of a Y chromosome makes a person genetically a female, regardless of the number of X chromosomes. Individuals with XO (Turner syndrome), XX, XXX, or XXXX karyotypes are therefore females, and individuals with XY, XXY, XXY, or XYY karyotypes are males. A YO condition is lethal because the genes on the X chromosome are necessary for survival. Secondary sexual characteristics are usually underdeveloped in both the XO female and the XXY male (called Klinefelter syndrome), and additional X chromosomes (XXXX or XXY) are often associated with some degree of mental retardation. As a result of hormonal imbalances, the morphological features (phenotype) may be reversed from the genetic constitution (genotype).

Cancer usually results from a series of somatic mutations that cause uncontrolled cell division and changes in the normal functions of cells. The genetics of cancer is discussed in the “Clinical Genetics” essay in chapter 4.

CLINICAL GENETICS

The Human Genome Project

The human genome consists of all the genes found in one homologous set of human chromosomes. It is estimated that humans have 25,000–30,000 genes. A **genomic map** is a description of the DNA nucleotide

sequences of the genes and their locations on the chromosomes (figure A). Celera, a private corporation working on the **Human Genome Project**, announced on February 12, 2001, that it had completed sequencing 99% of

the genome. Online Mendelian Inheritance in Man (OMIM) is a database that contains information about many human genes and genetic disorders (www.ncbi.nlm.nih.gov/omim).

FIGURE A Human Genomic Map

Representative genetic defects mapped to date. The bars and lines indicate the location of the genes listed for each chromosome.

Armed with a knowledge of the human genome and its effects on a person's physical, mental, and behavioral abilities, medicine and society will be transformed in many ways. Medicine, for example, will shift emphasis from the curative to the preventive. The disorders or diseases a person is likely to develop can be prevented or their severity lessened. When prevention is not possible, knowledge of the enzymes or other molecules involved in a disorder may result in new drugs and techniques that can compensate for the genetic

disorder. Knowledge of the genes involved in a disorder may result in **gene therapy**, or **genetic engineering**, that repairs or replaces defective genes, resulting in cures of or treatments for genetic disorders.

Despite the great promise of benefits from the Human Genome Project, the knowledge produced has raised a number of ethical and legal questions for society. Should a person's genomic information be public knowledge? Should persons with a genome that predisposes them to cancer or behavioral disorders

be barred from certain types of employment or be refused medical insurance because they are a high risk? Can a person demand to know a prospective mate's genome? Should parents know the genome of their fetus and be allowed to make decisions regarding abortion based on this knowledge? Should the same genetic-engineering techniques that provide alteration of the genome to cure genetic disorders be used to create genomes that are deemed to be superior? Such questions raise the specter of genetic discrimination.

SUMMARY

1. The plasma membrane forms the outer boundary of the cell.
2. The nucleus directs the activities of the cell.
3. Cytoplasm, between the nucleus and plasma membrane, is where most cell activities take place.

Functions of the Cell (p. 56)

1. Cells metabolize and release energy.
2. Cells synthesize molecules.
3. Cells provide a means of communication.
4. Cells reproduce and provide for inheritance.

How We See Cells (p. 58)

1. Light microscopes allow us to visualize the general features of cells.
2. Electron microscopes allow us to visualize the fine structure of cells.

Plasma Membrane (p. 58)

1. The plasma membrane passively or actively regulates what enters or leaves the cell.
2. The plasma membrane is composed of a phospholipid bilayer, in which proteins are suspended (fluid-mosaic model).

Membrane Lipids (p. 58)

Lipids give the plasma membrane most of its structure and some of its function.

Membrane Proteins (p. 58)

1. Membrane proteins function as marker molecules, attachment proteins, transport proteins, receptor proteins, and enzymes.
2. Transport proteins include channel proteins, carrier proteins (transporters), and ATP-powered pumps.

3. Some receptor molecules are linked to and control channel proteins.
4. Some receptor molecules are linked to G protein complexes, which in turn control numerous cellular activities.

Movement Through the Plasma Membrane (p. 64)

1. Lipid-soluble molecules pass through the plasma membrane readily by dissolving in the lipid bilayer.
2. Small molecules pass through membrane channels. Most channels are positively charged, allowing negatively charged ions and neutral molecules to pass through more readily than positively charged ions.
3. Large polar substances (e.g., glucose and amino acids) are transported through the membrane by carrier molecules.
4. Larger pieces of material enter cells in vesicles.

Diffusion

1. Diffusion is the movement of a substance from an area of higher solute concentration to one of lower solute concentration (down a concentration gradient).
2. The concentration gradient is the difference in solute concentration between two points divided by the distance separating the points.
3. The rate of diffusion increases with an increase in the concentration gradient, an increase in temperature, a decrease in molecular size, and a decrease in viscosity.
4. The end result of diffusion is a uniform distribution of molecules.
5. Diffusion requires no expenditure of energy.

Osmosis

1. Osmosis is the diffusion of water (solvent) across a selectively permeable membrane.
2. Osmotic pressure is the force required to prevent the movement of water across a selectively permeable membrane.

3. Isosmotic solutions have the same concentration of solute particles, hyperosmotic solutions have a greater concentration, and hypotonic solutions have a lesser concentration of solute particles than a reference solution.
4. Cells placed in an isotonic solution neither swell nor shrink. In a hypertonic solution, they shrink (crenate); in a hypotonic solution, they swell and may burst (lyse).

Filtration

1. Filtration is the movement of a liquid through a partition with holes that allow the liquid, but not everything in the liquid, to pass through them.
2. Liquid movement results from a pressure difference across the partition.

Mediated Transport

1. Mediated transport is the movement of a substance across a membrane by means of a transport protein. The substances transported tend to be large, water-soluble molecules.
 - The transport protein has binding sites that bind with either a single molecule or a group of similar molecules. This selectiveness is called specificity.
 - Similar molecules can compete for transport proteins, with each reducing the rate of transport of the other.
 - Once all the transport proteins are in use, the rate of transport cannot increase further (saturation).
2. Three kinds of mediated transport can be identified.
 - Facilitated diffusion moves substances down their concentration gradient and does not require energy (ATP) expenditure.
 - Active transport can move substances against their concentration gradient and requires ATP. An exchange pump is an active-transport mechanism that simultaneously moves two substances in opposite directions across the plasma membrane.
 - In secondary active transport, an ion is moved across the plasma membrane by active transport, and the energy produced by the ion diffusing back down its concentration gradient can transport another molecule, such as glucose, against its concentration gradient.

Endocytosis and Exocytosis (p. 71)

1. Endocytosis is the bulk movement of materials into cells.
 - Phagocytosis is the bulk movement of solid material into cells by the formation of a vesicle.
 - Pinocytosis is similar to phagocytosis, except that the ingested material is much smaller or is in solution.
2. Exocytosis is the secretion of materials from cells by vesicle formation.
3. Endocytosis and exocytosis use vesicles, can be specific (receptor-mediated endocytosis) for the substance transported, and require energy.

Cytoplasm (p. 76)

The cytoplasm is the material outside the nucleus and inside the plasma membrane.

Cytosol

1. Cytosol consists of a fluid part (the site of chemical reactions), the cytoskeleton, and cytoplasmic inclusions.
2. The cytoskeleton supports the cell and enables cell movements. It consists of protein fibers.
 - Microtubules are hollow tubes composed of the protein tubulin. They form spindle fibers and are components of centrioles, cilia, and flagella.

- Actin filaments are small protein fibrils that provide structure to the cytoplasm or cause cell movements.
 - Intermediate filaments are protein fibers that provide structural strength to cells.
3. Cytoplasmic inclusions, such as lipochromes, are not surrounded by membranes.

The Nucleus and Cytoplasmic Organelles (p. 77)

Organelles are subcellular structures specialized for specific functions.

Nucleus

1. The nuclear envelope consists of a double membrane with nuclear pores.
2. DNA and associated proteins are found inside the nucleus as chromatin.
3. DNA is the hereditary material of the cell. It controls the activities of the cell by producing proteins through RNA.
4. A gene is a portion of a DNA molecule. Genes determine the proteins in a cell.
5. Nucleoli consist of RNA and proteins and are the sites of ribosomal subunit assembly.

Ribosomes

1. Ribosomes consist of small and large subunits manufactured in the nucleolus and assembled in the cytoplasm.
2. Ribosomes are the sites of protein synthesis.
3. Ribosomes can be free or associated with the endoplasmic reticulum.

Endoplasmic Reticulum

1. The endoplasmic reticulum is an extension of the outer membrane of the nuclear envelope; it forms tubules or sacs (cisternae) throughout the cell.
2. The rough endoplasmic reticulum has ribosomes and is a site of protein synthesis and modification.
3. The smooth endoplasmic reticulum lacks ribosomes and is involved in lipid production, detoxification, and calcium storage.

Golgi Apparatus

The Golgi apparatus is a series of closely packed, modified cisternae that function to modify, package, and distribute lipids and proteins produced by the endoplasmic reticulum.

Secretory Vesicles

Secretory vesicles are membrane-bound sacs surrounded by membranes that carry substances from the Golgi apparatus to the plasma membrane, where the contents of the vesicle are released by exocytosis.

Lysosomes

1. Lysosomes are membrane-bound sacs containing hydrolytic enzymes. Within the cell, the enzymes break down phagocytized material and nonfunctional organelles (autophagia).
2. Enzymes released from the cell by lysis or enzymes secreted from the cell can digest extracellular material.

Peroxisomes

Peroxisomes are membrane-bound sacs containing enzymes that digest fatty acids and amino acids, as well as enzymes that catalyze the breakdown of hydrogen peroxide.

Proteasomes

Proteasomes are large, multienzyme complexes, not bound by membranes, which digest selected proteins within the cell.

Mitochondria

1. Mitochondria are the major sites of the production of ATP, which is used as an energy source by cells.
2. The mitochondria have a smooth outer membrane and an inner membrane that is infolded to produce cristae.
3. Mitochondria contain their own DNA, can produce some of their own proteins, and can replicate independently of the cell.

Centrioles and Spindle Fibers

1. Centrioles are cylindrical organelles located in the centrosome, a specialized zone of the cytoplasm. The centrosome is the site of microtubule formation.
2. Spindle fibers are involved in the separation of chromosomes during cell division.

Cilia and Flagella

1. Movement of materials over the surface of the cell is facilitated by cilia.
2. Flagella, much longer than cilia, propel sperm cells.

Microvilli

Microvilli increase the surface area of the plasma membrane for absorption or secretion.

Genes and Gene Expression (p. 86)

1. During transcription, information stored in DNA is copied to form mRNA.
2. During translation, the mRNA goes to ribosomes, where it directs the synthesis of proteins.

Transcription

1. DNA unwinds and, through nucleotide pairing, produces pre-mRNA (transcription).
2. Introns are removed and exons are spliced by spliceosomes during post-transcriptional processing.
3. Modifications to the ends of mRNA also occur during post-transcriptional processing.

Genetic Code

The genetic code, which specifies amino acids, consists of codons, which are sequences of three nucleotides in mRNA.

Translation

1. The mRNA moves through the nuclear pores to ribosomes.
2. Transfer RNA (tRNA), which carries amino acids, interacts at the ribosome with mRNA. The anticodons of tRNA bind to the codons of mRNA, and the amino acids are joined to form a protein (translation).
3. Proproteins, some of which are proenzymes, are modified into proteins, some of which are enzymes, during posttranslational processing.

Regulation of Genetic Expression

1. Cells become specialized because of inactivation of certain parts of the DNA molecule and activation of other parts.
2. The level of DNA activity and thus protein production can be controlled internally or can be affected by regulatory substances secreted by other cells.

Cell Life Cycle (p. 91)

The cell life cycle has two stages: interphase and cell division.

Interphase

- Interphase is the period between cell divisions. This is the time of DNA replication.

DNA Replication

- DNA unwinds, and each strand produces a new DNA molecule during replication.

Cell Division

1. Cell division includes nuclear division and cytoplasmic division.
2. Mitosis is the replication of the nucleus of the cell, and cytokinesis is division of the cytoplasm of the cell.
3. Mitosis is a continuous process divided into four phases.
 - *Prophase*. Chromatin condenses to become visible as chromosomes. Each chromosome consists of two chromatids joined at the centromere. Centrioles move to opposite poles of the cell, and astral fibers and spindle fibers form. Nucleoli disappear, and the nuclear envelope degenerates.
 - *Metaphase*. Chromosomes align at the equatorial plane.
 - *Anaphase*. The chromatids of each chromosome separate at the centromere. Each chromatid then is called a chromosome. The chromosomes migrate to opposite poles.
 - *Telophase*. Chromosomes unravel to become chromatin. The nuclear envelope and nucleoli reappear.
4. Cytokinesis begins with the formation of the cleavage furrow during anaphase. It is complete when the plasma membrane comes together at the equator, producing two new daughter cells.

Genetics (p. 93)

1. Genetics is the study of heredity, that is, characteristics inherited by children from their parents.
2. Genomic medicine uses an understanding of the biochemical relationship between genes and disease to diagnosis and manage disease.

Mendelian Genetics

1. The genes an organism has for a given trait is called the genotype. The expression of the genes is called the phenotype.
2. Alleles are alternate forms of genes. A dominant allele masks the effects of a recessive allele for the same trait.
3. An organism homozygous for a trait has two identical alleles for the trait, whereas an organism heterozygous for a trait has two different alleles for the trait.

Modern Concepts of Genetics

1. Chromosomes.
 - Somatic cells have a diploid number of chromosomes, whereas gametes have a haploid number. In humans, the diploid number is 46 and the haploid number is 23.
 - Humans have 22 pairs of autosomal chromosomes and one pair of sex chromosomes. Females have the sex chromosomes XX and males have XY.
 - A karyotype is a display of the chromosomes of a somatic cell during metaphase of mitosis.
 - Chromosome pairs are called homologous chromosomes.
2. The genome consists of all the genes found in the haploid number of chromosomes from one parent.

3. Each gene occupies a specific locus, or location on a chromosome.
4. Alleles exist in many different forms, called multiple alleles.
5. Gene dominance.
 - In complete dominance, the dominant allele masks the effects of the recessive allele.
 - In codominance, two alleles at the same locus are expressed so that separate, distinguishable phenotypes occur at the same time.
 - In incomplete dominance, the dominant allele does not completely mask the effects of the recessive allele.
6. Polygenic traits result from the interaction of many genes.
7. Sex linked traits.
 - Sex-linked traits are traits affected by genes on the sex chromosomes.
 - X-linked traits are affected by genes on the X chromosome, and Y-linked traits are traits affected by genes on the Y chromosome.
 - X-linked traits are seen more frequently in males than in females because males have only one X chromosome.

Meiosis and the Transmission of Genes

1. Meiosis results in the production of gametes.
2. A Punnett square can determine the probability of the transmission of alleles to the next generation.
3. A carrier for a recessive trait is a person who is heterozygous for the trait, with one normal allele and one disorder-causing allele.

Genetic Disorders

1. A mutation is a change in the number or kinds of nucleotides in DNA.
2. Some genetic disorders result from an abnormal distribution of chromosomes during gamete formation.
3. Cancer results from a series of somatic mutations.

REVIEW AND COMPREHENSION

1. In the plasma membrane, _____ form(s) the lipid bilayer, _____ determine(s) the fluid nature of the membrane, and _____ mainly determine(s) the function of the membrane.
 - a. phospholipids, cholesterol, proteins
 - b. phospholipids, proteins, cholesterol
 - c. proteins, cholesterol, phospholipids
 - d. cholesterol, phospholipids, proteins
 - e. cholesterol, proteins, phospholipids
2. Which of the following are functions of the proteins found in the plasma membrane?
 - a. channel proteins
 - b. marker molecules
 - c. receptor molecules
 - d. enzymes
 - e. all of the above
3. Integrins in the plasma membrane function as
 - a. channel proteins.
 - b. marker molecules.
 - c. attachment proteins.
 - d. enzymes.
 - e. receptor molecules.
4. In general, lipid-soluble molecules diffuse through the _____; small, water-soluble molecules diffuse through the _____.
 - a. membrane channels, membrane channels
 - b. membrane channels, lipid bilayer
 - c. lipid bilayer, carrier molecules
 - d. lipid bilayer, membrane channels
 - e. carrier proteins, membrane channels
5. Small pieces of matter, and even whole cells, can be transported across the plasma membrane in
 - a. membrane channels.
 - b. carrier molecules.
 - c. receptor molecules.
 - d. marker molecules.
 - e. vesicles.
6. The rate of diffusion increases if the
 - a. concentration gradient decreases.
 - b. temperature of a solution decreases.
 - c. viscosity of a solution decreases.
 - d. all of the above.
7. Concerning the process of diffusion, at equilibrium
 - a. the net movement of solutes stops.
 - b. random molecular motion continues.
 - c. there is an equal movement of solute in opposite directions.
 - d. the concentration of solute is equal throughout the solution.
 - e. all of the above.
8. Which of these statements about osmosis is true?
 - a. Osmosis always involves a membrane that allows water and all solutes to diffuse through it.
 - b. The greater the solute concentration, the smaller the osmotic pressure of a solution.
 - c. Osmosis moves water from a greater solute concentration to a lesser solute concentration.
 - d. The greater the osmotic pressure of a solution, the greater the tendency for water to move into the solution.
 - e. Osmosis occurs because of hydrostatic pressure outside the cell.
9. If a cell is placed in a _____ solution, lysis of the cell may occur.
 - a. hypertonic
 - b. hypotonic
 - c. isotonic
 - d. isosmotic
10. Container A contains a 10% salt solution, and container B contains a 20% salt solution. If the two solutions are connected, the net movement of water by diffusion is from _____ to _____, and the net movement of salt by diffusion is from _____ to _____.
 - a. A, B; A, B
 - b. A, B; B, A
 - c. B, A; A, B
 - d. B, A; B, A
11. Suppose that a woman ran a long-distance race in the summer. During the race, she lost a large amount of hyposmotic sweat. You would expect her cells to
 - a. shrink.
 - b. swell.
 - c. stay the same.
12. Suppose that a man is doing heavy exercise in the hot summer sun. He sweats profusely. He then drinks a large amount of distilled water. After he drank the water, you would expect his tissue cells to
 - a. shrink.
 - b. swell.
 - c. remain the same.

13. Unlike diffusion and osmosis, filtration depends on a _____ on the two sides of the partition.
- concentration gradient
 - pressure difference
 - difference in electric charge
 - difference in osmotic pressure
 - hyposmotic solution
14. Which of these statements about facilitated diffusion is true?
- In facilitated diffusion, net movement is down the concentration gradient.
 - Facilitated diffusion requires the expenditure of energy.
 - Facilitated diffusion does not require a carrier protein.
 - Facilitated diffusion moves materials through membrane channels.
 - Facilitated diffusion moves materials in vesicles.
15. Which of these statements concerning the symport of glucose into cells is true?
- The sodium–potassium exchange pump moves Na^+ into cells.
 - The concentration of Na^+ outside cells is less than inside cells.
 - A carrier protein moves Na^+ into cells and glucose out of cells.
 - The concentration of glucose can be greater inside cells than outside cells.
 - As Na^+ is actively transported into the cell, glucose is carried along.
16. A white blood cell ingests solid particles by forming vesicles. This describes the process of
- exocytosis.
 - facilitated diffusion.
 - secondary active transport.
 - phagocytosis.
 - pinocytosis.
17. Given these characteristics:
- requires energy
 - requires carrier proteins
 - requires membrane channels
 - requires vesicles
- Choose the characteristics that apply to exocytosis.
- 1, 2
 - 1, 3, 4
 - 1, 2, 3, 4
 - 1, 4
 - 1, 2, 3
18. Cytoplasm is found
- in the nucleus.
 - outside the nucleus and inside the plasma membrane.
 - outside the plasma membrane.
 - inside mitochondria.
 - everywhere in the cell.
19. Which of these elements of the cytoskeleton is composed of tubulin and forms essential components of centrioles, spindle fibers, cilia, and flagella?
- actin filaments
 - intermediate filaments
 - microtubules
20. Mature red blood cells cannot
- synthesize ATP.
 - transport oxygen.
 - synthesize new protein.
 - use glucose as a nutrient.
21. A large structure, normally visible in the nucleus of a cell, where ribosomal subunits are produced is called a (an)
- endoplasmic reticulum.
 - mitochondria.
 - nucleolus.
 - lysosome.
22. A cell that synthesizes large amounts of protein for use outside the cell has a large
- number of cytoplasmic inclusions.
 - number of mitochondria.
 - amount of rough endoplasmic reticulum.
 - amount of smooth endoplasmic reticulum.
 - number of lysosomes.
23. Which of these organelles produces large amounts of ATP?
- nucleus
 - mitochondria
 - ribosomes
 - endoplasmic reticulum
 - lysosomes
24. Cylindrically shaped extensions of the plasma membrane that do not move, are supported with actin filaments, and may function in absorption or as sensory receptors are
- centrioles.
 - spindle fibers.
 - cilia.
 - flagella.
 - microvilli.
25. A portion of an mRNA molecule that determines one amino acid in a polypeptide chain is called a (an)
- nucleotide.
 - gene.
 - codon.
 - exon.
 - intron.
26. In which of these organelles is mRNA synthesized?
- nucleus
 - ribosome
 - endoplasmic reticulum
 - nuclear envelope
 - peroxisome
27. During the cell life cycle, DNA replication occurs during the
- G_1 phase.
 - G_2 phase.
 - M phase.
 - S phase.
28. Given the following activities:
- repair
 - growth
 - gamete production
 - differentiation
- Which of the activities is (are) the result of mitosis?
- 2
 - 3
 - 1, 2
 - 3, 4
 - 1, 2, 4
29. A gene is
- the functional unit of heredity.
 - a certain portion of a DNA molecule.
 - a part of a chromosome.
 - all of the above.
30. Which of these terms is correctly matched with its definition?
- autosome—an X or a Y chromosome
 - phenotype—the genetic makeup of an individual
 - allele—genes occupying the same locus on homologous chromosomes
 - heterozygous—having two identical genes for a trait
 - recessive—a trait expressed when the genes are heterozygous
31. Which of these genotypes is heterozygous?
- DD
 - Dd
 - dd
 - both a and c
32. The ABO blood group is an example of
- dominant versus recessive alleles.
 - incomplete dominance.
 - codominance.
 - a polygenic trait.
 - sex-linked inheritance.
33. Assume that a trait is determined by an X-linked dominant gene. If the mother exhibits the trait, but the father does not, then their
- sons are more likely than their daughters to exhibit the trait.
 - daughters are more likely than their sons to exhibit the trait.
 - sons and daughters are equally likely to exhibit the trait.

CRITICAL THINKING

1. Why does a surgeon irrigate a surgical wound from which a tumor has been removed with sterile distilled water rather than with sterile isotonic saline?
2. Solution A is hyperosmotic to solution B. If solution A is separated from solution B by a selectively permeable membrane, does water move from solution A into solution B or vice versa? Explain.
3. A researcher wants to determine the nature of the transport mechanism that moved substance X into a cell. She could measure the concentration of substance X in the extracellular fluid and within the cell, as well as the rate of movement of substance X into the cell. She does a series of experiments and gathers the data shown in the following graph. Choose the transport process that is consistent with the data.
 - a. diffusion
 - b. active transport
 - c. facilitated diffusion
 - d. not enough information to make a judgment

Graph depicting the rate of movement of substance X from a fluid into a cell (y axis) versus the concentration of substance X within the cell minus the concentration outside the cell (x axis). At point A, the extracellular concentration of substance X is equal to the intracellular concentration of substance X (designated 0 on the x axis).

4. A dialysis membrane is selectively permeable, and substances smaller than proteins are able to pass through it. If you wanted to use a dialysis machine to remove only urea (a small molecule) from blood, what could you use for the dialysis fluid?
 - a. a solution that is isotonic and contains only large molecules, such as protein
 - b. a solution that is isotonic and contains the same concentration of all substances except that it has no urea
 - c. distilled water, which contains no ions or dissolved molecules
 - d. blood, which is isotonic and contains the same concentration of all substances, including urea
5. Predict the consequence of a reduced intracellular K^+ concentration on the resting membrane potential.
6. If you had the ability to inhibit mRNA synthesis with a drug, explain how you could distinguish between proteins released from secretory vesicles in which they had been stored and proteins released from cells in which they had been newly synthesized.
7. Given the following data from electron micrographs of a cell, predict the major function of the cell:
 - moderate number of mitochondria
 - well-developed rough endoplasmic reticulum
 - moderate number of lysosomes
 - well-developed Golgi apparatus
 - dense nuclear chromatin
 - numerous vesicles
8. Nondisjunction during the first meiotic division is called primary nondisjunction, whereas nondisjunction during the second meiotic division is called secondary nondisjunction. What type of nondisjunction produces the higher number of abnormal gametes? Explain.
9. Dimpled cheeks are inherited as a dominant trait. Is it possible for two parents, each of whom has dimpled cheeks, to have a child without dimpled cheeks? Explain.
10. The ability to roll the tongue to form a “tube” results from a dominant gene. Suppose that a woman and her son can roll their tongues, but her husband cannot. Is it possible to determine if the husband is the father of her son?
11. The ABO antigens are a group of molecules found on the surface of red blood cells. Can an individual who has blood type AB be a parent of a child with blood type O? Why or why not?

Histology

The Study of Tissues

4

In some ways, the human body is like a complex machine, such as a car. Both consist of many parts, which are made of materials consistent with their specialized functions. For example, car tires are made of synthetic rubber reinforced with a variety of fibers, the engine is made of a variety of metal parts, and the windows are made of transparent glass. All parts of a car cannot be made of a single type of material. Metal capable of withstanding the heat of the engine cannot be used for windows or tires. Similarly, the many parts of the human body are made of collections of specialized cells and the materials surrounding them. Muscle cells, which contract to produce body movements, are structurally different from and have different functions than those of epithelial cells, which protect, secrete, or absorb. Also, cells in the retina of the eye, specialized to detect light and allow us to see, do not contract as muscle cells do or exhibit the functions of epithelial cells.

The structure and function of tissues are so closely related that you should be able to predict the function of a tissue when given its structure, and vice versa. Knowledge of tissue structure and function is important in understanding the structure and function of organs, organ systems, and the complete organism. This chapter begins with brief discussions of *tissues and histology* (p. 110) and the development of *embryonic tissue* (p. 110) and then describes the structural and functional characteristics of the major tissue types: *epithelial tissue* (p. 110), *connective tissue* (p. 120), *muscle tissue* (p. 134), and *nervous tissue* (p. 136). In addition, the chapter provides an explanation of *membranes* (p. 137), *inflammation* (p. 138), *tissue repair* (p. 140), and *tissues and aging* (p. 142).

Colored SEM of simple columnar epithelial cells, with cilia, of the uterine tube.

TISSUES AND HISTOLOGY

Tissues (tish'ūz) are collections of similar cells and the substances surrounding them. Specialized cells and the extracellular matrix surrounding them form all the tissue types found at the **tissue level of organization**. The classification of tissue types is based on the structure of the cells; the composition of the noncellular substances surrounding cells, called the **extracellular matrix**; and the functions of the cells. The four primary tissue types, which include all tissues, and from which all organs of the body are formed, are

1. epithelial tissue
2. connective tissue
3. muscle tissue
4. nervous tissue

Epithelial and connective tissues are the most diverse in form. The different types of epithelial and connective tissues are classified by structure, including cell shapes, relationships of cells to one another, and the materials making up the extracellular matrix. In contrast, muscle and nervous tissues are classified by functional and structural characteristics.

The tissues of the body are interdependent. For example, muscle tissue cannot produce movement unless it receives oxygen carried by red blood cells, and new bone tissue cannot be formed unless epithelial tissue absorbs calcium and other nutrients from the digestive tract. Also, all tissues in the body die if cancer or another disease destroys the tissues of vital organs, such as the liver or kidneys.

Histology (his-tol'ō-jē) is the microscopic study of tissues. Much information about a person's health can be gained by examining tissues. A **biopsy** (bī'op-sē) is the process of removing tissue samples from patients surgically or with a needle for diagnostic purposes. Examining tissue samples from individuals with various disorders can distinguish the specific disease. For example, some red blood cells have an abnormal shape in people suffering from sickle-cell disease, and red blood cells are smaller than normal in people with iron-deficiency anemia. Cancer is identified and classified based on characteristic changes that occur in tissues. Changes in the structure of epithelial cells are used to identify cancer of the uterine cervix, and changes in white blood cells are used to identify people who have leukemia. Also, the number of white blood cells can be greatly increased in people who have infections. Epithelial cells from respiratory passages have an abnormal structure in people with chronic bronchitis and in people with lung cancer.

Tissue samples can be sent to a laboratory and are prepared for examination. Results are obtained from the examination of the prepared tissues. In some cases, tissues are removed surgically, they are prepared quickly, and the results are reported while the patient is still anesthetized. The appropriate therapy is based to a large degree on the results. For example, the amount of tissue removed as part of breast or other types of cancer treatment can be determined by the results.

An **autopsy** (aw'top-sē) is an examination of the organs of a dead body to determine the cause of death or to study the changes caused by a disease. Microscopic examination of tissue is often part of an autopsy.

- 1 **Name the four primary tissue types, and list three characteristics used to classify them. How does the classification of epithelial and connective tissue differ from the classification of muscle and nervous tissue?**
- 2 **Define histology. Explain how microscopic examination of tissues taken by biopsy or autopsy can be used to diagnose some diseases.**

EMBRYONIC TISSUE

Approximately 13 or 14 days after fertilization, the cells that give rise to a new individual, called embryonic stem cells, form a slightly elongated disk consisting of two layers called the ectoderm and the endoderm. Cells of the ectoderm then migrate between the two layers to form a third layer called the mesoderm. The ectoderm, mesoderm, and endoderm are called germ layers because the beginning of all adult structures can be traced back to one of them and they give rise to all the tissues of the body (see chapter 29).

The **endoderm** (en'dō-derm), the inner layer, forms the lining of the digestive tract and its derivatives. The **mesoderm** (mez'ō-derm), the middle layer, forms tissues such as muscle, bone, and blood vessels. The **ectoderm** (ek'tō-derm), the outer layer, forms the skin, and a portion of the ectoderm, called **neuroectoderm** (noor-ō-ek'tō-derm), becomes the nervous system (see chapter 29). Groups of cells that break away from the neuroectoderm during development, called **neural crest cells**, give rise to parts of the peripheral nerves (see chapter 29), skin pigment (see chapter 5), the medulla of the adrenal gland (see chapter 18), and many tissues of the face.

- 3 **Name the three embryonic germ layers.**
- 4 **What adult structures are derived from the endoderm, mesoderm, ectoderm, and neuroectoderm and neural crest cells?**

EPITHELIAL TISSUE

Epithelium (ep-i-thē'lē-ŭm; pl. *epithelia*, ep-i-thē'lē-ă), or **epithelial tissue**, can be thought of as a protective covering of surfaces, both outside and inside the body. Characteristics common to most types of epithelium are (figure 4.1)

1. Epithelium consists almost entirely of cells, with very little extracellular matrix between them.
2. Epithelium covers surfaces of the body and forms glands that are derived developmentally from body surfaces. The body surfaces include the outside surface of the body, the lining of the digestive and respiratory tracts, the heart and blood vessels, and the linings of many body cavities.
3. Most epithelial tissues have one **free**, or **apical** (ap'i-kāl), **surface** not attached to other cells; a **lateral surface** attached to other epithelial cells; and a **basal surface**. The free surface often lines the lumen of ducts, vessels, or cavities. The basal surface of most epithelial tissues is attached to a **basement membrane**. The basement membrane is a specialized type of extracellular material secreted by the epithelial cells and by connective tissue cells. It is like the adhesive on ScotchTM tape. It helps attach the epithelial cells to the underlying

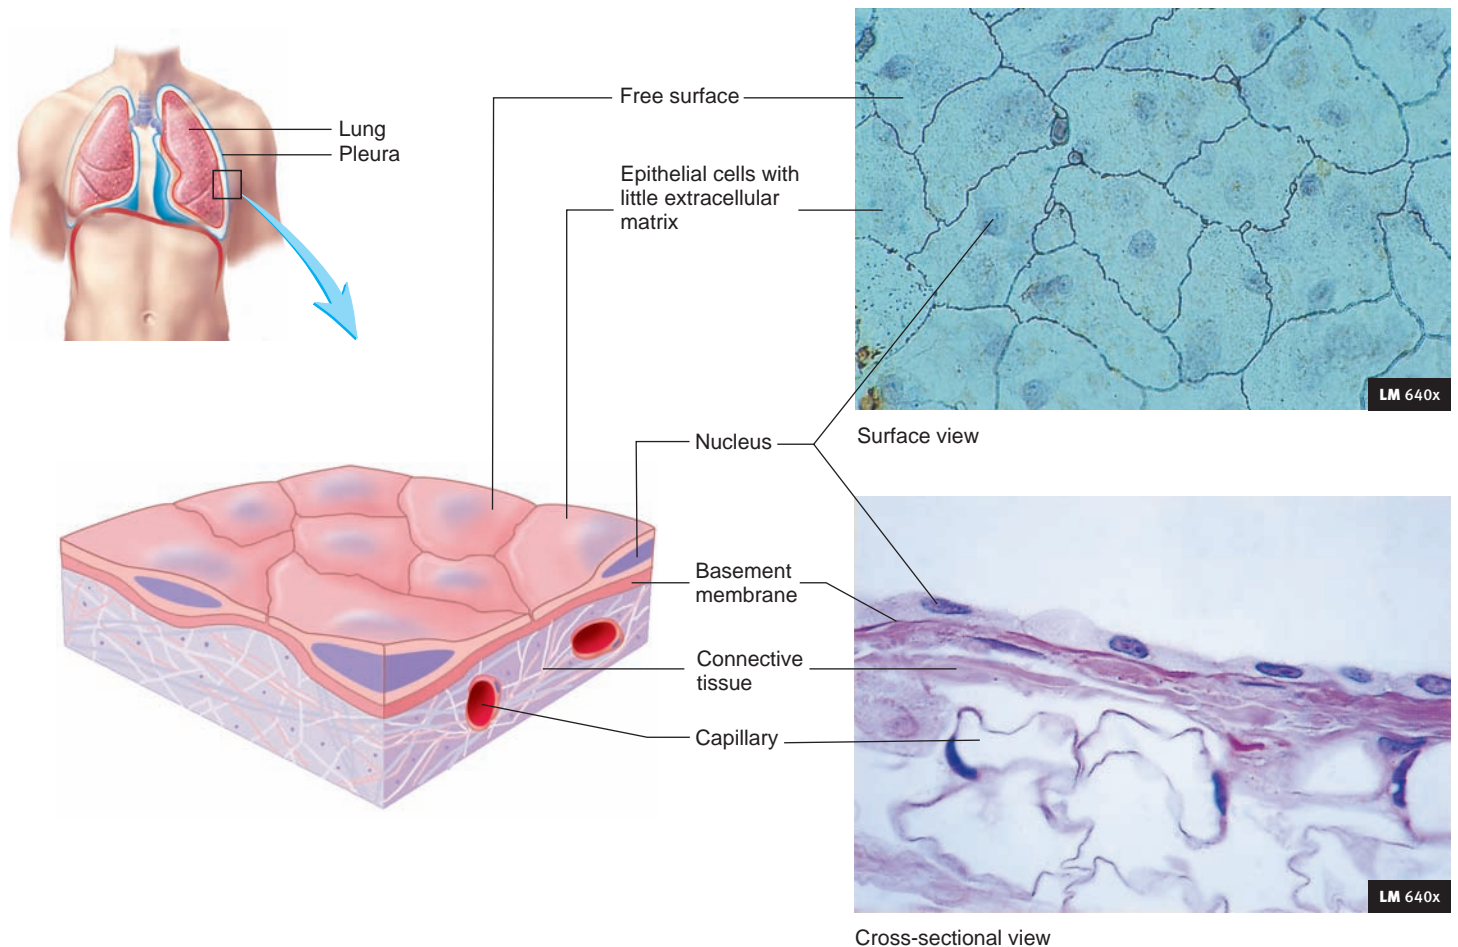

FIGURE 4.1 Characteristics of Epithelium

Surface and cross-sectional views of epithelium illustrate the following characteristics: little extracellular material between cells, a free surface, and a basement membrane attaching epithelial cells to underlying tissues. Capillaries in connective tissue do not penetrate the basement membrane. Nutrients, oxygen, and waste products must diffuse across the basement membrane between the capillaries and the epithelial cells.

- tissues, and it plays an important role in supporting and guiding cell migration during tissue repair. A few epithelial tissues, such as in lymphatic capillaries and liver sinusoids, do not have basement membranes, and some epithelial tissues, such as in some endocrine glands, do not have a free surface or a basal surface with a basement membrane.
- Specialized cell contacts bind adjacent epithelial cells together.
 - Blood vessels in the underlying connective tissue do not penetrate the basement membrane to reach the epithelium; thus, all gases and nutrients carried in the blood must reach the epithelium by diffusing from blood vessels across the basement membrane. In epithelial tissues with many layers of cells, the most metabolically active cells are close to the basement membrane.
 - Epithelial cells retain the ability to undergo mitosis and therefore are able to replace damaged cells with new epithelial cells. Undifferentiated cells (stem cells) continuously divide and produce new cells. In some types of epithelial tissues, such as in the skin and in the digestive tract, cells that are lost or die are continuously replaced by new cells.

- 5** List six characteristics common to most types of epithelium. Define free (apical), lateral, and basal surfaces of epithelial cells.
- 6** What is the basement membrane and what are its functions? Why must metabolically active epithelial cells be close to the basement membrane?

Functions of Epithelial Tissue

Major functions of epithelial tissue include

- Protecting underlying structures.** Examples are the outer layer of the skin and the epithelium of the oral cavity, which protect the underlying structures from abrasion.
- Acting as barriers.** Epithelium prevents the movement of many substances through the epithelial layer. For example, the skin acts as a barrier to water and reduces water loss from the body. The skin is also a barrier that prevents the entry of many toxic molecules and microorganisms into the body.
- Permitting the passage of substances.** Epithelium allows the movement of many substances through the epithelial layer. For

CLINICAL FOCUS

Microscopic Imaging

We see objects because light either passes through them or is reflected off them and enters our eyes (see chapter 15). We are limited, however, in what we can see with the unaided eye. Without the aid of magnifying lenses, the smallest objects we can resolve, or identify as separate objects, are approximately 100 μm , or 0.1 mm, in diameter, which is approximately the size of a fine pencil dot. The details of cells and tissues, which are much smaller than 100 μm , cannot be examined without the aid of a microscope.

Two basic types of microscopes have been developed: light microscopes and electron microscopes. As their names imply, light microscopes use light to produce an image, and electron microscopes use beams of electrons. **Light microscopes** usually use transmitted light, which is light that passes through the object being examined, but some light microscopes are equipped to use reflected light. Glass lenses are used in light microscopes to magnify images. The images can be observed directly by looking into the microscope, or the light from the images can be used to expose photographic film to make a photomicrograph of the images. Video or digital cameras are also used to record images, which can be stored or analyzed and enhanced electronically. The resolution of light microscopes is limited by the wavelength of light, the lower limit of which is approximately 0.1 μm —about the size of a small bacterium.

Recall that a biopsy is the process of removing tissue from living patients for

diagnostic examination. For example, changes in tissue structure allow pathologists to identify tumors and to distinguish between noncancerous (benign) and cancerous (malignant) tumors. Light microscopy is used on a regular basis to examine biopsy specimens. Light microscopy is used instead of electron microscopy because less time and effort are required to prepare materials for examination, and the resolution is adequate to diagnose most conditions that cause changes in tissue structure.

Because images are usually produced using transmitted light, tissues to be examined must be cut very thinly to allow the light to pass through them. Sections are routinely cut between 1 and 20 μm thick to make them thin enough for light microscopy. To cut such thin sections, the tissue must be fixed, or frozen, which is a process that preserves the tissue and makes it more rigid. Fixed tissues are then embedded in a material, such as wax or plastic, that makes the tissue rigid enough for cutting into sections. Frozen sections, which can be prepared rapidly, are rigid enough for sectioning, but tissue embedded in wax or plastic can be cut much thinner, which makes the image seen through the microscope clearer. Because most tissues are colorless and transparent when thinly sectioned, the tissue must be colored with a stain or dye so that the structural details can be seen. As a result, the colors seen in color photomicrographs are not the true colors of the tissue but instead are the colors of the stains used. The color of the stain can

also provide specific information about the tissue, because special stains color only certain structures.

To see objects much smaller than a cell, such as cell organelles, an **electron microscope**, which has a limit of resolution of approximately 0.1 nm, must be used; 0.1 nm is about the size of some molecules. In objects viewed through an electron microscope, a beam of electrons either is passed through objects using a transmission electron microscope (TEM) or is reflected off the surface of objects using a scanning electron microscope (SEM). The electron beam is focused with electromagnets. For both processes, the specimen must be fixed, and for TEM the specimen must be embedded in plastic and thinly sectioned (0.01–0.15 μm thick). Care must be taken when examining specimens in an electron microscope because a focused electron beam can cause most tissues to disintegrate quickly. Furthermore, the electron beam is not visible to the human eye; thus, it must be directed onto a fluorescent or photographic plate on which the electron beam is converted into a visible image. Because the electron beam does not transmit color information, electron micrographs are black and white unless color enhancement has been added using computer technology.

The magnification ability of SEM is not as great as that of TEM; however, depth of focus of SEM is much greater and allows for the production of a clearer three-dimensional image of tissue structure.

example, oxygen and carbon dioxide are exchanged between the air and blood by diffusion through the epithelium in the lungs. Epithelium acts as a filter in the kidney, allowing many substances to pass from the blood into the urine but retaining other substances, such as blood cells and proteins, in the blood.

4. **Secreting substances.** Mucous glands, sweat glands, and the enzyme-secreting portions of the pancreas secrete their products onto epithelial surfaces or into ducts that carry them to other areas of the body.
5. **Absorbing substances.** The plasma membranes of certain epithelial tissues contain carrier proteins (see chapter 3), which regulate the absorption of materials.

7 List the major functions of epithelial tissue.

Classification of Epithelium

Epithelium is classified primarily according to the number of cell layers and the shape of the superficial cells. There are three major types of epithelium based on the number of cell layers in each type.

1. **Simple epithelium** consists of a single layer of cells, with each cell extending from the basement membrane to the free surface.
2. **Stratified epithelium** consists of more than one layer of cells, but only the basal layer of cells attaches the deepest layer to the basement membrane.
3. **Pseudostratified columnar epithelium** is a special type of simple epithelium. The prefix *pseudo-* means false, so this type of epithelium appears to be stratified but is not.

It consists of one layer of cells, with all the cells attached to the basement membrane. There is an appearance of two or more layers of cells because some of the cells are tall and extend to the free surface, whereas others are shorter and do not extend to the free surface.

There are three types of epithelium based on the shape of the epithelial cells.

1. **Squamous** (skwā'mūs; flat) cells are flat or scalelike.
2. **Cuboidal** (cubelike) cells are cube-shaped; they are about as wide as they are tall.
3. **Columnar** (tall and thin, similar to a column) cells are taller than they are wide.

In most cases, an epithelium is given two names, such as simple squamous, stratified squamous, simple columnar, or pseudostratified columnar. The first name indicates the number of layers, and the second indicates the shape of the cells (table 4.1) at the free surface. Tables 4.2–4.4 provide an overview of the major types of epithelial tissues and their distributions.

Simple squamous epithelium consists of one layer of flat, or scalelike, cells that rest on a basement membrane (see table 4.2*a*). Stratified squamous epithelium consists of several layers of cells. Near the basement membrane, the cells are more cuboidal, but at the free surface the cells are flat or scalelike (see table 4.3*a*). Pseudostratified columnar epithelial cells are columnar in shape in that they are taller than they are wide and, although they appear to

TABLE 4.1 Classification of Epithelium

Number of Layers or Category	Shape of Cells
Simple (single layer of cells)	Squamous
	Cuboidal
	Columnar
Stratified (more than one layer of cells)	Squamous
	Nonkeratinized (moist)
	Keratinized
	Cuboidal (very rare)
	Columnar (very rare)
Pseudostratified (modification of simple epithelium)	Columnar
Transitional (modification of stratified epithelium)	Roughly cuboidal to columnar when not stretched and squamouslike when stretched

consist of more than one layer, all of the cells rest on the basement membrane (see table 4.4*a*).

Stratified squamous epithelium can be classified further as either nonkeratinized (moist) or keratinized, according to the condition of the outermost layer of cells. **Nonkeratinized**

TABLE 4.2 Simple Epithelium

(a) Simple Squamous Epithelium

Structure: Single layer of flat, often hexagonal cells; the nuclei appear as bumps when viewed as a cross section because the cells are so flat

Function: Diffusion, filtration, some secretion and some protection against friction

Location: Lining of blood vessels and the heart, lymphatic vessels (endothelium) and small ducts, alveoli of the lungs, portions of the kidney tubules, lining of serous membranes (mesothelium) of body cavities (pleural, pericardial, peritoneal), and inner surface of the eardrums

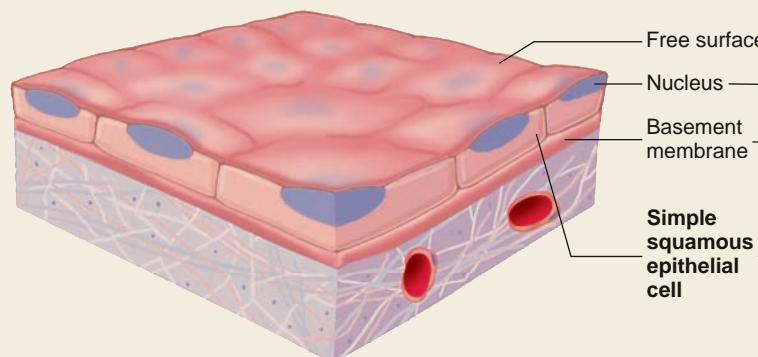

TABLE 4.2 Simple Epithelium—Continued

(b) Simple Cuboidal Epithelium

Structure: Single layer of cube-shaped cells; some cells have microvilli (kidney tubules) or cilia (terminal bronchioles of the lungs)

Function: Active transport and facilitated diffusion result in secretion and absorption by cells of the kidney tubules; secretion by cells of glands and choroid plexuses; movement of particles embedded in mucus out of the terminal bronchioles by ciliated cells

Location: Kidney tubules, glands and their ducts, choroid plexuses of the brain, lining of terminal bronchioles of the lungs, surfaces of the ovaries

(c) Simple Columnar Epithelium

Structure: Single layer of tall, narrow cells; some cells have cilia (bronchioles of lungs, auditory tubes, uterine tubes, and uterus) or microvilli (intestines)

Function: Movement of particles out of the bronchioles of the lungs by ciliated cells; partially responsible for the movement of oocytes through the uterine tubes by ciliated cells; secretion by cells of the glands, the stomach, and the intestines; absorption by cells of the intestine

Location: Glands and some ducts, bronchioles of lungs, auditory tubes, uterus, uterine tubes, stomach, intestines, gallbladder, bile ducts, ventricles of the brain

Lining of stomach and intestines

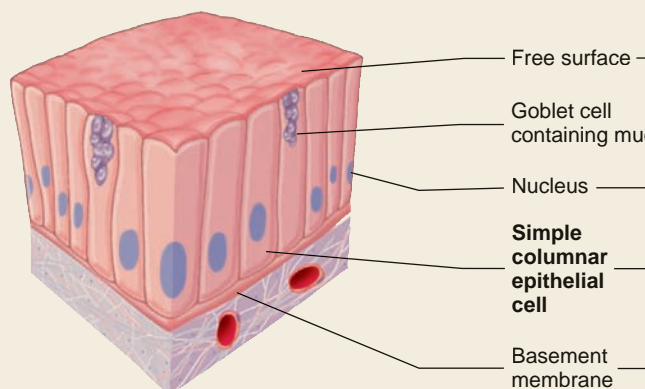

TABLE 4.3 Stratified Epithelium

(a) Stratified Squamous Epithelium

Structure: Multiple layers of cells that are cuboidal in the basal layer and progressively flattened toward the surface; the epithelium can be nonkeratinized (moist) or keratinized; in nonkeratinized stratified squamous epithelium, the surface cells retain a nucleus and cytoplasm, in keratinized stratified epithelium; the cytoplasm of cells at the surface is replaced by a protein called keratin, and the cells are dead

Function: Protection against abrasion, barrier against infection, reduction of water loss from the body

Location: Keratinized—skin; nonkeratinized (moist)—mouth, throat, larynx, esophagus, anus, vagina, inferior urethra, cornea

(b) Stratified Cuboidal Epithelium

Structure: Multiple layers of somewhat cube-shaped cells

Function: Secretion, absorption, protection against infection

Location: Sweat gland ducts, ovarian follicular cells, salivary gland ducts

TABLE 4.3 Stratified Epithelium—Continued**(c) Stratified Columnar Epithelium**

Structure: Multiple layers of cells with tall, thin cells resting on layers of more cuboidal cells; the cells are ciliated in the larynx

Function: Protection and secretion

Location: Mammary gland ducts, larynx, a portion of the male urethra

(moist) **stratified squamous epithelium** (see table 4.3a), found in areas such as the mouth, esophagus, rectum, and vagina, consists of living cells in the deepest and outermost layers. A layer of fluid covers the outermost layers of cells, which makes them moist. In contrast, **keratinized** (ker'ă-ti-nizd) **stratified squamous epithelium**, found in the skin (see chapter 5), consists of living cells in the deepest layers, and the outer layers are composed of dead cells containing the protein keratin. The dead, keratinized cells give the tissue a durable, moisture-resistant, dry character.

A unique type of stratified epithelium called **transitional epithelium** (see table 4.4b) lines the urinary bladder; ureters; pelvis of the kidney, including the major and minor calyces (kal'i-sēz); and superior part of the urethra (see chapter 26). These are structures where considerable expansion can occur. The shape of the cells and the number of cell layers vary, depending on the degree to which transitional epithelium is stretched. The surface cells and the underlying cells are roughly cuboidal or columnar when the epithelium is not stretched, and they become more flattened or squamouslike as the epithelium is stretched. Also, the number of layers of epithelial cells decreases in response to stretch. As the epithelium is stretched, the epithelial cells can shift on one another so that the number of layers decreases from five or six to two or three.

- 8 Describe simple, stratified, and pseudostratified epithelial tissues. Distinguish among squamous, cuboidal, and columnar epithelial cells.
- 9 How do nonkeratinized (moist) stratified squamous epithelium and keratinized stratified squamous epithelium differ? Where is each type found?
- 10 Describe the changes in cell shape and number of cell layers in transitional epithelium as it is stretched. Where is transitional epithelium found?

Functional Characteristics

Epithelial tissues have many functions (table 4.5), including forming a barrier between a free surface and the underlying tissues and secreting, transporting, and absorbing selected molecules. The type and arrangement of organelles within each cell (see chapter 3), the shape of cells, and the organization of cells within each epithelial type reflect these functions. Accordingly, structural specializations of epithelial cells are consistent with the functions they perform.

Cell Layers and Cell Shapes

Simple epithelium, with its single layer of cells, covers surfaces and allows diffusion of gases (lungs), filters blood (kidneys), secretes

TABLE 4.4 Pseudostratified Columnar Epithelium and Transitional Epithelium

(a) Pseudostratified Columnar Epithelium

Structure: Single layer of cells; some cells are tall and thin and reach the free surface, and others do not; the nuclei of these cells are at different levels and appear stratified; the cells are almost always ciliated and are associated with goblet cells that secrete mucus onto the free surface

Function: Synthesize and secrete mucus onto the free surface and move mucus (or fluid) that contains foreign particles over the surface of the free surface and from passages

Location: Lining of nasal cavity, nasal sinuses, auditory tubes, pharynx, trachea, bronchi of lungs

(b) Transitional Epithelium

Structure: Stratified cells that appear cuboidal when the organ or tube is not stretched and squamous when the organ or tube is stretched by fluid

Function: Accommodates fluctuations in the volume of fluid in organs or tubes; protects against the caustic effects of urine

Location: Lining of urinary bladder, ureters, superior urethra

TABLE 4.5 Function and Location of Epithelial Tissue

Function	Simple Squamous Epithelium	Simple Cuboidal Epithelium	Simple Columnar Epithelium
Diffusion	Blood and lymph capillaries, alveoli of lungs, thin segments of loops of Henle		
Filtration	Bowman's capsules of kidneys		
Secretion or absorption	Mesothelium (serous fluid)	Choroid plexus (produces cerebrospinal fluid), part of kidney tubules, many glands and their ducts	Stomach, small intestine, large intestine, uterus, many glands
Protection (against friction and abrasion)	Endothelium (e.g., epithelium of blood vessels) Mesothelium (e.g., epithelium of body cavities)		
Movement of mucus (ciliated)		Terminal bronchioles of lungs	Bronchioles of lungs, auditory tubes, uterine tubes, uterus
Capable of great stretching			
Miscellaneous	Inner part of the eardrums, smallest ducts of glands	Surface of ovaries, inside lining of eyes (pigmented epithelium of retina), ducts of glands	Bile duct, gallbladder, ependyma (lining of brain ventricles and central canal of spinal cord), ducts of glands

cellular products (glands), and absorbs nutrients (intestines). The selective movement of materials through epithelium is hindered by a stratified epithelium, which is found in areas where protection is a major function. The multiple layers of cells in stratified epithelium are well adapted for a protective role because, as the outer cells are damaged, they are replaced by cells from deeper layers and a continuous barrier of epithelial cells is maintained in the tissue. Stratified squamous epithelium is found in areas of the body where abrasion can occur, such as the skin, mouth, throat, esophagus, anus, and vagina.

Differing functions are also reflected in cell shape. Cells that allow substances to diffuse through them and that filter are normally flat and thin. For example, simple squamous epithelium forms blood and lymphatic capillaries, the alveoli (air sacs) of the lungs, and parts of the kidney tubules. Cells that secrete or absorb are usually cuboidal or columnar. They have greater cytoplasmic volume, compared with that of squamous epithelial cells; this cytoplasmic volume results from the presence of organelles responsible for the tissues' functions. For example, pseudostratified columnar epithelium, which secretes large amounts of mucus, lines the respiratory tract (see chapter 23) and contains large **goblet cells**, which are specialized columnar epithelial cells. The goblet cells contain abundant organelles responsible for the synthesis and secretion of mucus, such as ribosomes, endoplasmic reticulum, Golgi apparatuses, and secretory vesicles filled with mucus.

11 What functions would a single layer of epithelial cells be expected to perform? A stratified layer?

12 In locations in which diffusion or filtration is occurring, what shape would you expect the epithelial cells to be?

13 Why are cuboidal or columnar cells found where secretion or absorption is occurring?

PREDICT 1

Explain the consequences of having (a) nonkeratinized stratified epithelium rather than simple columnar epithelium lining the digestive tract, (b) nonkeratinized stratified squamous epithelium rather than keratinized stratified squamous epithelium in the skin, and (c) simple columnar epithelium rather than nonkeratinized stratified squamous epithelium lining the mouth.

Cell Surfaces

The free surfaces of epithelial tissues can be smooth, contain microvilli, be ciliated, or be folded. Smooth surfaces reduce friction. The lining of blood vessels is a simple squamous epithelium that reduces friction as blood flows through the vessels (see chapter 21).

Microvilli and cilia were described in chapter 3. Microvilli are nonmotile and contain microfilaments. They greatly increase surface area and are found in cells that absorb or secrete, such as serous membranes or the lining of the small intestine (see chapter 24). Stereocilia are elongated microvilli. They are found in sensory structures, such as the inner ear (see chapter 15), and they play a role in sound detection. They are found in some places where absorption is important, such as in the epithelium of the epididymis. Cilia contain microtubules and they move materials across the surface of the cell (see chapter 3). Simple ciliated cuboidal, simple ciliated columnar, and pseudostratified ciliated columnar epithelial tissues are in the respiratory tract (see chapter 23), where cilia move mucus that contains foreign particles, such as dust, out of the respiratory passages. Cilia are also found on the apical surface of the simple columnar epithelial cells of the uterus and uterine tubes. The cilia help move mucus and oocytes.

Stratified Squamous Epithelium	Stratified Cuboidal Epithelium	Stratified Columnar Epithelium	Pseudostratified Columnar Epithelium	Transitional Epithelium
Skin (epidermis), corneas, mouth and throat, epiglottis, larynx, esophagus, anus, vagina			Larynx, nasal cavity, paranasal sinuses, nasopharynx, auditory tubes, trachea, bronchi of lungs	
				Urinary bladder, ureter, superior part of urethra
Lower part of urethra, sebaceous gland ducts	Sweat gland ducts	Part of male urethra, epididymides, ductus deferens, mammary gland ducts	Part of male urethra, salivary gland ducts	

Transitional epithelium has a rather unusual plasma membrane specialization: More rigid sections of membrane are separated by very flexible regions in which the plasma membrane is folded. When transitional epithelium is stretched, the folded regions of the plasma membrane can unfold. Transitional epithelium is specialized to expand. It is found in the urinary bladder, ureters, kidney pelvis, calyces of the kidney, and superior part of the urethra.

14 *What is the function of an epithelial free surface that is smooth, has cilia, has microvilli, or is folded? Give an example of epithelium in which each surface type is found.*

Cell Connections

Lateral and basilar surfaces have structures that hold cells to one another or to the basement membrane (figure 4.2). These structures do three things: (1) mechanically bind the cells together, (2) help form a permeability barrier, and (3) provide a mechanism for intercellular communication. Epithelial cells secrete glycoproteins that attach the cells to the basement membrane and to one another. This relatively weak binding between cells is reinforced by **desmosomes** (dez'mō-sōmz), disk-shaped structures with especially adhesive glycoproteins that bind cells to one another and intermediate filaments that extend into the cytoplasm of the cells. Many desmosomes are found in epithelial tissues that are subjected to stress, such as the stratified squamous epithelium of the skin. **Hemidesmosomes**, similar to one-half of a desmosome, attach epithelial cells to the basement membrane.

Tight junctions hold cells together and form a permeability barrier (see figure 4.2). They consist of a zonula adherens and a zonula occludens, which are found in close association with each other. The **zonula adherens** (zō'nū-lā, zon'ū-lā ad-hēr'enz) is located between

FIGURE 4.2 Cell Connections

Desmosomes anchor cells to one another and hemidesmosomes anchor cells to the basement membrane. Tight junctions consist of a zonula occludens and zonula adherens. Gap junctions allow adjacent cells to communicate with each other. Few cells have all of these different connections.

the plasma membranes of adjacent cells and acts as a weak glue that holds cells together. The zonulae adherens are best developed in simple epithelial tissues; they form a girdle of adhesive glycoprotein around the lateral surface of each cell, binding adjacent cells together. These connections are not as strong as that of desmosomes.

The **zonula occludens** (ō-klood'enz) forms a permeability barrier. It is formed by plasma membranes of adjacent cells that join one another in a jigsaw fashion to form a tight seal (see figure 4.2). Near the free surface of simple epithelial cells, the zonulae occludens form a ring that completely surrounds each cell and binds adjacent cells together. The zonulae occludens prevent the passage of materials between cells. For example, in the stomach and in the urinary bladder, chemicals cannot pass between cells. Thus, water and other substances must pass through the epithelial cells, which can actively regulate what is absorbed or secreted. Zonulae occludens are found in areas where a layer of simple epithelium forms a permeability barrier. For example, water can diffuse through epithelial cells, and active transport, symport, and facilitated diffusion move most nutrients through the epithelial cells of the intestine.

A **gap junction** is a small, specialized contact region between cells containing protein channels that aid intercellular communication by allowing ions and small molecules to pass from one cell to another (see figure 4.2). The function of gap junctions in epithelium is not entirely clear. Gap junctions between ciliated epithelial cells may coordinate the movements of cilia. Gap junctions are important in coordinating the function of cardiac and smooth muscle tissues. Because ions can pass through the gap junctions from one cell to the next, electric signals can pass from cell to cell to coordinate the contraction of cardiac and smooth muscle cells. Thus, electric signals that originate in one cell of the heart can spread from cell to cell and cause the entire heart to contract. The gap junctions between cardiac muscle cells are found in specialized cell-to-cell connections called **intercalated disks** (see chapter 20).

15 *Name the ways in which epithelial cells are bound to one another and to the basement membrane.*

16 *In addition to holding cells together, name an additional function of tight junctions. What is the general function of gap junctions?*

PREDICT 2

If a simple epithelial type has well-developed zonula occludens, explain how NaCl can be moved from one side of the epithelial layer to the other, what type of epithelium it is likely to be, and how the movement of NaCl causes water to move in the same direction.

Glands

Glands are secretory organs. Many glands are composed primarily of epithelium, with a supporting network of connective tissue. These glands develop from an infolding or outfolding of epithelium in the embryo. If the gland maintains an open contact with the epithelium from which it developed, a duct is present. Glands with ducts are called **exocrine** (ek'sō-krin) **glands**, and their ducts are lined with epithelium. Alternatively, some glands become separated from the epithelium of their origin. Glands that have no ducts are called **endocrine** (en'dō-krin) **glands**. Endocrine glands have extensive blood

vessels in the connective tissue of the glands. The cellular products of endocrine glands, which are called **hormones** (hōr'mōnz), are secreted into the bloodstream and are carried throughout the body. Some of the endocrine glands form from nonepithelial tissue. For example, the medulla of the adrenal gland is formed from neural crest cells, and the cortex of the adrenal gland is formed from mesoderm. In addition, cardiac muscle cells can function as endocrine glands.

Most exocrine glands are composed of many cells and are called **multicellular glands**, but some exocrine glands are composed of a single cell and are called **unicellular glands** (figure 4.3a). **Goblet cells** (see table 4.2c) of the respiratory system are unicellular glands that secrete mucus. Multicellular glands can be classified further according to the structure of their ducts (figure 4.3b–i). Glands that have ducts with few branches are called **simple**, and glands with ducts that branch repeatedly are called **compound**. Further classification is based on whether the ducts end in **tubules** (small tubes), in saclike structures called **acini** (as'i-nī; grapes, suggesting a cluster of grapes or small sacs), or in **alveoli** (al-vē'ō-lī; hollow sacs). Tubular glands can be classified as straight or coiled. Most tubular glands are simple and straight, simple and coiled, or compound and coiled. Acinar glands can be simple or compound.

Exocrine glands can also be classified according to how products leave the cell. **Merocrine** (mer'ō-krin) **glands**, such as water-producing sweat glands and the exocrine portion of the pancreas, secrete products with no loss of actual cellular material (figure 4.4a). Secretions are either actively transported or packaged in vesicles and then released by the process of exocytosis at the free surface of the cell. **Apocrine** (ap'ō-krin) **glands**, such as the milk-producing mammary glands, discharge fragments of the gland cells in the secretion (figure 4.4b). Products are retained within the cell, and portions of the cell are pinched off to become part of the secretion. Apocrine glands, however, also produce merocrine secretions. Most of the volume secreted by apocrine glands are merocrine in origin. **Holocrine** (hol'ō-krin) **glands**, such as sebaceous (oil) glands of the skin, shed entire cells (figure 4.4c). Products accumulate in the cytoplasm of each epithelial cell, the cell ruptures and dies, and the entire cell becomes part of the secretion.

Endocrine glands are so variable in their structure that they are not classified easily. They are described in chapters 17 and 18.

17 *Define the term gland. Explain how epithelial tissues give rise to exocrine and some endocrine glands, and give examples of endocrine glands formed by nonepithelial tissues.*

18 *Distinguish between exocrine and endocrine glands. Describe the classification scheme for multicellular exocrine glands on the basis of their duct systems.*

19 *Describe three ways in which exocrine glands release their secretions. Give an example of each method.*

CONNECTIVE TISSUE

Connective tissue is abundant, and it makes up part of every organ in the body. The major structural characteristic that distinguishes connective tissue from the other three tissue types is that it consists of cells separated from each other by abundant extracellular matrix. Connective tissue structure is diverse, and it performs a variety of important functions.

FIGURE 4.3 Structure of Exocrine Glands

The names of exocrine glands are based on the shapes of their secretory units and their ducts.

Functions of Connective Tissue

Connective tissues perform the following major categories of functions:

1. *Enclosing and separating.* Sheets of connective tissues form capsules around organs, such as the liver and kidneys. Connective tissue also forms layers that separate tissues and organs. For example, connective tissues separate muscles, arteries, veins, and nerves from one another.
2. *Connecting tissues to one another.* For example, tendons are strong cables, or bands, of connective tissue that attach muscles to bone, and ligaments are connective tissue bands that hold bones together.
3. *Supporting and moving.* Bones of the skeletal system provide rigid support for the body, and the semirigid cartilage supports structures such as the nose, ears, and surfaces of joints. Joints between bones allow one part of the body to move relative to other parts.
4. *Storing.* Adipose tissue (fat) stores high-energy molecules, and bones store minerals, such as calcium and phosphate.
5. *Cushioning and insulating.* Adipose tissue cushions and protects the tissue it surrounds and provides an insulating layer beneath the skin that helps conserve heat.

FIGURE 4.4 Exocrine Glands and Secretion Types

Exocrine glands are classified according to the type of secretion.

6. **Transporting.** Blood transports substances throughout the body, such as gases, nutrients, enzymes, hormones, and cells of the immune system.
7. **Protecting.** Cells of the immune system and blood provide protection against toxins and tissue injury, as well as from microorganisms. Bones protect underlying structures from injury.

20 *What is the major characteristic that distinguishes connective tissue from other tissues?*

21 *List the major functions of connective tissues, and give an example of a connective tissue that performs each function.*

Cells of Connective Tissue

The specialized cells of the various connective tissues produce the extracellular matrix. The names of the cells end with suffixes that identify the cell functions as blasts, cytes, or clasts. **Blasts** create the matrix, **cytes** maintain it, and **clasts** break it down for remodeling. For example, **fibroblasts** are cells that form fibrous connective tissue and **fibrocytes** maintain it. **Chondroblasts** form cartilage (*chondro-* refers to cartilage) and **chondrocytes** maintain it. **Osteoblasts** form bone (*osteo-* means bone), **osteocytes** maintain it, and **osteoclasts** break it down (see chapter 6).

Adipose (ad'i-pōs; fat), or **fat cells**, also called **adipocytes** (ad'i-pō-sītz), contain large amounts of lipid. The lipid pushes the rest of the cell contents to the periphery so that each cell appears to contain a large, centrally located lipid droplet with a thin layer of cytoplasm around it. Adipose cells are rare in some connective tissue types, such as cartilage; are abundant in others, such as loose connective tissue; or are predominant, such as in adipose tissue.

Mast cells are commonly found beneath membranes in loose connective tissue and along small blood vessels of organs. They contain chemicals such as heparin, histamine, and proteolytic enzymes. These substances are released in response to injury, such as trauma and infection, and play important roles in inflammation.

White blood cells, or **leukocytes** (see chapter 18) continuously move from blood vessels into connective tissues. The rate of movement increases dramatically in response to injury or infection. In addition, accumulations of lymphocytes, a type of white blood cell, are common in some connective tissues, such as in the connective tissue beneath the epithelial lining of certain parts of the digestive system.

Macrophages are found in some connective tissue types. They are derived from monocytes, a white blood cell type. Macrophages are either **fixed** and do not move through the connective tissue in which they are found or are **wandering macrophages** and move by amoeboid movement through the connective tissue. Macrophages phagocytize foreign and injured cells, and they play a major role in providing protection against infections.

Undifferentiated mesenchymal cells, sometimes called **stem cells**, are embryonic cells that persist in adult connective tissue. They have the potential to differentiate to form adult cell types, such as fibroblasts or smooth muscle cells, in response to injury.

22 *Explain the difference among connective tissue cells that are termed blast, cyte, or clast cells.*

23 *Describe and give the functions of the cells of connective tissue.*

Extracellular Matrix

The extracellular matrix of connective tissue has three major components: (1) protein fibers, (2) ground substance consisting of nonfibrous protein and other molecules, and (3) fluid. The structure of the matrix gives connective tissue types most of their functional characteristics, such as the ability of bones and cartilage to bear weight, of tendons and ligaments to withstand tension, and of the skin's dermis to withstand punctures, abrasions, and other abuses.

Protein Fibers of the Matrix

Three types of protein fibers—collagen, reticular, and elastic fibers—help form connective tissue.

Collagen (kol' a-jen) **fibers** consist of collagen, which accounts for one-fourth to one-third of total body protein, or 6% of total body weight. Within fibroblasts, chains of amino acids called **collagen α -chains** are synthesized, and three collagen α -chains wind around each other to form a microscopic, ropelike helix called a **collagen molecule**. After collagen molecules are secreted, they are modified. Some amino acids are cleaved off of the collagen molecules to produce **tropocollagen** (trō-pō-kol' a-jen) molecules. The tropocollagen molecules are then linked together to make long **collagen fibrils**. The collagen fibrils are then joined together in bundles to form collagen fibers (figure 4.5a). Approximately 25 types of collagen α -chains, each encoded by a separate gene, are known, and they combine to form approximately 20 types of collagen. Collagen fibers are very strong and flexible but quite inelastic. There are at least 20 types of collagen fibers, many of which are specific to certain tissues. Collagen fibers differ in the types of amino acids that make up the polypeptide chains. Of the 20 types of collagen fibers, 6 types are most common. Tendons, ligaments, skin, and bone contain mainly type I collagen, cartilage is mainly type II collagen, and reticular fibers are mainly type III collagen.

Reticular (re-tik' ū-lār; netlike) **fibers** are very fine collagen fibers and therefore are not a chemically distinct category of fibers. They are very short, thin fibers that branch to form a network and appear different microscopically from other collagen fibers. Reticular fibers are not as strong as most collagen fibers, but networks of reticular fibers fill spaces between tissues and organs.

Elastic fibers consist of proteins called **elastin** (e-las'tin). As the name suggests, this protein has the ability to return to its original shape after being stretched or compressed. Elastin gives the tissue in which it is found an elastic quality. Fibroblasts secrete polypeptide chains, which are then linked together to form a network. The polypeptide chains recoil when they are stretched (figure 4.5b).

Other Matrix Molecules

Two types of large, nonfibrous molecules, called hyaluronic acid and proteoglycans, are part of the extracellular matrix. These molecules constitute most of the **ground substance** of the matrix, the “shapeless” background against which the collagen fibers are seen through the microscope. The molecules themselves, however, are not shapeless but are highly structured. **Hyaluronic** (hī' ā-loo-ron' ik; glassy appearance) **acid** is a long, unbranched polysaccharide chain

(a) Collagen fibers. Collagen molecules are secreted by fibroblasts and enzymes cleave off amino acids and the 3 collagen α -chains form tropocollagen. Each tropocollagen molecule consists of 3 collagen α -chains coiled together. Tropocollagen molecules are then linked to form collagen fibrils. The collagen fibrils are joined together to form collagen fibers.

(b) Elastic fibers. Fibroblasts secrete polypeptide chains, which are then linked together to form a network of polypeptide chains. The network stretches in response to a force. When the force is removed, the network recoils.

(c) Proteoglycan aggregates. Proteoglycan monomers are formed from 80 to 100 glycosaminoglycans, such as chondroitin sulfate, attached by one end to a protein core. The protein cores of many proteoglycan monomers can attach through link proteins to a long molecule of hyaluronic acid. Water molecules are trapped by the glycosaminoglycans.

FIGURE 4.5 Molecules of Connective Tissue Matrix

composed of repeating disaccharide units. It gives a very slippery quality to the fluids that contain it; for that reason, it is a good lubricant for joint cavities (see chapter 8). Hyaluronic acid is also found in large quantities in connective tissue and is the major component of the vitreous humor of the eye (see chapter 15).

A **proteoglycan** (prō' tē-ō-gli' kan; formed from proteins and polysaccharides) **monomer** is a large molecule that consists of 80 to 100 polysaccharides, called **glycosaminoglycans** (gli' kōs-am-i-nō-gli' kanz), such as **chondroitin sulfate**, each attached by one end to a protein core. The protein cores of many proteoglycan monomers can attach through link proteins to a long molecule of hyaluronic acid to form a **proteoglycan aggregate** (figure 4.5c). Proteoglycan aggregates trap large quantities of water, which allows them to return to their original shape when compressed or deformed. There are several types of glycosaminoglycans, and their abundance varies with each connective tissue type.

Several **adhesive molecules** are found in ground substance. These adhesive molecules hold the proteoglycan aggregates together and to structures such as the plasma membranes. A specific adhesive molecule type predominates in certain types of ground substance. For example, **chondronectin** is in the ground substance of cartilage, **osteonectin** is in the ground substance of bone, and **fibronectin** is in the ground substance of fibrous connective tissues.

24 *What three components are found in the extracellular matrix of connective tissue?*

25 *Contrast the structure and characteristics of collagen fibers, reticular fibers, and elastin fibers.*

26 *Describe the structure and function of hyaluronic acid and proteoglycan aggregates. What is the function of adhesive molecules?*

Classification of Connective Tissue

Connective tissue types blend into one another, and the transition points cannot be defined precisely. As a result, the classification scheme for connective tissues is somewhat arbitrary. Classification schemes for connective tissue are influenced by (1) protein fibers and the arrangement of protein fibers in the extracellular matrix, (2) protein fibers and ground substance in the extracellular matrix, and (3) a fluid extracellular matrix. The classification of connective tissues used in this book is presented in table 4.6.

The two major categories of connective tissue are embryonic and adult connective tissue.

Embryonic Connective Tissue

Embryonic connective tissue is called **mesenchyme** (mez'en-kīm). It is made up of irregularly shaped fibroblasts surrounded by abundant, semifluid extracellular matrix in which delicate collagen fibers are distributed (table 4.7a). It forms in the embryo during the third and fourth weeks of development from mesoderm and neural crest cells (see chapter 29), and all adult connective tissue types develop from it. By 8 weeks of development, most of the mesenchyme has become specialized to form the types of connective tissue seen in adults, as well as muscle, blood vessels, and other tissues. The major source of remaining embryonic connective tissue in the newborn is found in

TABLE 4.6 Classification of Connective Tissue

b. Compact
6. Blood and hemopoietic tissue

the umbilical cord, where it is called **mucous connective tissue**, or **Wharton's jelly** (table 4.7b). The structure of mucous connective tissue is similar to that of mesenchyme.

Adult Connective Tissue

Adult connective tissue consists of six types: loose, dense, connective tissue with special properties, cartilage, bone, and blood and hemopoietic tissue.

Loose Connective Tissue

Loose connective tissue (table 4.8), which is sometimes referred to as **areolar** (ă-rē'ō-lār; area) **tissue**, consists of protein fibers that form a lacy network, with numerous fluid-filled spaces. Areolar tissue is the “loose packing” material of most organs and other tissues; it attaches the skin to underlying tissues. It contains collagen, reticular, and elastic fibers and a variety of cells. For example, fibroblasts produce the fibrous matrix; macrophages move through the tissue, engulfing bacteria and cell debris; mast cells contain chemicals that help mediate inflammation; and lymphocytes are involved in immunity. The loose packing of areolar tissue is often associated with other connective tissue types, such as reticular tissue and fat (adipose tissue).

Dense Connective Tissue

Protein fibers of **dense connective tissue** form thick bundles and fill nearly all of the extracellular space. Most of the cells of developing

TABLE 4.7 Embryonic Connective Tissue**(a) Mesenchyme**

Structure: The mesenchymal cells are irregularly shaped; the extracellular matrix is abundant and contains scattered reticular fibers

Location: Mesenchyme is the embryonic tissue from which connective tissues, as well as other tissues, arise

Umbilical cord

Intercellular matrix
Nuclei of mucous connective tissue cells

dense connective tissue are spindle-shaped fibroblasts. Once the fibroblasts become completely surrounded by matrix, they are fibrocytes. Dense connective tissue can be subdivided into two major groups: regular and irregular.

Dense regular connective tissue has protein fibers in the extracellular matrix that are oriented predominantly in one direc-

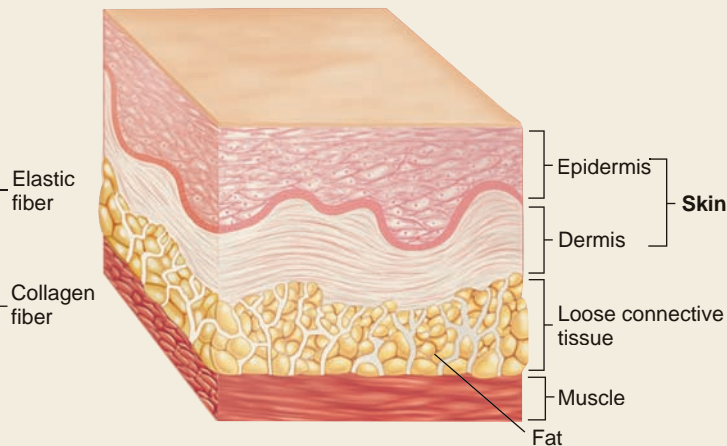

tion. **Dense regular collagenous connective tissue** (table 4.9a) has abundant collagen fibers. The collagen fibers give this tissue a white appearance. Dense regular collagenous connective tissue forms structures such as tendons, which connect muscles to bones (see chapter 11), and most ligaments, which connect bones to bones (see chapter 8). The collagen fibers of dense connective

TABLE 4.8 Loose Connective Tissue

Structure: Cells (e.g., fibroblasts, macrophages, and lymphocytes) within a fine network of mostly collagen fibers; often merges with denser connective tissue

Function: Loose packing, support, and nourishment for the structures with which it is associated

Location: Widely distributed throughout the body; substance on which epithelial basement membranes rest; packing between glands, muscles, and nerves; attaches the skin to underlying tissues

tissue resist stretching and give the tissue considerable strength in the direction of the fiber orientation. Tendons and most ligaments consist almost entirely of thick bundles of densely packed parallel collagen fibers with the orientation of the collagen fibers in one direction, which makes the tendons and ligaments very strong, cablelike structures.

The general structures of tendons and ligaments are similar, but there are major differences between them, such as the following: (1) collagen fibers of ligaments are often less compact, (2) some fibers of many ligaments are not parallel, and (3) ligaments usually are more flattened than tendons and form sheets or bands of tissues.

Dense regular elastic connective tissue (table 4.9*b*) consists of parallel bundles of collagen fibers and abundant elastic fibers. The elastin in elastic ligaments gives them a slightly yellow color. Dense regular elastic connective tissue forms some elastic ligaments, such as those in the vocal folds and the **nuchal** (noo'kāl; back of the neck) **ligament**, which lies along the posterior of the neck, helping hold the head upright. When elastic ligaments are stretched, they tend to shorten to their original length, much as an elastic band does.

PREDICT 3

Explain the advantages of having elastic ligaments that extend from vertebra to vertebra in the vertebral column and why it would be a disadvantage if tendons, which connect skeletal muscles to bone, were elastic.

Dense irregular connective tissue contains protein fibers arranged as a meshwork of randomly oriented fibers. Alternatively, the fibers within a given layer of dense irregular connective tissue can be oriented in one direction, whereas the

fibers of adjacent layers are oriented at nearly right angles to that layer. Dense irregular connective tissue forms sheets of connective tissue that have strength in many directions, but less strength in any single direction than does regular connective tissue.

PREDICT 4

Scars consist of dense irregular connective tissue made of collagen fibers. Vitamin C is required for collagen synthesis. Predict the effect of scurvy, which is a nutritional disease caused by vitamin C deficiency, on wound healing.

Dense irregular collagenous connective tissue (table 4.9*c*) forms most of the dermis of the skin, which is the tough, inner portion of the skin (see chapter 5) and of the connective tissue capsules that surround organs such as the kidney and spleen.

Dense irregular elastic connective tissue (table 4.9*d*) is found in the wall of elastic arteries. In addition to collagen fibers, oriented in many directions, there are abundant elastic fibers in the layers of this tissue.

- 27** List the two types of embryonic connective tissue. To what does mesenchyme give rise in the adult?
- 28** Describe the fiber arrangement in loose (areolar) connective tissue. What are the functions of this tissue type?
- 29** Structurally and functionally, what is the difference between dense regular connective tissue and dense irregular connective tissue?
- 30** Name the two kinds of dense regular connective tissue, and give an example of each. Do the same for dense irregular connective tissue.

TABLE 4.9 Dense Connective Tissue

(a) Dense Regular Collagenous Connective Tissue

Structure: Matrix composed of collagen fibers running in somewhat the same direction

Function: Ability to withstand great pulling forces exerted in the direction of fiber orientation, great tensile strength and stretch resistance

Location: Tendons (attach muscle to bone) and ligaments (attach bones to each other)

(b) Dense Regular Elastic Connective Tissue

Structure: Matrix composed of regularly arranged collagen fibers and elastin fibers

Function: Capable of stretching and recoiling like a rubber band, with strength in the direction of fiber orientation

Location: Ligaments between the vertebrae and along the dorsal aspect of the neck (nucha) and in the vocal cords

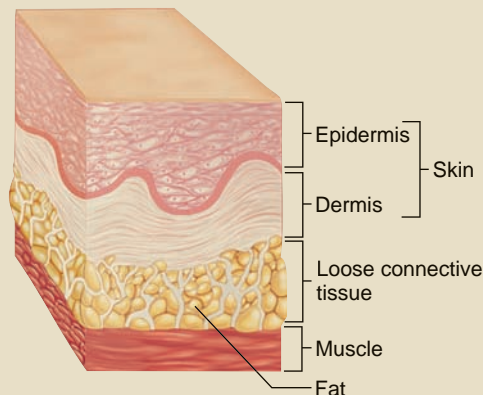

TABLE 4.9 Dense Connective Tissue—Continued**(c) Dense Irregular Collagenous Connective Tissue**

Structure: Matrix composed of collagen fibers that run in all directions or in alternating planes of fibers oriented in a somewhat single direction

Function: Tensile strength capable of withstanding stretching in all directions

Location: Sheaths; most of the dermis of the skin; organ capsules and septa; outer covering of body tubes

**(d) Dense Irregular Elastic Connective Tissue**

Structure: Matrix composed of bundles and sheets of collagenous and elastin fibers oriented in multiple directions

Function: Capable of strength with stretching and recoil in several directions

Location: Elastic arteries

**Connective Tissue with Special Properties**

Adipose tissue and reticular tissue are connective tissues with special properties. **Adipose tissue** (table 4.10a) consists of adipocytes, or fat cells, which contain large amounts of lipid. Unlike other connective tissue types, adipose tissue is composed of large cells and a small amount of extracellular matrix, which consists of loosely arranged collagen and reticular fibers with some scattered elastic fibers. Blood vessels form a network in the extracellular matrix. The fat cells are usually arranged in clusters or lobules separated from one another by loose connective tissue. Adipose tissue functions as an insulator, a protective tissue, and a site of energy storage. Lipids take up less space per calorie than either carbohydrates or proteins and therefore are well adapted for energy storage.

Adipose tissue exists in both yellow (white) and brown forms. **Yellow adipose** tissue is by far the most abundant. Yellow adipose tissue appears white at birth, but it turns yellow with age because of the accumulation of pigments, such as carotene, a plant pigment that humans can metabolize as a source of vitamin A. Storage, insulation, and protection are the functions of yellow adipose tissue. Brown adipose tissue is found only in specific areas of the body, such as the axillae (armpits), the neck, and near the kidneys. The brown color results from the cytochrome pigments in its numerous mitochondria and its abundant blood supply. Although brown fat is much more prevalent in babies than in adults, it is difficult to distinguish brown fat from yellow fat in babies because the color difference between them is not great. Brown fat is specialized to generate heat as a result of oxidative metabolism of lipid

TABLE 4.10 Connective Tissue with Special Properties**(a) Adipose Tissue**

Structure: Little extracellular matrix surrounding cells; the adipocytes, or fat cells, are so full of lipid that the cytoplasm is pushed to the periphery of the cell

Function: Packing material, thermal insulator, energy storage, and protection of organs against injury from being bumped or jarred

Location: Predominantly in subcutaneous areas, in mesenteries, in renal pelvis, around kidneys, attached to the surface of the colon, in mammary glands, in loose connective tissue that penetrates into spaces and crevices

Nucleus
Adipocytes or fat cells

LM 100x

**(b) Reticular Tissue**

Structure: Fine network of reticular fibers irregularly arranged

Function: Provides a superstructure for the lymphatic and hemopoietic

Location: Within the lymph nodes, spleen, and bone marrow

LM 100x

molecules in mitochondria and can play a significant role in body temperature regulation in newborn babies.

Reticular tissue forms the framework of lymphatic tissue (table 4.10b), such as in the spleen and lymph nodes, as well as in bone marrow and the liver. It is characterized by a network of reticular fibers and reticular cells. **Reticular cells** produce the reticular fibers and remain closely attached to them. The spaces between the reticular fibers can contain a wide variety of other cells, such as dendritic cells, which look very much like reticular

cells but are cells of the immune system, macrophages, and blood cells (see chapter 22).

- 31** What feature of the extracellular matrix distinguishes adipose tissue from other connective tissue types? What is an adipocyte?
- 32** List the functions of adipose tissue. Name the two types of adipose tissue. Which one is important in generating heat?
- 33** What is the function of reticular tissue? Where is it found?

Cartilage

Cartilage (kar'ti-lij) is composed of cartilage cells, or **chondrocytes** (kon'drō-sītz), located in spaces called **lacunae** (lā-koo'nē) within an extensive and relatively rigid matrix. Next to bone, cartilage is the firmest structure in the body. The matrix contains protein fibers, ground substance, and fluid. The protein fibers are collagen fibers or collagen and elastic fibers. The ground substance consists of proteoglycans and other organic molecules. Most of the proteoglycans in the matrix form aggregates with hyaluronic acid. Within the cartilage matrix, proteoglycan aggregates function as minute sponges capable of trapping large quantities of water. This trapped water allows cartilage to spring back after being compressed. The collagen fibers give cartilage considerable strength.

The surface of nearly all cartilage is surrounded by a layer of dense irregular connective tissue called the **perichondrium** (per-i-kon'drē-ūm). The structure of the perichondrium is described in more detail in chapter 6. Cartilage cells arise from the perichondrium and secrete cartilage matrix. Once completely surrounded by matrix, the cartilage cells are called chondrocytes and the spaces in which they are located are called lacunae. Cartilage has no blood vessels or nerves, except those of the perichondrium; it therefore heals very slowly after an injury because the cells and nutrients necessary for tissue repair cannot reach the damaged area easily.

There are three types of cartilage.

1. **Hyaline** (hī'ā-lin) **cartilage** has large amounts of both collagen fibers and proteoglycans (table 4.11*a*). Collagen fibers are evenly dispersed throughout the ground substance,

and in joints hyaline cartilage has a very smooth surface. Specimens appear to have a glassy, translucent matrix when viewed through a microscope. Hyaline cartilage is found in areas in which strong support and some flexibility are needed, such as in the rib cage and the cartilage within the trachea and bronchi (see chapter 23). It also covers the surfaces of bones that move smoothly against each other in joints. Hyaline cartilage forms most of the skeleton before it is replaced by bone in the embryo, and it is involved in growth that increases the length of bones (see chapter 6).

2. **Fibrocartilage** has more collagen fibers than proteoglycans (table 4.11*b*). Compared with hyaline cartilage, fibrocartilage has much thicker bundles of collagen fibers dispersed through its matrix. Fibrocartilage is slightly compressible and very tough. It is found in areas of the body where a great deal of pressure is applied to joints, such as in the knee, in the jaw, and between vertebrae.
3. **Elastic cartilage** has elastic fibers in addition to collagen and proteoglycans (table 4.11*c*). The numerous elastic fibers are dispersed throughout the matrix of elastic cartilage. It is found in areas, such as the external ears, that have rigid but elastic properties.

PREDICT 5

One of several changes caused by rheumatoid arthritis in joints is the replacement of hyaline cartilage with dense irregular collagenous connective tissue. Predict the effect of replacing hyaline cartilage with fibrous connective tissue.

TABLE 4.11 Connective Tissue: Cartilage

(a) Hyaline Cartilage

Structure: Collagen fibers are small and evenly dispersed in the matrix, making the matrix appear transparent; the cartilage cells, or chondrocytes, are found in spaces, or lacunae, within the firm but flexible matrix

Function: Allows growth of long bones; provides rigidity with some flexibility in the trachea, bronchi, ribs, and nose; forms rugged, smooth, yet somewhat flexible articulating surfaces; forms the embryonic skeleton

Location: Growing long bones, cartilage rings of the respiratory system, costal cartilage of ribs, nasal cartilages, articulating surface of bones, embryonic skeleton

Chondrocyte in a lacuna
Nucleus
Matrix

LM 240x

TABLE 4.11 Connective Tissue: Cartilage—Continued**(b) Fibrocartilage**

Structure: Collagenous fibers similar to those in hyaline cartilage; the fibers are more numerous than in other cartilages and are arranged in thick bundles

Function: Somewhat flexible and capable of withstanding considerable pressure; connects structures subjected to great pressure

Location: Intervertebral disks, symphysis pubis, articular disks (e.g., knee and temporomandibular [jaw] joints)

**(c) Elastic Cartilage**

Structure: Similar to hyaline cartilage, but matrix also contains elastin fibers

Function: Provides rigidity with even more flexibility than hyaline cartilage because elastic fibers return to their original shape after being stretched

Location: External ears, epiglottis, auditory tubes

**Bone**

Bone is a hard connective tissue that consists of living cells and mineralized matrix. Bone matrix has an organic and an inorganic portion. The organic portion consists of protein fibers, primarily collagen, and other organic molecules. The mineral, or inorganic, portion consists of specialized crystals called **hydroxyapatite** (hī-drok'sē-ap-ă-tīt), which contain calcium and phosphate. The strength and rigidity of the mineralized matrix allow bones to support and protect other tissues and organs. Bone cells, or **osteocytes** (os'tē-ō-sītz), are located within holes in the matrix,

which are called lacunae and are similar to the lacunae of cartilage.

Two types of bone exist.

1. **Cancellous** (kan'sē-lūs), or **spongy bone** has spaces between **trabeculae** (tră-bek'ū-lē; beams), or plates, of bone and therefore resembles a sponge (table 4.12a).
2. **Compact bone** is more solid with almost no space between many thin layers, or **lamellae** (lă-mel'ē sing. lă-mel'ă) of bone (table 4.12b).

TABLE 4.12 Connective Tissue: Bones**(a) Cancellous Bone**

Structure: Latticelike network of scaffolding characterized by trabeculae with large spaces between them filled with hemopoietic tissue; the osteocytes, or bone cells, are located within lacunae in the trabeculae

Function: Acts as a scaffolding to provide strength and support without the greater weight of compact bone

Location: In the interior of the bones of the skull, vertebrae, sternum, and pelvis, and in the ends of the long bones

**(b) Compact Bone**

Structure: Hard, bony matrix predominates; many osteocytes (not seen in this bone preparation) are located within lacunae that are distributed in a circular fashion around the central canals; small passageways connect adjacent lacunae

Function: Provides great strength and support; forms a solid outer shell on bones that keeps them from being easily broken or punctured

Location: Outer portions of all bones, the shafts of long bones

Bone, unlike cartilage, has a rich blood supply. For this reason, bone can repair itself much more readily than can cartilage. Bone is described more fully in chapter 6.

Blood and Hemopoietic Tissue

Blood is unusual among the connective tissues because the matrix between the cells is liquid (table 4.13a). Like many other connective tissues, blood has abundant extracellular matrix. The cells of most

other connective tissues are more or less stationary within a relatively rigid matrix, but blood cells are free to move within a fluid matrix. Some blood cells leave the bloodstream and wander through other tissues. The liquid matrix of blood allows it to flow rapidly through the body, carrying food, oxygen, waste products, and other materials. The matrix of blood is also unusual in that most of it is produced by cells contained in other tissues, rather than by blood cells. Blood is discussed more fully in chapter 19.

TABLE 4.13 Connective Tissue: Blood and Hemopoietic Tissue**(a) Blood**

Structure: Blood cells and a fluid matrix

Function: Transports oxygen, carbon dioxide, hormones, nutrients, waste products, and other substances; protects the body from infections and is involved in temperature regulation

Location: Within the blood vessels; produced by the hemopoietic tissues; white blood cells frequently leave the blood vessels and enter the interstitial spaces

**(b) Bone Marrow**

Structure: Reticular framework with numerous blood-forming cells (red marrow)

Function: Production of new blood cells (red marrow); lipid storage (yellow marrow)

Location: Within marrow cavities of bone; two types: red marrow (hemopoietic, or blood-forming, tissue) in the ends of long bones and in short, flat, and irregularly shaped bones; yellow marrow is mostly adipose tissue and is found in the shafts of long bones

Hemopoietic (hē'mō-poy-et'ik) **tissue** forms blood cells. In adults, hemopoietic tissue is found in **bone marrow** (mar'ō; table 4.13b), which is the soft connective tissue in the cavities of bones. There are two types of bone marrow: **red marrow** and **yellow marrow** (see chapter 6). Red marrow is hemopoietic tissue surrounded by a framework of reticular fibers. Hemopoietic tissue produces red and white blood cells; it is described in detail in chapter 19. In children, the marrow of most bones is red marrow. Yellow marrow consists of yellow adipose tissue and does not

produce blood cells. As children grow, yellow marrow replaces much of the red marrow in bones (see chapter 6).

- 34** Describe the cells and matrix of cartilage. What are lacunae? What is the perichondrium? Why does cartilage heal slowly?
- 35** How do hyaline cartilage, fibrocartilage, and elastic cartilage differ in structure and function? Give an example of each.
- 36** Describe the cells and matrix of bone. Differentiate between cancellous bone and compact bone.

37 What characteristic separates blood from the other connective tissues?

38 Describe the function of hemopoietic tissue. Explain the difference between red marrow and yellow marrow.

Marfan Syndrome

Marfan syndrome is an autosomal dominant genetic disorder that affects approximately 1 in 5000 people. The gene for Marfan syndrome, called the **fibrillin gene**, is located on chromosome 15. It codes for a protein called fibrillin-1, which is necessary for the normal structure of the elastic fibers of connective tissue, including the fibers holding the lens of the eye in place. Children of a person with Marfan syndrome have a 50% chance of inheriting the disorder because it is an autosomal dominant trait (see chapter 3). About 25% of the cases of Marfan syndrome, however, occur in children whose parents do not have the disorder. In these cases, a mutation of the gene occurs during the formation of sperm cells or oocytes. Many different mutations are possible because changes can occur anywhere in the nucleotide sequence of the fibrillin gene. Several hundred different alleles (variants) of the fibrillin gene are known.

Many people with Marfan syndrome have limbs, fingers, and toes that are disproportionately long in relation to the rest of the body. Connective tissues are weakened. As a consequence, the heart valves, which are comprised largely of connective tissue, do not function normally, resulting in heart murmurs (abnormal heart sounds). Poor vision is common because the lenses of the eyes are positioned abnormally. The lungs are prone to collapse, and dilation of large arteries, such as the aorta, can occur. A common cause of death in people with Marfan syndrome is rupture of the aorta. There is no cure for the condition, but treatments can reduce the danger of having Marfan syndrome. For example, drugs that lower blood pressure reduce the effects of Marfan syndrome on the aorta.

MUSCLE TISSUE

The main characteristic of **muscle tissue** is that it contracts, or shortens, with a force and therefore is responsible for movement. Muscle contraction is accomplished by the interaction of contractile proteins, which are described in chapter 9. Muscles contract to move the entire body, to pump blood through the heart and blood vessels, and to decrease the size of hollow organs, such as the stomach and urinary bladder. The three types of muscle tissue—skeletal, cardiac, and smooth muscle—are grouped according to both structure and function (table 4.14).

Skeletal muscle is what normally is thought of as “muscle” (table 4.15a). It is the meat of animals and constitutes about 40% of a person’s body weight. As the name implies, skeletal muscle attaches to the skeleton and enables body movement. Skeletal muscle is described as being under voluntary (conscious) control because one can purposefully cause skeletal muscle contraction to achieve specific body movements. However, the nervous system can cause skeletal muscles to contract without conscious involvement, such as during reflex movements and maintenance of muscle tone. Skeletal muscle cells are long, cylindrical cells with several nuclei per cell. The nuclei are located near the periphery of the cells. Some skeletal muscle cells extend the length of an entire muscle. Skeletal muscle cells are **striated** (stri’āt-ed), or banded, because of the arrangement of contractile proteins within the cells (see chapter 9).

Cardiac muscle is the muscle of the heart; it is responsible for pumping blood (table 4.15b). It is under involuntary (unconscious) control, although one can learn to influence the heart rate by using techniques such as meditation and biofeedback. Cardiac muscle cells are cylindrical but much shorter than skeletal muscle cells. Cardiac muscle cells are striated and usually have one nucleus per cell. They

TABLE 4.14 Comparison of Muscle Types

	Skeletal Muscle	Cardiac Muscle	Smooth Muscle
Location	Attached to bones	Heart	Walls of hollow organs, blood vessels, eyes, glands, skin
Cell Shape	Very long, cylindrical cells (1–4 cm and may extend the entire length of the muscle; 10–100 μm in diameter)	Cylindrical cells that branch (100–500 μm in length; 12–20 μm in diameter)	Spindle-shaped cells (15–200 μm in length; 5–8 μm in diameter)
Nucleus	Multinucleated, peripherally located	Single, centrally located	Single, centrally located
Striations	Yes	Yes	No
Control	Voluntary (conscious)	Involuntary (unconscious)	Involuntary (unconscious)
Ability to Contract Spontaneously	No	Yes	Yes
Function	Body movement	Contraction provides the major force for moving blood through the blood vessels.	Movement of food through the digestive tract, emptying of the urinary bladder, regulation of blood vessel diameter, change in pupil size, contraction of many gland ducts, movement of hair, and many more functions
Special Features		Branching fibers, intercalated disks containing gap junctions joining the cells to each other	Gap junctions

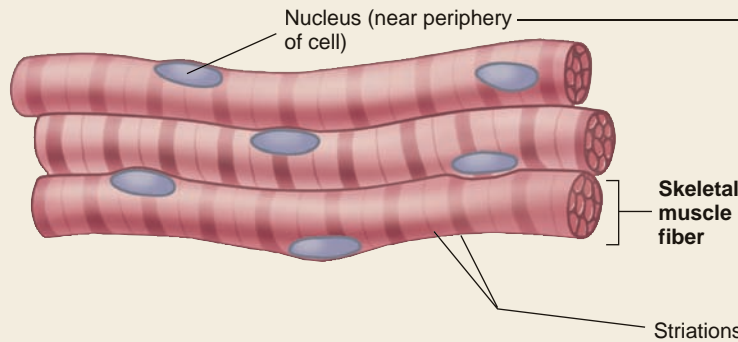

TABLE 4.15 Muscle Tissue

(a) Skeletal Muscle

Structure: Skeletal muscle cells or fibers appear striated (banded); cells are large, long, and cylindrical, with many nuclei located at the periphery

Function: Movement of the body; under voluntary (conscious) control

Location: Attaches to bone or other connective tissue

(b) Cardiac Muscle

Structure: Cardiac muscle cells are cylindrical and striated and have a single, centrally located nucleus; they are branched and connected to one another by intercalated disks, which contain gap junctions

Function: Pumps the blood; under involuntary (unconscious) control

Location: In the heart

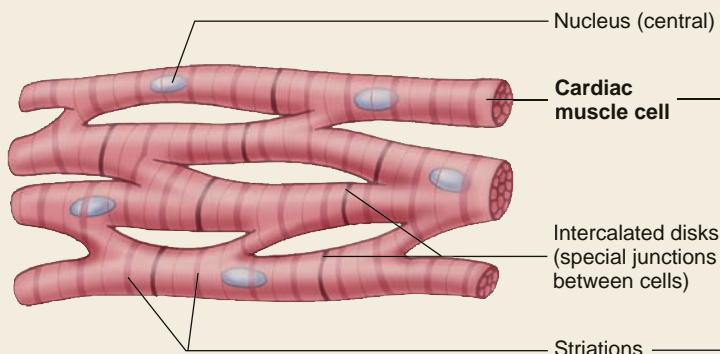

TABLE 4.15 Muscle Tissue—Continued

(c) Smooth Muscle

Structure: Smooth muscle cells are tapered at each end, are not striated, and have a single nucleus

Function: Regulates the size of organs, forces fluid through tubes, controls the amount of light entering the eye, and produces “goose flesh” in the skin; under involuntary (unconscious) control

Location: In hollow organs, such as the stomach and intestine

often are branched and connected to one another by **intercalated** (in-ter'kă-lā-ted, inserted between) **disks**. The intercalated disks, which contain specialized gap junctions, are important in coordinating the contractions of the cardiac muscle cells (see chapter 20).

Smooth muscle forms the walls of hollow organs (except the heart); it is found in the skin and the eyes (table 4.15c). It is responsible for a number of functions, such as movement of food through the digestive tract and emptying of the urinary bladder. Like cardiac muscle, smooth muscle is controlled involuntarily. Smooth muscle cells are tapered at each end, have a single nucleus, and are not striated.

39 *Functionally, what is unique about muscle tissue?*

40 *Compare the structure of skeletal, cardiac, and smooth muscle cells.*

41 *Which of the muscle types is under voluntary control?*

42 *What tasks does each muscle type perform?*

NERVOUS TISSUE

The fourth, and final, class of tissue is **nervous tissue**. It is found in the brain, spinal cord, and nerves and is characterized by the ability to conduct electric signals called **action potentials**. It consists of neurons, which are responsible for this conductive ability, and support cells called neuroglia.

Neurons, or **nerve cells** (table 4.16), are the conducting cells of nervous tissue. Just as an electrical wiring system transports electricity throughout a house, neurons transport electric signals throughout the body. They are composed of three major parts: cell body, dendrites, and axon. The **cell body** contains the nucleus and is the site of general cell functions. Dendrites and axons are two types of nerve cell processes, both consisting of projections of cytoplasm surrounded by membrane. **Dendrites** (den'drītz) usually receive action potentials. They are much shorter than axons and usually taper to a fine tip. **Axons** (ak'sonz) usually conduct action potentials away from the cell body. They can be much longer than dendrites, and they have a constant diameter along their entire length.

Neurons that possess several dendrites and one axon are called **multipolar neurons** (table 4.16a). Neurons that possess a single dendrite and an axon are called **bipolar neurons**. Some very specialized neurons, called **unipolar neurons** (table 4.16b), have only one axon and no dendrites. Within each subgroup are many shapes and sizes of neurons, especially in the brain and the spinal cord.

Neuroglia (noo-rog'lē-ă; nerve glue) are the support cells of the brain, spinal cord, and peripheral nerves (figure 4.6). The term *neuroglia* originally referred only to the support cells of the central nervous system, but it is now applied to cells in the peripheral nervous system as well. Neuroglia nourish, protect, and insulate neurons. Neurons and neuroglial cells are described in greater detail in chapter 11.

TABLE 4.16 Types of Neurons**(a) Multipolar Neuron**

Structure: The neuron consists of dendrites, a cell body, and a long axon; neuroglia, or support cells, surround the neurons

Function: Neurons transmit information in the form of action potentials, store “information,” and integrate and evaluate data; neuroglia support, protect, and form specialized sheaths around axons

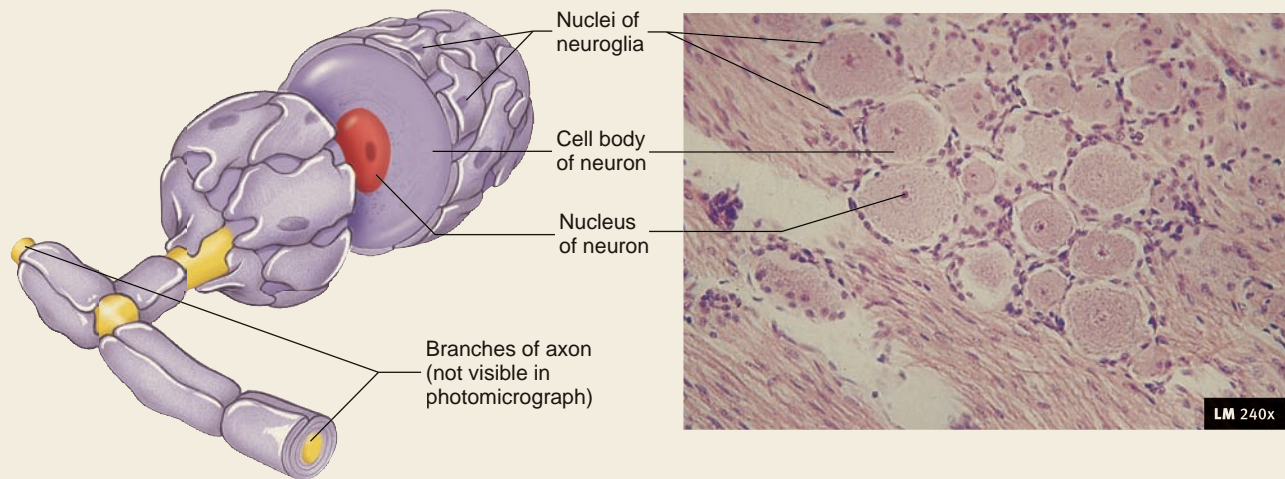

Location: In the brain, spinal cord, ganglia

**(b) Unipolar Neuron**

Structure: The neuron consists of a cell body with one axon

Function: Conducts action potentials from the periphery to the brain or spinal cord

Location: In ganglia outside of the brain and spinal cord

- 43** Functionally, what is unique about nervous tissue?
- 44** Define and list the functions of the cell body, dendrites, and axons of a neuron.
- 45** Differentiate among multipolar, bipolar, and unipolar neurons.
- 46** What is the general function of neuroglia?

MEMBRANES

A membrane is a thin sheet or layer of tissue that covers a structure or lines a cavity. Most membranes are formed from epithelium and the connective tissue on which it rests. The skin, or cutaneous, membrane (see chapter 5) is the external membrane. The three

FIGURE 4.6 Neuroglia

major categories of internal membranes are mucous membranes, serous membranes, and synovial membranes.

A **mucous** (mū'kūs) **membrane** consists of epithelial cells, their basement membrane, a thick layer of loose connective tissue called the **lamina propria** (lam'i-nā prō'prē-ă), and sometimes a layer of smooth muscle cells. Mucous membranes line cavities and canals that open to the outside of the body, such as the digestive, respiratory, excretory, and reproductive passages (figure 4.7a). Many, but not all, mucous membranes contain goblet cells or multicellular mucous glands, which secrete a viscous substance called **mucus** (mū'kūs). The functions of the mucous membranes vary, depending on their location, and include protection, absorption, and secretion.

A **serous** (ser'ūs) **membrane** consists of three components: a layer of simple squamous epithelium called **mesothelium** (mez-ō-thē'lē-ūm), its basement membrane, and a delicate layer of loose connective tissue. Serous membranes line cavities, such as the pericardial, pleural, and peritoneal cavities, that do not open to the exterior (figure 4.7b). Serous membranes do not contain glands but are moistened by a small amount of fluid called **serous fluid**, produced by the serous membranes. Serous fluid lubricates the serous membranes, making their surfaces slippery. Serous membranes protect the internal organs from friction, help hold them in place, and act as selectively permeable barriers to prevent the accumulation of large amounts of fluid within the serous cavities.

A **synovial** (si-nō'vē-ăl) **membrane** consists of modified connective tissue cells, either intermixed with part of the dense connective tissue of the joint capsule or separated from the capsule by areolar or adipose tissue. Synovial membranes line freely movable joints (see chapter 8; figure 4.7c). They produce a fluid rich in hyaluronic acid, which makes the joint fluid very slippery, thereby facilitating smooth movement within the joint.

47 Compare mucous, serous, and synovial membranes according to the type of cavities they line and their secretions.

FIGURE 4.7 Membranes

(a) Mucous membranes line cavities that open to the outside and often contain mucous glands, which secrete mucus. (b) Serous membranes line cavities that do not open to the exterior and do not contain glands but do secrete serous fluid. (c) Synovial membranes line cavities that surround synovial joints.

INFLAMMATION

The inflammatory response occurs when tissues are damaged (figure 4.8) or when associated with an immune response. Although many agents cause injury, such as microorganisms, cold, heat, radiant energy, chemicals, electricity, and mechanical trauma, the inflammatory response to all causes is similar. The inflammatory response mobilizes the body's defenses, isolates and destroys microorganisms and other injurious agents, and removes foreign materials and damaged cells so that tissue repair can proceed (see chapter 22).

1. A splinter in the skin causes damage and introduces bacteria. Mediators of inflammation are released or activated in injured tissues and adjacent blood vessels. Some blood vessels are ruptured, causing bleeding.

2. Mediators of inflammation cause capillaries to dilate, causing the skin to become red. Mediators of inflammation also increase capillary permeability, and fluid leaves the capillaries, producing swelling (*arrows*).

3. White blood cells (e.g., neutrophils and macrophages) leave the dilated blood vessels and move to the site of bacterial infection, where they begin to phagocytize bacteria and other debris.

PROCESS FIGURE 4.8 Inflammation

Inflammation has five major manifestations: redness, heat, swelling, pain, and disturbance of function. Although unpleasant, these processes usually benefit recovery, and each of the symptoms can be understood in terms of events that occur during the inflammatory response.

After a person is injured, chemical substances called **mediators of inflammation** are released or activated in the tissues and the adjacent blood vessels. The mediators include histamine, kinins, prostaglandins, leukotrienes, and others. Some mediators induce dilation of blood vessels and produce redness and heat. Dilation

of blood vessels is beneficial because it increases the speed with which white blood cells and other substances important for fighting infections and repairing the injury arrive at the site of injury.

Mediators of inflammation also stimulate pain receptors and increase the permeability of blood vessels. The increased permeability allows the movement of materials, such as clotting proteins and white blood cells, out of the blood vessels and into the tissue, where they can deal directly with the injury. As proteins from the blood move into the tissue, they change the osmotic relationship between the blood and the tissue. Water follows

the proteins by osmosis, and the tissue swells, producing **edema** (e-dē'mă). Edema increases the pressure in the tissue, which can also stimulate neurons and cause pain.

Clotting proteins found in blood diffuse into the interstitial spaces and form a clot. Clotting also occurs in the more severely injured blood vessels. Clotting isolates the injurious agent and separates it from the rest of the body. Foreign particles and microorganisms at the site of injury are “walled off” from tissues by the clotting process. Pain, limitation of movement resulting from edema, and tissue destruction all contribute to the disturbance of function. This disturbance can be valuable because it warns the person to protect the injured structure from further damage. Sometimes the inflammatory response lasts longer or is more intense than is desirable, and drugs are used to suppress the symptoms. Antihistamines block the effects of histamine, aspirin prevents the synthesis of prostaglandins, and cortisone reduces the release of several mediators of inflammation. On the other hand, the inflammatory response by itself may not be enough to combat the effects of injury or fight off an infection. Medical intervention, such as administering antibiotics, may be required.

48 *What is the function of the inflammatory response?*

49 *Name five manifestations of the inflammatory response, and explain how each is produced.*

PREDICT 6

In some injuries, tissues are so severely damaged that some cells are killed and blood vessels are destroyed. For such injuries, where do the signs of inflammation, such as redness, heat, edema, and pain, occur?

Chronic Inflammation

When the agent responsible for an injury is not removed or if interference occurs with the process of healing, the inflammatory response persists and is called **chronic inflammation**. For example, a lung infection can result in a brief period of inflammation followed by repair, but a prolonged infection causes chronic inflammation, which results in tissue destruction and permanent damage to the lung. Chronic inflammation of the stomach or small intestine may result in an ulcer. Prolonged infections; prolonged exposure to irritants, such as silica, in the lung; or abnormal immune responses can result in chronic inflammation. White blood cells invade areas of chronic inflammation, and ultimately healthy tissues are destroyed and replaced by a fibrous connective tissue, which is an important cause of the loss of organ function. Chronic inflammation of the lungs, the liver, the kidney, or other vital organs can lead to death.

TISSUE REPAIR

Tissue repair is the substitution of viable cells for dead cells, and it can occur by regeneration or replacement. In **regeneration** (rē'jen-er-ā'shŭn), the new cells are the same type as those that were destroyed, and normal function is usually restored. In **replacement**, a new type of tissue develops that eventually causes scar production and the loss of some tissue function. Most wounds heal through

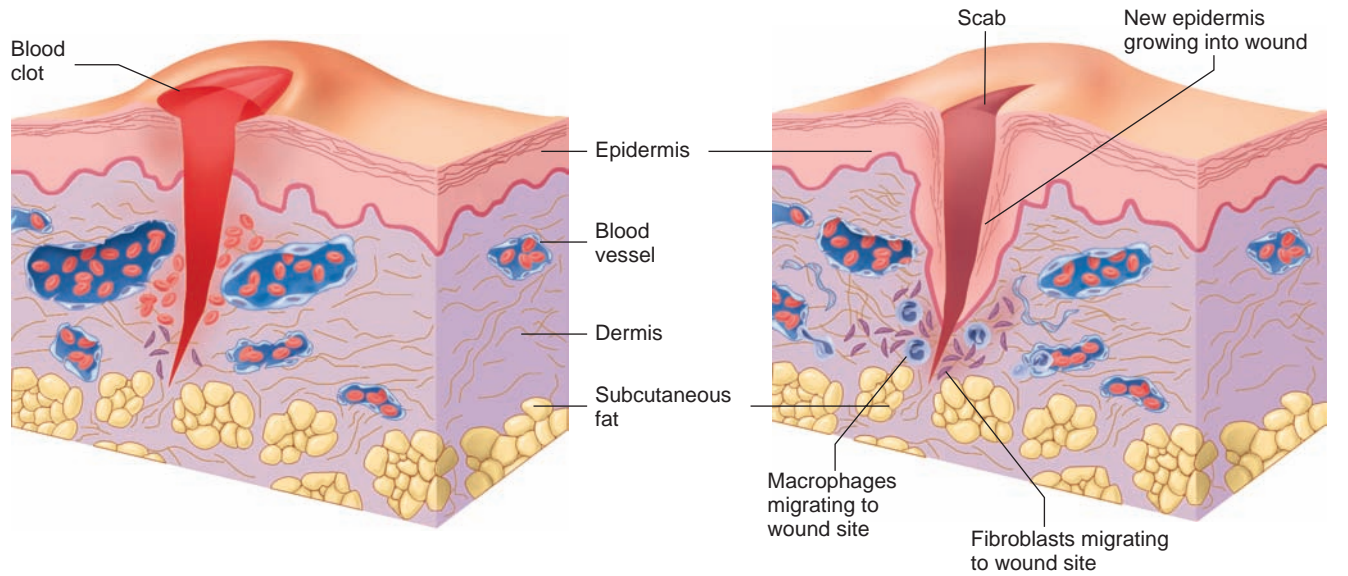

regeneration and replacement; which process dominates depends on the tissues involved and the nature and extent of the wound.

Cells are classified into three groups—labile, stable, or permanent cells—according to their ability to regenerate. **Labile cells**, including cells of the skin, mucous membranes, and hemopoietic and lymphatic tissues, continue to divide throughout life. Damage to these cells can be repaired completely by regeneration. **Stable cells**, such as the cells of connective tissues and glands, including the liver, pancreas, and endocrine glands, do not divide after growth ceases, but they retain the ability to divide and are capable of regeneration in response to injury. **Permanent cells** have very limited ability to replicate and, if killed, are usually replaced by a different type of cell. Neurons fit into this category, although neurons are able to recover from damage. If the cell body of a neuron is not destroyed, most neurons can replace a damaged axon or dendrite, but if the neuron cell body is destroyed, the remainder of the neuron dies. Some undifferentiated cells of the central nervous system can undergo mitosis and form functional neurons, although the degree to which mitosis occurs and its functional significance is not clear. Undifferentiated cells of skeletal and cardiac muscle also have very limited ability to regenerate in response to injury, although individual skeletal and cardiac muscle cells can repair themselves. In contrast, smooth muscle readily regenerates following injury.

Skin repair is a good example of tissue repair (figure 4.9). The basic pattern of the repair is the same as for other tissues, especially ones covered by epithelium. If the edges of the wound are close together, such as in a surgical incision, the wound heals by a process called **primary union**, or **primary intention**. If the edges are not close together, or if extensive loss of tissue has occurred, the process is called **secondary union**, or **secondary intention**.

In primary union, the wound fills with blood, and a clot forms (see chapter 19). The clot contains a threadlike protein, **fibrin** (fī'brin), which binds the edges of the wound together. The surface of the clot dries to form a **scab**, which seals the wound and helps prevent infection. An inflammatory response induces vasodilation and brings more blood cells and other substances to the area. Blood vessel permeability increases, resulting in edema. Fibrin and blood cells move into the wounded tissues because of the increased vascular permeability. Fibrin isolates and walls off microorganisms and other foreign matter. Some of the white blood cells that move into the tissue are phagocytic cells called **neutrophils** (noo'trō-filz; see figure 4.9). They ingest bacteria, thus helping fight infection, and they ingest tissue debris and clear the area for repair. Neutrophils are killed in this process and can accumulate as a mixture of dead cells and fluid, called **pus** (pūs).

Fibroblasts from surrounding connective tissue migrate into the clot and produce collagen and other extracellular matrix components. Capillaries grow from blood vessels at the edge of the wound and revascularize the area, and fibrin in the clot is broken down and removed. The result is the replacement of the clot by a delicate connective tissue, called **granulation tissue**, which consists of fibroblasts, collagen, and capillaries. A large amount of granulation tissue is converted to a **scar**, which consists of dense irregular collagenous connective tissue. At first, a scar is bright red because

1. A fresh wound cuts through the epithelium (epidermis) and underlying connective tissue (dermis), and a clot forms.

2. Approximately 1 week after the injury, a scab is present, and epithelium (new epidermis) is growing into the wound.

3. Approximately 2 weeks after the injury, the epithelium has grown completely into the wound, and granulation tissue has formed.

4. Approximately 1 month after the injury, the wound has completely closed, the scab has been sloughed, and the granulation tissue is being replaced with dermis.

PROCESS FIGURE 4.9 Tissue Repair

of vascularization of the tissue. Later, the scar becomes white as collagen accumulates and the vascular channels are compressed.

Repair by secondary union proceeds in a similar fashion, but some differences exist. Because the wound edges are far apart, the clot may not close the gap completely, and it takes the epithelial cells much longer to regenerate and cover the wound. With increased tissue damage, the degree of inflammation is greater, there is more

cell debris for the phagocytes to remove, and the risk of infection is greater. Much more granulation tissue forms, and **wound contraction** occurs as a result of the contraction of fibroblasts in the granulation tissue. Wound contraction leads to disfiguring and debilitating scars. Thus, it is advisable to suture a large wound so that it can heal by primary rather than secondary union. Healing is faster, the risk of infection is lowered, and the degree of scarring is reduced.

CLINICAL FOCUS

Cancer Tissue

Cancer (kan'ser) is a malignant, spreading tumor, as well as the illness that results from it. A **tumor** (too'mōr) is any swelling, although modern usage has limited the term to swellings that involve neoplastic tissue. **Neoplasm** (nē'ō-plazm) means new growth and refers to abnormal tissue growth, resulting in rapid cellular proliferation, which continues after the growth of normal tissue has stopped or slowed considerably. **Oncology** (ong-kol'ō-jē) is the study of tumors and the problems they cause. A neoplasm can be either **benign** (bē-nīn'; L. kind), not inclined to spread and not likely to become worse, or **malignant** (ma-lig'nānt; with malice or intent to cause harm), able to spread and become worse. Although benign tumors are usually less dangerous than malignant tumors, they can cause problems. As a benign tumor enlarges, it can compress surrounding tissues and impair their functions. In some cases, such as in some benign brain tumors, the result can be death.

Cells of malignant neoplasms, or cancer cells, differ from cells of normal tissues in several ways; the greater the degree to which they differ, the more dangerous they are. Cancer cells are more spherical because they do not adhere tightly to surrounding normal cells. They appear to be more embryonic, or less mature, than the normal tissue from which they arise. For example, a skin cancer cell is more spherical and softer than the stratified squamous epithelial cells of the skin. Cancer cells are also invasive. That is, they have the ability to squeeze into spaces and enter

surrounding tissues. They secrete enzymes that cut paths through healthy tissue, so they are able to grow irregularly, sending processes in all directions. Cancer cells can dislodge; enter blood vessels, lymphatic vessels, or body cavities; and travel to distant sites, where they attach and invade tissues. The process by which cancer spreads to distant sites is called **metastasis** (me-tas'ta-sis). Cancer cells secrete substances that cause blood vessels to grow into the tumor and supply oxygen and nutrients. Cancer cells also produce a number of substances that can be found on their plasma membranes or are secreted. For example, prostate specific antigen (PSA) is an enzyme, produced by prostate gland cells, that is involved with the liquefaction of semen. Normal blood levels of PSA are low. Prostate cancer cells secrete PSA in increasing amounts, and these proteins are released into the blood. Therefore, blood levels of PSA can be monitored to determine if a person is likely to have prostate cancer.

There are many types of cancer and special terms to name them. For example, a **carcinoma** (kar-si-nō'ma) is a cancer derived from epithelial tissue. **Basal cell** and **squamous cell carcinomas** are types of skin cancer derived from epithelial tissue. **Adenocarcinomas** (ad'ē-nō-kar-si-nō'maz) are derived from glandular epithelium. Most breast cancers are adenocarcinomas. A **sarcoma** (sar-kō'mā) is cancer derived from connective tissue. For example, an **osteosarcoma** (os'tē-ō-sar-kō'mā) is cancer of bone and a **chondrosarcoma** (kon'drō-sar-kō'mā) is cancer of cartilage.

Cancer therapy concentrates primarily on trying to confine and then kill the malignant cells. This goal is accomplished currently by killing the tissue with x-rays or lasers, by removing the tumor surgically, or by treating the patient with drugs that kill rapidly dividing cells or reduce the blood supply to the tumor. The major problem with current therapy is that some cancers cannot be removed completely by surgery or killed completely by x-rays or laser therapy. These treatments can also kill normal tissue adjacent to the tumor. Many drugs used in cancer therapy kill not only cancer tissue but also other rapidly growing tissues, such as bone marrow, where new blood cells are produced, and the lining of the intestinal tract. Loss of these tissues can result in anemia, caused by the lack of red blood cells, and nausea, caused by the loss of the intestinal lining.

A newer class of drugs eliminates these unwanted side effects. These drugs prevent blood vessel development, thus depriving the cancer tissue of a blood supply, rather than attacking dividing cells. Other normal tissues, in which cells divide rapidly, have well-established blood vessels and are therefore not affected by these drugs.

Promising anticancer therapies are also being developed in which the cells responsible for immune responses can be stimulated to recognize tumor cells and destroy them. A major advantage in such anticancer treatments is that the cells of the immune system can specifically attack the tumor cells and not other, healthy tissues.

- 50** Define tissue repair. Differentiate between tissue repair that occurs by regeneration and by replacement.
- 51** Compare labile cells, stable cells, and permanent cells. Give examples of each type. What is the significance of these cell types to tissue repair?
- 52** Describe the process of wound repair. Contrast healing by primary union and healing by secondary union.
- 53** What is pus? Describe granulation tissue. How does granulation tissue contribute to scars and wound contraction?

TISSUES AND AGING

Age-related changes—for example, reduced visual acuity and reduced smell, taste, and touch sensation—are well documented. A clear decline in many types of athletic performance can be measured after approximately age 30–35. Ultimately, there is a substantial decrease in the number of neurons and muscle cells. The functional capacity of systems, such as the respiratory and cardiovascular systems, declines. The rate of healing and scarring are very different in the elderly than in the very young, and

CLINICAL GENETICS

Genetic Changes in Cancer Cells

Most cancers are caused by mutations of genes within somatic cells. When DNA is replicated prior to cell division, a small number of replication errors occur in which the nucleotide sequence in the replicated DNA is different from the original DNA. A DNA sequence, with replication errors in it, is a mutation (see chapter 3). Factors such as radiation, certain chemicals and toxins, and some viruses also cause mutations because they damage or alter DNA. Because mutations are most likely to occur during DNA replication, cancer usually develops in tissues that are undergoing frequent cell divisions.

If mutations affect genes that regulate cell divisions, and if the result is uncontrolled cell divisions, a neoplasm can be produced. A neoplasm can become cancer if additional mutations change the structure and function of its cells. For example, some mutations increase the ability of cancer cells to invade and destroy surrounding tissues, some mutations allow cancer cells to metastasize, and some mutations make cancer cells resistant to drug treatments, such as the drugs used in chemotherapy.

Two major mechanisms help prevent the development of cancer in cells: (1) DNA repair enzymes detect and correct errors that occur during replication and (2) a self-destruction mechanism destroys cells with abnormal DNA. **Apoptosis** (ap'op-to'sis) is a process by which cells self destruct. Many cells, such as epithelial cells, have a limited life span, whereas others, such as neurons and skeletal muscle cells last a lifetime. Apoptosis is a normal process involved in the self-destruction of cells that have a limited life span. Apoptosis can also cause self destruction in cells with damaged DNA. Therefore, apoptosis can cause self-destruction in cells with mutations, and apoptosis can, therefore, remove cells with mutations before cancer develops. The likelihood that cancer will

develop is increased if the genes controlling DNA repair enzymes undergo mutations, resulting in defective DNA repair enzymes, so that mutated genes persist in cells. Mutation of genes responsible for apoptosis can also result in the persistence of cells with mutations, and these cells can continue to divide.

Because mutations are most likely to occur when DNA replicates, mutations leading to cancer are most likely to occur in cells undergoing cell division, such as rapidly dividing epithelial cells, rather than in nondividing cells, such as in skeletal muscle cells and neurons.

Cancer develops in somatic cells because of mutations that occur during cell divisions. Therefore, few cancers are inherited. Approximately 10% of human cancers, however, are inherited because of an increased genetic susceptibility to cancer. For example, a person can inherit a normal allele and a mutated allele for a regulatory gene that is involved in the development of cancer. As long as the normal allele functions, the effect of the mutated allele is masked. However, if the normal allele mutates during cell division of a somatic tissue, expression of the allele involved in the development of cancer can be expressed. Compared with a person with two normal alleles for a regulatory gene involved in the development of cancer, a person with a genetic susceptibility for cancer is much more likely to develop cancer because only one allele has to mutate, instead of two. Certain kinds of colon cancers and breast cancers are examples of genetic susceptibility to cancer.

The accumulation of mutations resulting in cancer occurs over many generations of cells and may require several years to develop. This is one reason that cancer becomes more common in people as they become older. Once a mutation alters a gene in a cell, that altered gene can be passed to the daughter cells when the parent cell undergoes cell division. For cells that survive

and undergo cell division, altered genes are passed to all of the offspring of the original cell in which the mutation occurred. For example, a single mutation may cause a cell to undergo cell division at an increased rate. This mutation is passed to the offspring of that cell. Another mutation may occur in one of these cells and it, along with the original mutation, is passed to its offspring. In this fashion, mutations responsible for the development of cancer accumulate in cells. Therefore, cancer is polygenic (see chapter 3).

Some genes promote cell division, whereas others suppress it. Genes that promote cell division are called proto-oncogenes. Mutations in proto-oncogenes can give rise to abnormal regulatory genes, called **oncogenes** (ong'ko-jenz), which increase the rate of cell division. Oncogenes can code for growth factors, growth factor receptors, or chemical signals that control cell divisions. Many types of oncogenes have been identified in human cancers. **Tumor suppressor genes** are normal genes that slow or stop cell division. Mutations that delete or inactivate tumor suppressor genes can also increase the rate of cell division by taking off the brakes, so to speak, of the processes that promote cell division. Many altered tumor suppressor genes have been identified in human cancer cells.

Additional mutations cause the structure and functions of the cancer cells to differ from those of normal cells. For example, these mutations increase the ability of cancer cells to invade and destroy surrounding tissues and to metastasize. The continued accumulation of mutations in cancer cells is also responsible for changes in the characteristics of the cancer cells over time. These changes can result in cancer cells in a tumor becoming less sensitive to treatment designed to kill the cancer cells. Some mutations help make cancer cells less sensitive to chemotherapeutic drugs.

major changes in the structural characteristics of the skin develop. Characteristic alterations in brain function also develop in the elderly. All these changes result in the differences among young, middle-age, and older people.

At the tissue level, age-related changes affect cells and the extracellular materials they produce. In general, cells divide more slowly in older than in younger people. Collagen fibers become more irregular in structure, even though they may increase in number. As a consequence, connective tissues with abundant collagen, such as tendons and ligaments, become less flexible and more fragile. Elastic fibers fragment, bind to calcium ions, and become less elastic. Consequently, elastic connective tissues become less elastic.

Changes in the structure of elastic and collagen fibers of arterial walls cause them to become less elastic. Atherosclerosis results as plaques form in the walls of blood vessels, which contain collagen fibers, lipids, and calcium deposits (see chapter 21). These

changes result in reduced blood supply to tissues and increased susceptibility to blockage and rupture. The rate of red blood cell synthesis declines in the elderly as well. Reduced flexibility and elasticity of connective tissue is responsible for increased wrinkling of skin, as well as the increased tendency for bones to break in older people.

Injuries in the very young heal more rapidly and more completely than in older people. A fracture in an infant's femur is likely to heal quickly and eventually leave no evidence of the fracture in the bone. A similar fracture in an adult heals more slowly and a scar, seen in x-rays of the bone, is likely to persist throughout life.

54 Describe the age-related changes that occur in cells such as nerve cells, muscle cells, and cells of hemopoietic tissues.

55 Describe the age-related changes in tissues with abundant collagen and elastic fibers.

SUMMARY

Tissues and Histology (p. 110)

1. Tissues are collections of similar cells and the substances surrounding them.
2. The four primary tissue types are epithelial, connective, muscle, and nervous tissues.
3. Histology is the microscopic study of tissues.

Embryonic Tissue (p. 110)

All four of the primary tissue types are derived from each of the three germ layers (mesoderm, ectoderm, and endoderm).

Epithelial Tissue (p. 110)

1. Epithelium consists of cells with little extracellular matrix, it covers surfaces, it has a basement membrane, and it does not have blood vessels.
2. The basement membrane is secreted by the epithelial cells and attaches the epithelium to the underlying tissues.

Functions of Epithelial Tissues

Epithelial tissues (1) protect underlying structures, act as barriers, permit the passage of some substances through epithelial layers, secrete substances, and absorb substances.

Classification of Epithelium

1. Simple epithelium has a single layer of cells, stratified epithelium has two or more layers, and pseudostratified epithelium has a single layer that appears stratified.
2. Cells can be squamous (flat), cuboidal, or columnar.
3. Stratified squamous epithelium can be nonkeratinized or keratinized.
4. Transitional epithelium is stratified, with cells that can change shape from cuboidal to flattened.

Functional Characteristics

1. Simple epithelium is usually involved in diffusion, filtration, secretion, or absorption. Stratified epithelium serves a protective role. Squamous cells function in diffusion and filtration. Cuboidal or columnar cells, with a larger cell volume that contains many organelles, secrete or absorb.
2. A smooth free surface reduces friction (mesothelium and endothelium), microvilli increase absorption (intestines), and cilia move materials across the free surface (respiratory tract and uterine tubes). Transitional epithelium has a folded surface that allows the cell to change shape, and the number of cells making up the epithelial layers changes.
3. Cells are bound together mechanically by glycoproteins, desmosomes, and the zonulae adherens and to the basement membrane by hemidesmosomes. The zonulae occludens and zonulae adherens form a permeability barrier or tight junction, and gap junctions allow intercellular communication.

Glands

1. Glands are organs that secrete. Exocrine glands secrete through ducts, and endocrine glands release hormones that are absorbed directly into the blood.
2. Glands are classified as unicellular or multicellular. Goblet cells are unicellular glands. Multicellular exocrine glands have ducts, which are simple or compound (branched). The ducts can be tubular or end in small sacs (acini or alveoli). Tubular glands can be straight or coiled.
3. Glands are classified according to their mode of secretion. Merocrine glands (pancreas) secrete substances as they are produced, apocrine glands (mammary glands) accumulate secretions that are released when a portion of the cell pinches off, and holocrine glands (sebaceous glands) accumulate secretions that are released when the cell ruptures and dies.

Connective Tissue (p. 120)

Connective tissue is distinguished by its extracellular matrix.

Functions of Connective Tissue

Connective tissues enclose and separate organs and tissue; connect tissues to one another; play a role in support for movement; store high-energy molecules; cushion; insulate; transport; and protect.

Cells of Connective Tissue

1. The extracellular matrix results from the activity of specialized connective tissue cells; in general, blast cells form the matrix, cyte cells maintain it, and clast cells break it down. Fibroblasts form protein fibers of many connective tissues, osteoblasts form bone, and chondroblasts form cartilage.
2. Adipose (fat) cells, mast cells, white blood cells, macrophages, and mesenchymal cells (stem cells) are commonly found in connective tissue.

Extracellular Matrix

1. The extracellular matrix of connective tissue has protein fibers, ground substance, and fluid as major components.
2. Protein fibers of the matrix have the following characteristics
 - Tropocollagens are linked together to form collagen fibrils, which are joined to form collagen fibers. The collagen fibers resemble ropes. They are strong and flexible but resist stretching.
 - Reticular fibers are fine collagen fibers that form a branching network that supports other cells and tissues.
 - Elastin fibers have a structure similar to that of a spring. After being stretched, they tend to return to their original shape.
3. Ground substance has the following as major components:
 - Hyaluronic acid makes fluids slippery.
 - Proteoglycan aggregates trap water, which gives tissues the capacity to return to their original shape when compressed or deformed.
 - Adhesive molecules hold proteoglycans together and to plasma membranes.

Classification of Connective Tissue

Connective tissue is classified according to the type of protein and the proportions of protein, ground substance, and fluid in the matrix.

Embryonic Connective Tissue

Mesenchyme arises early, consists of irregularly shaped cells and abundant matrix, and gives rise to adult connective tissue.

Adult Connective Tissue

1. *Loose connective tissue*
 - Loose (areolar) connective tissue has many different cell types and a random arrangement of protein fibers with space between the fibers. This tissue fills spaces around the organs and attaches the skin to underlying tissues.
2. *Dense connective tissue*
 - Dense regular connective tissue is composed of fibers arranged in one direction, which provides strength in a direction parallel to the fiber orientation. Two types of dense regular connective tissue exist: collagenous (tendons and most ligaments) and elastic (ligaments of vertebrae).
 - Dense irregular connective tissue has fibers organized in many directions, which produces strength in different directions.

Two types of dense irregular connective tissue exist: collagenous (capsules of organs and dermis of skin) and elastic (large arteries).

3. *Connective tissue with special properties*
 - Adipose tissue has fat cells (adipocytes) filled with lipid and very little extracellular matrix (a few reticular fibers). Adipose tissue functions as energy storage, insulation, and protection. Adipose tissue can be yellow (white) or brown. Brown fat is specialized for generating heat.
 - Reticular tissue is a network of reticular fibers and forms the framework of lymphoid tissue, bone marrow, and the liver.
 - Hemopoietic tissue, or red bone marrow, is the site of blood cell formation, and yellow bone marrow is a site of fat storage.
4. *Cartilage*
 - Cartilage has a relatively rigid matrix composed of protein fibers and proteoglycan aggregates. The major cell type is the chondrocyte, which is located within lacunae. Hyaline cartilage has evenly dispersed collagen fibers that provide rigidity with some flexibility. Examples include the costal cartilage, the covering over the ends of bones in joints, the growing portion of long bones, and the embryonic skeleton. Fibrocartilage has collagen fibers arranged in thick bundles; it can withstand great pressure, and it is found between vertebrae, in the jaw, and in the knee. Elastic cartilage is similar to hyaline cartilage, but it has elastin fibers. It is more flexible than hyaline cartilage. It is found in the external ear.
5. *Bone*
 - Bone cells, or osteocytes, are located in lacunae that are surrounded by a mineralized matrix (hydroxyapatite) that makes bone very hard. Cancellous bone has spaces between bony trabeculae, and compact bone is more solid.
6. *Blood and hemopoietic tissue*
 - Blood cells are suspended in a fluid matrix.
 - Hemopoietic tissue forms blood cells.

Muscle Tissue (p. 134)

1. Muscle tissue has the ability to contract.
2. Skeletal (striated voluntary) muscle attaches to bone and is responsible for body movement. Skeletal muscle cells are long, cylindrically shaped cells with many peripherally located nuclei.
3. Cardiac (striated involuntary) muscle cells are cylindrical, branching cells with a single, central nucleus. Cardiac muscle is found in the heart and is responsible for pumping blood through the circulatory system.
4. Smooth (nonstriated involuntary) muscle forms the walls of hollow organs, the iris of the eye, and other structures. Its cells are spindle-shaped with a single, central nucleus.

Nervous Tissue (p. 136)

1. Nervous tissue is able to conduct electric impulses and is composed of neurons (conductive cells) and neuroglia (support cells).
2. Neurons have cell processes called dendrites and axons. The dendrites can receive electric impulses, and the axons can conduct them.

Neurons can be multipolar (several dendrites and an axon), bipolar (one dendrite and one axon), or unipolar (one axon).

Membranes (p 137)

1. Mucous membranes consist of epithelial cells, their basement membrane, the lamina propria, and sometimes smooth muscle cells; they line cavities that open to the outside and often contain mucous glands, which secrete mucus.
2. Serous membranes line cavities that do not open to the exterior and do not contain glands but do secrete serous fluid.
3. Synovial membranes are formed by connective tissue and line joint cavities.

Inflammation (p. 138)

1. The function of the inflammatory response is to isolate injurious agents from the rest of the body and to attack and destroy the injurious agent.
2. The inflammatory response produces five symptoms: redness, heat, swelling, pain, and disturbance of function.

Tissue Repair (p. 140)

1. Tissue repair is the substitution of viable cells for dead ones. Tissue repair occurs by regeneration or replacement.
 - Labile cells divide throughout life and can undergo regeneration.
 - Stable cells do not ordinarily divide after growth is complete but can regenerate if necessary.
 - Permanent cells cannot replicate. If killed, permanent tissue is repaired by replacement.
2. Tissue repair by primary union occurs when the edges of the wound are close together. Secondary union occurs when the edges are far apart.

Tissues and Aging (p. 142)

1. Age-related changes in tissues result from reduced rates of cell division and changes in the extracellular fibers.
2. Collagen fibers become less flexible and have reduced strength.
3. Elastic fibers become fragmented and less elastic.

REVIEW AND COMPREHENSION

1. Given these characteristics:
 1. capable of contraction
 2. covers free body surfaces
 3. lacks blood vessels
 4. composes various glands
 5. anchored to connective tissue by a basement membrane
 Which of these are characteristics of epithelial tissue?
 - a. 1,2,3
 - b. 2,3,5
 - c. 3,4,5
 - d. 1,2,3,4
 - e. 2,3,4,5
2. Which of these embryonic germ layers gives rise to muscle, bone, and blood vessels?
 - a. ectoderm
 - b. endoderm
 - c. mesoderm
3. A tissue that covers a surface, is one cell layer thick, and is composed of flat cells is
 - a. simple squamous epithelium.
 - b. simple cuboidal epithelium.
 - c. simple columnar epithelium.
 - d. stratified squamous epithelium.
 - e. transitional epithelium.
4. Epithelium composed of two or more layers of cells with only the deepest layer in contact with the basement membrane is
 - a. stratified epithelium.
 - b. simple epithelium.
 - c. pseudostratified epithelium.
 - d. columnar epithelium.
 - e. cuboidal epithelium.
5. Stratified epithelium is usually found in areas of the body where the principal activity is
 - a. filtration.
 - b. protection.
 - c. absorption.
 - d. diffusion.
 - e. secretion.
6. Which of these characteristics do *not* describe nonkeratinized stratified squamous epithelium?
 - a. many layers of cells
 - b. surface cells are flat
 - c. surface cells are living
 - d. found in the skin
 - e. outer layers covered by fluid
7. In parts of the body, such as the urinary bladder, where considerable expansion occurs, one can expect to find which type of epithelium?
 - a. cuboidal
 - b. pseudostratified
 - c. transitional
 - d. squamous
 - e. columnar
8. A tissue that contains cells with these characteristics:
 1. covers a surface
 2. one layer of cells
 3. cells are flat
 Performs which of the following functions?
 - a. phagocytosis
 - b. active transport
 - c. secretion of many complex lipids and proteins
 - d. allow certain substances to diffuse across it
 - e. protection from abrasion
9. Epithelial cells with microvilli are most likely found
 - a. lining blood vessels.
 - b. lining the lungs.
 - c. lining the uterine tube.
 - d. lining the small intestine.
 - e. in the skin.
10. Pseudostratified ciliated columnar epithelium can be found lining the
 - a. digestive tract.
 - b. trachea.
 - c. thyroid gland.
 - d. kidney tubules.
 - e. urinary bladder.
11. A type of cell connection whose *only* function is to prevent the cells from coming apart is the
 - a. desmosome.
 - b. gap junction.
 - c. tight junction.
12. The glands that lose their connection with epithelium during embryonic development and secrete their cellular products into the bloodstream are called _____ glands.
 - a. apocrine
 - b. endocrine
 - c. exocrine
 - d. holocrine
 - e. merocrine
13. Glands that accumulate secretions and release them only when the individual secretory cells rupture and die are called _____ glands.
 - a. apocrine
 - b. holocrine
 - c. merocrine

14. A _____ gland has a duct that branches repeatedly, and the ducts end in saclike structures.
- simple tubular
 - compound tubular
 - simple coiled tubular
 - simple acinar
 - compound acinar
15. The fibers in dense connective tissue are produced by
- fibroblasts.
 - adipocytes.
 - osteoblasts.
 - osteoclasts.
 - macrophages.
16. Mesenchymal cells
- form embryonic connective tissue.
 - give rise to all adult connective tissues.
 - in adults produce new connective tissue cells in response to injury.
 - all of the above.
17. A tissue with a large number of collagen fibers organized parallel to each other would most likely be found in
- a muscle.
 - a tendon.
 - adipose tissue.
 - a bone.
 - cartilage.
18. Extremely delicate fibers that make up the framework for organs such as the liver, spleen, and lymph nodes are
- elastic fibers.
 - reticular fibers.
 - microvilli.
 - cilia.
 - collagen fibers.
19. In which of these locations are dense irregular elastic connective tissue found?
- ligaments
 - nuchal ligament
 - dermis of the skin
 - large arteries
 - adipose tissue
20. Which of these is *not* true of adipose tissue?
- It is the site of energy storage.
 - It is a type of connective tissue.
 - It acts as a protective cushion.
 - Brown adipose is found only in babies.
 - It functions as a heat insulator.
21. Which of these types of connective tissue has the smallest amount of extracellular matrix?
- adipose
 - bone
 - cartilage
 - loose connective tissue
 - blood
22. Given these characteristics:
- cells located in lacunae
 - proteoglycans in ground substance
 - no collagen fibers present
 - perichondrium on surface
 - heals rapidly after injury
- Which of these characteristics apply to cartilage?
- 1,2,3
 - 1,2,4
 - 2,4,5
 - 1,2,4,5
 - 2,3,4,5
23. Fibrocartilage is found
- in the cartilage of the trachea.
 - in the rib cage.
 - in the external ear.
 - on the surface of bones in moveable joints.
 - between vertebrae.
24. A tissue in which cells are located in lacunae surrounded by a hard matrix of hydroxyapatite is
- hyaline cartilage.
 - bone.
 - nervous tissue.
 - dense regular collagenous connective tissue.
 - fibrocartilage.
25. Which of these characteristics apply to smooth muscle?
- striated, involuntary
 - striated, voluntary
 - unstriated, involuntary
 - unstriated, voluntary
26. Which of these statements about nervous tissue is *not* true?
- Neurons have cytoplasmic extensions called axons.
 - Electric signals (action potentials) are conducted along axons.
 - Bipolar neurons have two axons.
 - Neurons are nourished and protected by neuroglia.
 - Dendrites receive electric signals and conduct them toward the cell body.
27. The linings of the digestive, respiratory, excretory, and reproductive passages are composed of
- serous membranes.
 - mucous membranes.
 - mesothelium.
 - synovial membranes.
 - endothelium.
28. Chemical mediators of inflammation
- cause blood vessels to constrict.
 - decrease the permeability of blood vessels.
 - initiate processes that lead to edema.
 - help prevent clotting.
 - decrease pain.
29. Which of these types of cells are labile?
- neurons
 - skin
 - liver
 - pancreas
30. Permanent cells
- divide and replace damaged cells in replacement tissue repair.
 - form granulation tissue.
 - are responsible for removing scar tissue.
 - are usually replaced by a different cell type if they are destroyed.
 - are replaced during regeneration tissue repair.

Answers in Appendix E

CRITICAL THINKING

- Given the observation that a tissue has more than one layer of cells lining a free surface, (1) list the possible tissue types that exhibit those characteristics, and (2) explain what additional observations need to be made to identify the tissue type.
- A patient suffered from kidney failure a few days after he was exposed to a toxic chemical. A biopsy of his kidney indicated that many of the thousands of epithelium-lined tubules that make up the kidney had lost many of the simple cuboidal epithelial cells that normally line them, although the basement membranes appeared to be mostly intact. Predict how likely this person is to recover fully.
- Compare the cell shapes and surface specializations of an epithelium that resists abrasion with those of an epithelium that carries out the absorption of materials.

4. Tell how to distinguish between a gland that produces a merocrine secretion and a gland that produces a holocrine secretion. Assume that you have the ability to chemically analyze the composition of secretions.
5. Name a tissue that has the following characteristics: abundant extra cellular matrix consisting almost entirely of collagen fibers that are parallel to each other. Injuries of which of the following types result from damage to this kind of tissue: dislocated neck vertebrae, a torn tendon, a ruptured intervertebral disk?
6. Indicate whether the following statement is correct or not: "If a tissue is capable of contracting, is under involuntary control, and has mono-nucleated cells, it is smooth muscle." Explain your answer.
7. Antihistamines block the effect of a chemical mediator of inflammation called histamine, which is released during the inflammatory response. What effect does administering antihistamines have on the inflammatory response, and is the use of an antihistamine beneficial?
8. A gland produces a watery secretion containing solutes and is close to being isotonic. Which of the processes responsible for producing secretions functions in this gland?
9. A tissue has the following characteristics: a free surface; a single layer of cells, cells; narrow, tall cells; microvilli, many mitochondria, and goblet cells. Describe the tissue type and as many functions of the cell as possible.
10. Most people who develop breast cancer do not have a known family history of breast cancer. However, approximately 7% of breast cancers are associated with the dominant breast cancer susceptibility genes called BRCA1, located on chromosome 17, and BRCA2, located on chromosome 13. The BRCA1 gene is also associated with an increased probability of ovarian cancer. However, not all people who have these genes develop cancer. Explain how that might occur.

Integumentary System

5

The **integumentary** (in-teg-ū-men'tă-rē) **system** consists of the skin and accessory structures, such as hair, nails, and glands. *Integument* means covering, and the integumentary system is familiar to most people because it covers the outside of the body and is easily observed. In addition, humans are concerned with the appearance of the integumentary system. Skin without blemishes is considered attractive, whereas acne is a source of embarrassment for many people. The development of wrinkles and the graying or loss of hair are signs of aging that some people find unattractive. Because of these feelings, much time, effort, and money are spent on changing the appearance of the integumentary system. For example, people apply lotion to their skin, color their hair, and trim their nails. They also try to prevent sweating with antiperspirants and body odor with washing, deodorants, and perfumes.

The appearance of the integumentary system can indicate physiological imbalances in the body. Some disorders, such as acne or warts, affect just the integumentary system. Disorders of other parts of the body can be reflected there, and thus the integumentary system is useful for diagnosis. For example, reduced blood flow through the skin during a heart attack can cause a pale appearance, whereas increased blood flow as a result of fever can cause a flushed appearance. Also, the rashes of some diseases are very characteristic, such as the rashes of measles, chicken pox, and allergic reactions.

This chapter provides an *overview of the integumentary system* (p. 150) and an explanation of the *skin* (p. 150), the *hypodermis* (p. 157), and the *accessory skin structures* (p. 158). A *summary of integumentary system functions* (p. 163) and the *effects of aging on the integumentary system* (p. 165) are also presented.

Skin, hair, nails, and glands form the integumentary system. This colorized scanning electron micrograph shows the shaft of a hair (yellow) protruding through the surface of the skin. Tightly bound epithelial cells form the hair shaft, and flat, scalelike epithelial cells form the skin's surface. Like the shingles on the roof of a house, the skin's tough cells protect underlying structures. Dandruff is excessive flaking of these epithelial cells from the scalp.

OVERVIEW OF THE INTEGUMENTARY SYSTEM

Although we are often concerned with how the integumentary system looks, it has many important functions that go beyond appearance. The integumentary system forms the boundary between the body and the external environment, thereby separating us from the external environment while allowing us to interact with it. The following are the major functions of the integumentary system:

1. *Protection.* The skin protects against abrasion and ultraviolet light. It also prevents the entry of microorganisms and prevents dehydration by reducing water loss from the body.
2. *Sensation.* The integumentary system has sensory receptors that can detect heat, cold, touch, pressure, and pain.
3. *Temperature regulation.* Body temperature is regulated through the control of blood flow through the skin and the activity of sweat glands.
4. *Vitamin D production.* When exposed to ultraviolet light, the skin produces a molecule that can be transformed into vitamin D.
5. *Excretion.* Small amounts of waste products are lost through the skin and in gland secretions.

1 Provide an example for each function of the integumentary system.

SKIN

The skin is made up of two major tissue layers. The **epidermis** (ep-i-derm'is; on the dermis) is the most superficial layer of the skin; it consists of epithelial tissue (figure 5.1). The epidermis resists abrasion on the skin's surface and reduces water loss through the skin. The epidermis rests on the **dermis** (derm'is; skin), which is a layer of connective tissue. The dermis is responsible for most of the structural strength of the skin. The strength of the dermis is seen in leather, which is produced from the hide (skin) of an animal. The epidermis is removed, and the dermis is preserved by tanning.

The skin rests on the **hypodermis** (hi-pō-der'mis; below the skin), which is a layer of loose connective tissue (see figure 5.1). The hypodermis is not part of the skin or the integumentary system, but it does connect the skin to underlying muscle or bone. Table 5.1 summarizes the structures and functions of the skin and hypodermis.

Epidermis

The epidermis is stratified squamous epithelium, and it is separated from the dermis by a basement membrane. The epidermis is not as thick as the dermis, contains no blood vessels, and is

FIGURE 5.1 Skin and Hypodermis

The skin, consisting of the epidermis and the dermis, is connected by the hypodermis to underlying structures. Note the accessory structures (hairs, glands, and arrector pili), some of which project into the hypodermis, and the large amount of fat in the hypodermis.

TABLE 5.1 Comparison of the Skin (Epidermis and Dermis) and Hypodermis

Part	Structure	Function
Epidermis	Superficial part of skin; stratified squamous epithelium; composed of four or five strata	Barrier that prevents water loss and the entry of chemicals and microorganisms; protects against abrasion and ultraviolet light; produces vitamin D; gives rise to hair, nails, and glands
Stratum corneum	Most superficial strata of the epidermis; 25 or more layers of dead squamous cells	Provision of structural strength by keratin within cells; prevention of water loss by lipids surrounding cells; sloughing off of most superficial cells resists abrasion
Stratum lucidum	Three to five layers of dead cells; appears transparent; present in thick skin, absent in most thin skin	Dispersion of keratohyalin around keratin fibers
Stratum granulosum	Two to five layers of flattened, diamond-shaped cells	Production of keratohyalin granules; lamellar bodies release lipids from cells; cells die
Stratum spinosum	A total of 8–10 layers of many-sided cells	Production of keratin fibers; formation of lamellar bodies
Stratum basale	Deepest strata of the epidermis; single layer of cuboidal or columnar cells; basement membrane of the epidermis attaches to the dermis	Production of cells of the most superficial strata; melanocytes produce and contribute melanin, which protects against ultraviolet light
Dermis	Deep part of skin; connective tissue composed of two layers	Responsible for the structural strength and flexibility of the skin; the epidermis exchanges gases, nutrients, and waste products with blood vessels in the dermis
Papillary layer	Papillae project toward the epidermis; loose connective tissue	Brings blood vessels close to the epidermis; dermal papillae form fingerprints and footprints
Reticular layer	Mat of collagen and elastin fibers; dense irregular connective tissue	Main fibrous layer of the dermis; strong in many directions; forms cleavage lines
Hypodermis	Not part of the skin; loose connective tissue with abundant fat deposits	Attaches the dermis to underlying structures; fat tissue provides energy storage, insulation, and padding; blood vessels and nerves from the hypodermis supply the dermis

nourished by diffusion from capillaries of the dermis (figure 5.2). Most cells of the epidermis are called **keratinocytes** (ke-rat'i-nō-sītz) because they produce a protein mixture called **keratin** (ker'ă-tin), which makes the cells hard. Keratinocytes are responsible for the ability of the epidermis to resist abrasion and reduce water loss. Other cells of the epidermis include **melanocytes** (mel'ă-nō-sītz), which contribute to skin color, **Langerhans cells**, which are part of the immune system (see chapter 22), and **Merkel cells**, which are specialized epidermal cells associated with nerve endings responsible for detecting light touch and superficial pressure (see chapter 14).

Cells are produced by mitosis in the deepest layers of the epidermis. As new cells are formed, they push older cells to the surface, where they slough off, or **desquamate** (des'kwă-māt). The outermost cells in this stratified arrangement protect the cells underneath, and the deeper replicating cells replace cells lost from the surface. As they move from the deeper epidermal layers to the surface, the cells change shape and chemical composition. This process is called **keratinization** (ker'ă-tin-i-ză'shŭn) because the cells become filled with keratin. During keratinization, these cells eventually die and produce an outer layer of dead, hard cells that resists abrasion and forms a permeability barrier.

Keratinization and Disease

The study of keratinization is important because many skin diseases result from malfunctions in this process. For example, large scales of epidermal tissue are sloughed off in **psoriasis** (sō-rī'ă-sis; see “Clinical Focus: Clinical Disorders of the Integumentary System,” p. 167). By comparing normal and abnormal keratinization, scientists may be able to develop effective therapies.

Although keratinization is a continual process, distinct transitional stages can be recognized as the cells change. On the basis of these stages, the many layers of cells in the epidermis are divided into regions, or **strata** (sing. *stratum*; see figure 5.2; figure 5.3). From the deepest to the most superficial, the five strata are the stratum basale, stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum. The number of cell layers in each stratum and even the number of strata in the skin vary, depending on their location in the body.

Stratum Basale

The deepest portion of the epidermis is a single layer of cuboidal or columnar cells called the **stratum basale** (bă'să-lē), or **stratum germinativum** (jer'mi-nă-tīv'um; see figures 5.2 and 5.3, step 1).

FIGURE 5.2 Dermis and Epidermis

(a) Photomicrograph of dermis covered by the epidermis. The dermis consists of the papillary and reticular layers. The papillary layer has projections, called papillae, that extend into the epidermis. (b) Higher-magnification photomicrograph of the epidermis resting on the papillary layer of the dermis. Note the strata of the epidermis.

Structural strength is provided by hemidesmosomes, which anchor the epidermis to the basement membrane, and by desmosomes, which hold the keratinocytes together (see chapter 4). Keratinocytes are strengthened internally by keratin fibers (intermediate filaments) that insert into the desmosomes. Keratinocytes undergo mitotic divisions approximately every 19 days. One daughter cell becomes a new stratum basale cell and divides again, but the other daughter cell is pushed toward the surface and becomes **keratinized** (ker'ă-ti-nīzd). It takes approximately 40–56 days for the cell to reach the epidermal surface and desquamate.

Stratum Spinosum

Superficial to the stratum basale is the **stratum spinosum** (spī-nō'sūm), consisting of 8–10 layers of many-sided cells (see figures 5.2 and 5.3, step 2). As the cells in this stratum are pushed to the surface, they flatten; desmosomes are broken apart, and new desmosomes are formed. During preparation

for microscopic observation, the cells usually shrink from one another, except where they are attached by desmosomes, causing the cells to appear spiny—hence the name stratum spinosum. Additional keratin fibers and lipid-filled, membrane-bound organelles called **lamellar** (lam'ě-lār, lă-mel'ar) **bodies** are formed inside the keratinocytes. A limited amount of cell division takes place in the stratum spinosum. Mitosis does not occur in the more superficial strata.

Stratum Granulosum

The **stratum granulosum** (gran-ū-lō'sūm) consists of two to five layers of somewhat flattened, diamond-shaped cells with long axes that are oriented parallel to the surface of the skin (see figures 5.2 and 5.3, step 3). This stratum derives its name from the nonmembrane-bound protein granules of **keratohyalin** (ker'ă-tō-hī'ă-lin), which accumulate in the cytoplasm of the cell. The lamellar bodies of these cells move to the plasma membrane and

PROCESS FIGURE 5.3 Epidermal Layers and Keratinization

release their lipid contents into the intercellular space. Inside the cell, a protein envelope forms beneath the plasma membrane. In the most superficial layers of the stratum granulosum, the nucleus and other organelles degenerate, and the cell dies. Unlike the other organelles, however, the keratin fibers and keratohyalin granules do not degenerate.

Stratum Lucidum

The **stratum lucidum** (loo'si-dŭm) appears as a thin, clear zone above the stratum granulosum (see figures 5.2 and 5.3, step 4); it consists of several layers of dead cells with indistinct boundaries. Keratin fibers are present, but the keratohyalin, which was evident as granules in the stratum granulosum, has dispersed around the keratin fibers, and the cells appear somewhat transparent. The stratum lucidum is present in only a few areas of the body (see “Thick and Thin Skin” on p. 154).

Stratum Corneum

The last, and most superficial, stratum of the epidermis is the **stratum corneum** (kōr'nē-ŭm; see figures 5.2 and 5.3, step 5). This stratum is composed of 25 or more layers of dead squamous cells joined by desmosomes. Eventually, the desmosomes break apart, and the cells are desquamated from the surface of the skin. Excessive desquamation of the stratum corneum of the scalp is called dandruff. Less noticeably, cells are continually shed as clothes rub against the body or as the skin is washed.

The stratum corneum consists of **cornified cells**, which are dead cells, with a hard protein envelope, filled with the protein keratin. **Keratin** is a mixture of keratin fibers and keratohyalin. The envelope and the keratin are responsible for the structural strength of the stratum corneum. The type of keratin found in the skin is soft keratin. Another type of keratin, hard keratin, is found in nails and the external parts of hair. Cells containing hard keratin are more durable than cells with soft keratin, and they do not desquamate.

Surrounding the cells are the lipids released from lamellar bodies. The lipids are responsible for many of the permeability characteristics of the skin.

- 2 **From deepest to most superficial, name and describe the five strata of the epidermis. In which strata are new cells formed by mitosis? Which strata have live cells, and which have dead cells?**
- 3 **Describe the structural features resulting from keratinization that make the epidermis structurally strong and resistant to water loss.**

PREDICT 1

Some drugs are administered by applying them to the skin (e.g., a nicotine skin patch to help a person stop smoking). The drug diffuses through the epidermis to blood vessels in the dermis. What kind of substances can pass easily through the skin by diffusion? What kind have difficulty?

CLINICAL GENETICS

Skin Cancer

Skin cancer is the most common type of cancer. Most skin cancers result from damage caused by the ultraviolet (UV) radiation in sunlight. Some skin cancers are induced by chemicals, x-rays, depression of the immune system, and inflammation, and some are inherited.

UV radiation damages the genes (DNA) in epidermal cells, producing mutations. If a mutation is not repaired, when a cell divides by mitosis the mutation is passed to one of the two daughter cells. An accumulation of mutations affecting oncogenes and tumor suppressing genes in epidermal cells can lead to uncontrolled cell division and skin cancer (see “Cancer,” chapter 4).

The amount of protective melanin in the skin affects the likelihood of developing skin cancer. Fair-skinned individuals, with less mel-

anin, are genetically predisposed to develop skin cancer, compared with dark-skinned individuals, who have more melanin. Long-term or intense exposure to UV radiation also increases the risk of developing skin cancer. Thus, individuals who are older than 50, who have engaged in repeated recreational or occupational exposure to the sun, or who have experienced sunburn are at increased risk. The sites of development of most skin cancers are the parts of the body most exposed to sunlight, such as the face, neck, ears, and dorsum of the forearm and hand.

There are three types of skin cancer: basal cell carcinoma, squamous cell carcinoma, and melanoma (figure A). **Basal cell carcinoma**, the most common type of skin cancer, arises from cells in the stratum basale. Basal cell carcinomas have a varied appearance. Some are open sores that bleed, ooze, or crust for several

weeks. Others are reddish patches; shiny, pearly, or translucent bumps; or scarlike areas of shiny, taut skin. A physician should be consulted for the diagnosis and treatment of all skin cancers. Removal or destruction of the tumor cures most cases of basal cell carcinoma.

An **actinic keratosis** (ak-tin'ik ker-ă-tō'sis) is a small, scaly, crusty bump that arises on the surface of the skin. If untreated, about 2%–5% of actinic keratoses can progress to **squamous cell carcinoma**, the second most common type of skin cancer. Squamous cell carcinoma arises from cells in the stratum spinosum and can appear as a wartlike growth; a persistent, scaly red patch; an open sore; or an elevated growth with a central depression. Bleeding from these lesions can occur. Removal or destruction of the tumor cures most cases of squamous cell carcinoma.

FIGURE A Cancer of the Skin

Thick and Thin Skin

When we say a person has thick or thin skin, we are usually referring metaphorically to the person's ability to take criticism. However, all of us in a literal sense have both thick and thin skin. Skin is classified as thick or thin on the basis of the structure of the epidermis. **Thick skin** has all five epithelial strata, and the stratum corneum has many layers of cells. Thick skin is found in areas subject to pressure or friction, such as the palms of the hands, the soles of the feet, and the fingertips.

Thin skin covers the rest of the body and is more flexible than thick skin. Each stratum contains fewer layers of cells than are found in thick skin; the stratum granulosum frequently consists of only one or two layers of cells, and the stratum lucidum generally is absent. Hair is found only in thin skin.

The entire skin, including both the epidermis and the dermis, varies in thickness from 0.5 mm in the eyelids to 5.0 mm on the back and shoulders. The terms *thin* and *thick*, which refer to the epidermis only, should not be used when total skin thickness is considered. Most of the difference in total skin thickness results from variation in the thickness of the dermis. For example, the skin of the back is thin skin, whereas that of the palm is thick skin; however, the total skin thickness of the back is greater than that of the palm because more dermis exists in the skin of the back.

In skin subjected to friction or pressure, the number of layers in the stratum corneum greatly increases to produce a thickened area called a **callus** (kal'ūs). The skin over bony prominences may develop a cone-shaped structure called a **corn**. The base of the

Melanoma (mel'ă-nō'mă) is the least common, but most deadly, type of skin cancer, accounting for over 77% of the skin cancer deaths in the United States. Because they arise from melanocytes, most melanomas are black or brown, but occasionally a melanoma stops producing melanin and appears skin-colored, pink, red, or purple. About 40% of melanomas develop in preexisting moles. Treatment of melanomas when they are confined to the epidermis is almost always successful. If a melanoma invades the dermis and metastasizes to other parts of the body, it is difficult to treat and can be deadly.

Early detection and treatment of melanoma before it metastasizes can prevent death. Detection of melanoma can be accomplished by routine examination of the skin and the application of the **ABCDE rule**, in which *A* stands for asymmetry (one side of the lesion does not match the other side), *B* is for border irregularity (the edges are ragged, notched, or blurred), *C* is for color (pigmentation is not uniform), *D* is for diameter (greater than 6 mm), and *E* is for evolving (lesion changes over time). Evolving lesions change size, shape, elevation, or color; they may bleed, crust, itch, or become tender.

In order for cancer cells to metastasize, they must leave their site of origin, enter the circulation, and become established in a new location. For example, melanoma cells first spread within the epidermis. Melanoma cells that break through the basement membrane and invade the dermis may enter lymphatic or blood vessels and spread to other parts of the body. The ability to metastasize requires an accumulation of mutations that enables cells to detach from similar cells, recognize and digest the basement membrane, and become established elsewhere when surrounded by different cell types.

Basal cell carcinomas very rarely metastasize and only 2%–6% of squamous cell carcinomas metastasize. Compared with keratinocytes, melanocytes may be more likely to give rise to tumors that metastasize because, in their developmental past, they had the ability to migrate and become established in new locations. In the embryo, melanocytes are derived from a population of cells, called neural crest cells, that originate along the midline of the back (see “Development of the CNS,” chapter 13). Whereas many neural crest cells give rise to parts of the nervous system, others migrate to the skin and become melanocytes. A gene called *Slug* on chromosome 8 regulates neural crest cell migration. In normal melanocytes, the *Slug* gene is inactive, but in metastasizing melanoma cells it is reactivated. The reactivation of other genes regulating the migration of embryonic cells may play a role in other metastasizing cancers.

Most skin cancers result from a series of genetic changes in somatic cells. In some cases, however, there is a genetic susceptibility to developing skin cancer. For example, the risk of developing melanoma is two to three times greater than for the general population if a person's parent, sibling, or child has melanoma. Defects in tumor suppressor genes on chromosome 9 have been found in some cases of familial melanoma. Individuals who inherit these defective genes have already started down the cancer-developing pathway at birth. They are at increased risk of developing melanoma because fewer mutations later in life are required to develop melanoma.

Xeroderma pigmentosum (zēr'ō-der'mă pig'men-tō'sūm) is a rare, autosomal recessive trait in which a DNA repair gene is defective. The severity of the disorder varies, depending

on which of seven different genes is affected and on how the gene is affected—that is, what alleles are present. The most common defective gene is located on chromosome 9. Because damage to genes by UV radiation is not repaired, exposure to UV radiation results in the development of fatal skin cancers in childhood. Minimizing UV radiation exposure to a level as close as possible to zero can delay the development of the disorder.

Limiting exposure to the sun and using sunscreens can reduce the likelihood of developing skin cancer in everyone. Two types of UV radiation play a role. Ultraviolet-B (UVB; 290–320 nm) radiation is the most potent for causing sunburn, is the main cause of basal and squamous cell carcinomas, and is a significant cause of melanoma. Ultraviolet-A (UVA; 320–400 nm) also contributes to skin cancer development, especially melanoma. It also penetrates into the dermis, causing wrinkling and leathering of the skin. A broad-spectrum sunscreen, which protects against both UVB and UVA, with a sun protection factor (SPF) of at least 15, is recommended by the Skin Cancer Foundation.

Someday, increased protection against UV radiation may be achieved by stimulating tanning. Melanotan I is being tested. It is a synthetic version of melanocyte-stimulating hormone, which stimulates increased melanin production by melanocytes.

Sunless tanning stains the dead surface cells of the epidermis with dihydroxyacetone (DHA). At best, DHA provides a SPF of only 2 to 4. Although it does not provide adequate protection against UV radiation, it is beneficial in the sense that a tanned appearance is achieved without exposing the skin to the damaging effects of UV radiation.

cone is at the surface, but the apex extends deep into the epidermis, and pressure on the corn may be quite painful. Calluses and corns can develop in both thin and thick skin.

4 Compare the structure and location of thick skin and thin skin. Is hair found in thick or thin skin?

Skin Color

Pigments in the skin, blood circulating through the skin, and the thickness of the stratum corneum together determine skin color. **Melanin** (mel'ă-nin) is the group of pigments responsible for skin, hair, and eye color. Melanin provides protection against ultraviolet light from the sun. Large amounts of melanin

are found in certain regions of the skin, such as freckles, moles, nipples, areolae of the breasts, axillae, and genitalia. Other areas of the body, such as the lips, palms of the hands, and soles of the feet, contain less melanin.

In the production of melanin, the enzyme tyrosinase (tī'rō-si-nās, tīr'ō-si-nās) converts the amino acid tyrosine to dopaquinone (dō'pă-kwin'ōn, dō'pă-kwī-nōn). Dopaquinone can be converted to a variety of related molecules, most of which are brown to black pigments, but some of which are yellowish or reddish.

Melanin is produced by **melanocytes** (mel'ă-nō-sītz), irregularly shaped cells with many long processes that extend between the keratinocytes of the stratum basale and the stratum spinosum (figure 5.4). The Golgi apparatuses of the melanocytes package melanin into vesicles called **melanosomes** (mel'ă-nō-sōmz), which

1. Melanosomes are produced by the Golgi apparatus of the melanocyte.
2. Melanosomes move into melanocyte cell processes.
3. Epithelial cells phagocytize the tips of the melanocyte cell processes.
4. The melanosomes, which were produced inside the melanocytes, have been transferred to epithelial cells and are now inside them.

PROCESS FIGURE 5.4 Melanin Transfer from Melanocyte to Keratinocytes

Melanocytes make melanin, which is packaged into melanosomes and transferred to many keratinocytes.

move into the cell processes of the melanocytes. Keratinocytes phagocytize (see chapter 3) the tips of the melanocyte cell processes, thereby acquiring melanosomes. Although all keratinocytes can contain melanin, only the melanocytes produce it.

Melanin production is determined by genetic factors, exposure to light, and hormones. Genetic factors are primarily responsible for the variations in skin color among different races and among people of the same race. The amount and types of melanin produced by the melanocytes, as well as the size, number, and distribution of the melanosomes, are genetically determined. Skin colors are not determined by the number of melanocytes because all races have essentially the same number. Although many genes are responsible for skin color, a single mutation (see chapter 3) can prevent the manufacture of melanin. **Albinism** (al'bi-nizm) usually is a recessive genetic trait causing an inability to produce tyrosinase. The result is a deficiency or absence of pigment in the skin, hair, and eyes.

Exposure to ultraviolet light darkens melanin already present and stimulates melanin production, resulting in tanning of the skin.

During pregnancy, certain hormones, such as estrogen and melanocyte-stimulating hormone, cause an increase in melanin production in the mother, which in turn causes darkening of the nipples, areolae, and genitalia. The cheekbones, forehead, and chest also may darken, resulting in the “mask of pregnancy,” and a dark line of pigmentation may appear on the midline of the abdomen. Diseases, such as Addison disease, that cause an increased secretion of adrenocorticotropic hormone and melanocyte-stimulating hormone also cause increased pigmentation.

Blood flowing through the skin imparts a reddish hue. **Erythema** (er-ĭ-thē'mā) is increased redness of the skin resulting from increased blood flow through the skin. An inflammatory response (see chapter 4) stimulated by infections, sunburn, allergic reactions, insect bites, or other causes can produce erythema,

as can exposure to the cold, blushing, or flushing when angry or hot. A decrease in blood flow, such as occurs in shock, can make the skin appear pale, and a decrease in the blood oxygen content produces **cyanosis** (sī-ā-nō'sis), a bluish skin color.

Carotene (kar'ō-tēn) is a yellow pigment found in plants, such as carrots and corn. Humans normally ingest carotene and use it as a source of vitamin A. Carotene is lipid-soluble, and, when large amounts of carotene are consumed, the excess accumulates in the stratum corneum and in the adipose cells of the dermis and hypodermis, causing the skin to develop a yellowish tint, which slowly disappears once carotene intake is reduced.

The location of pigments and other substances in the skin affects the color produced. If a dark pigment is located in the dermis or hypodermis, light reflected off the dark pigment can be scattered by collagen fibers of the dermis to produce a blue color. The same effect produces the blue color of the sky as light is reflected from dust particles in the air. The deeper within the dermis or hypodermis any dark pigment is located, the bluer the pigment appears because of the light-scattering effect of the overlying tissue. This effect causes the blue color of tattoos, bruises, and some superficial blood vessels.

- 5 Which cells of the epidermis produce melanin? What happens to the melanin once it is produced?
- 6 How do genetic factors, exposure to light, and hormones determine the amount of melanin in the skin?
- 7 How do melanin, carotene, and blood affect skin color?

PREDICT 2

Explain the differences in skin color between (a) the palms of the hands and the lips, (b) the palms of the hands of a person who does heavy manual labor and one who does not, (c) the anterior and posterior surfaces of the forearm, and (d) the genitals and the soles of the feet.

Dermis

The dermis is connective tissue with fibroblasts, a few adipose cells, and macrophages. Collagen is the main connective tissue fiber, but elastin and reticular fibers are also present. Adipose cells and blood vessels are scarce in the dermis, compared with the hypodermis. Nerve endings, hair follicles, smooth muscles, glands, and lymphatic vessels are also in the dermis (see figure 5.1). The nerve endings are varied in structure and function: free nerve endings for pain, itch, tickle, and temperature sensations; hair follicle receptors for light touch; Pacinian corpuscles for deep pressure; Meissner corpuscles for the ability to detect simultaneous stimulation at two points on the skin; and Ruffini end organs for continuous touch or pressure (see figure 14.1).

The dermis is divided into two layers (see figures 5.1 and 5.2): the deeper **reticular** (re-tik'ū-lār) **layer** and the superficial **papillary** (pap'i-lār-ē) **layer**. The papillary layer derives its name from projections called **dermal papillae** (pă-pil'ē) that extend toward the epidermis (see figure 5.2). The papillary layer is loose connective tissue with thin fibers that are somewhat loosely arranged. The papillary layer also contains blood vessels that supply the overlying epidermis with nutrients, remove waste products, and aid in regulating body temperature.

The dermal papillae underlying thick skin are in parallel, curving ridges that shape the overlying epidermis into fingerprints and footprints. The ridges increase friction and improve the grip of the hands and feet.

Fingerprints and Criminal Investigations

Fingerprints were first used in criminal investigation in 1880 by Henry Faulds, a Scottish medical missionary. Faulds used a greasy fingerprint left on a bottle to identify a thief who had been drinking purified alcohol from a dispensary. Everyone has unique fingerprints and footprints, even identical twins.

The reticular layer, which is composed of dense irregular connective tissue, is the main layer of the dermis. It is continuous with the hypodermis and forms a mat of irregularly arranged fibers that are resistant to stretching in many directions. The elastin and collagen fibers are oriented more in some directions than in others and produce **cleavage**, or **tension**, **lines** in the skin (figure 5.5). Knowledge of cleavage line directions is important because an incision made parallel to the cleavage lines is less likely to gap than is an incision made across them. The closer together the edges of a wound, the less likely is the development of infections and the formation of considerable scar tissue.

If the skin is overstretched, the dermis may rupture and leave lines that are visible through the epidermis. These lines of scar tissue, called **striae** (strī'ē), or **stretch marks**, can develop on the abdomen and breasts of a woman during pregnancy.

- 8 **Name and compare the two layers of the dermis. Which layer is responsible for most of the structural strength of the skin?**
- 9 **What are cleavage lines and striae?**

FIGURE 5.5 Cleavage Lines

The orientation of collagen fibers produces cleavage, or tension, lines in the skin.

HYPODERMIS

Just as a house rests on a foundation, the skin rests on the **hypodermis** (hī-pō-der'mis), which attaches it to underlying bone and muscle and supplies it with blood vessels and nerves (see figure 5.1). The hypodermis consists of loose connective tissue with collagen and elastin fibers. The main types of cells within the hypodermis are fibroblasts, adipose cells, and macrophages. The hypodermis, which is not part of the skin, is sometimes called **subcutaneous** (süb-koo-tā'nē-ūs) **tissue**, or **superficial fascia** (fash'ē-ă).

Approximately half the body's stored fat is in the hypodermis, where it functions as a source of energy, insulation, and padding. The hypodermis can be used to estimate total body fat. The skin is pinched at selected locations, and the thickness of the fold of skin and underlying hypodermis is measured. The thicker the fold, the greater the amount of total body fat.

The amount of fat in the hypodermis varies with age, sex, and diet. Most babies have a chubby appearance because they have proportionately more fat than adults. Women have proportionately more fat than men, especially over the thighs, buttocks, and breasts, which accounts for some of the differences in body shape between women and men.

The amount of fat in the hypodermis is also responsible for some of the differences in body shape between individuals of the same sex.

10 Name the types of tissue forming the hypodermis.

11 How is the hypodermis related to the skin?

12 List the functions of the fat within the hypodermis.

Injections

There are three types of injections. An **intra-dermal injection**, such as for the tuberculin skin test, is an injection into the dermis. It is administered by drawing the skin taut and inserting a small needle at a shallow angle into the skin. A **subcutaneous injection** is an injection into the fatty tissue of the hypodermis, such as for an insulin injection. This injection is achieved by pinching the skin to form a “tent” into which a short needle is inserted. An **intramuscular injection** is an injection into a muscle deep to the hypodermis. It is accomplished by inserting a long needle at a 90-degree angle to the skin. Intramuscular injections are used for injecting most vaccines and certain antibiotics.

ACCESSORY SKIN STRUCTURES

Accessory skin structures include hair and hair follicles, smooth muscles called the arrector pili, sweat and sebaceous glands, and nails.

Hair

The presence of **hair** is one of the characteristics common to all mammals; if the hair is dense and covers most of the body surface, it is called fur. In humans, hair is found everywhere on the skin except the palms, the soles, the lips, the nipples, parts of the external genitalia, and the distal segments of the fingers and toes.

By the fifth or sixth month of fetal development, delicate, unpigmented hair called **lanugo** (lā-noo'gō) has developed and covered the fetus. Near the time of birth, **terminal hairs**, which are long, coarse, and pigmented, replace the lanugo of the scalp, eyelids, and eyebrows. **Vellus** (vel'ūs) **hairs**, which are short, fine, and usually unpigmented, replace the lanugo on the rest of the body. At puberty, terminal hair, especially in the pubic and axillary regions, replaces much of the vellus hair. The hair of the chest, legs, and arms is approximately 90% terminal hair in males, compared with approximately 35% in females. In males, terminal hairs replace the vellus hairs of the face to form the beard. The beard, pubic, and axillary hair are signs of sexual maturity. In addition, pubic and axillary hair may function as wicks for dispersing odors produced by secretions from specialized glands in the pubic and axillary regions. It also has been suggested that pubic hair protects against abrasion during intercourse and axillary hair reduces friction when the arms move.

Hair Structure

A hair is divided into the **shaft** and the **root** (figure 5.6a). The shaft protrudes above the surface of the skin, and the root is located below the surface. The base of the root is expanded to form the

hair bulb (figure 5.6b). Most of the root and the shaft of the hair are composed of columns of dead keratinized epithelial cells arranged in three concentric layers: the medulla, the cortex, and the cuticle (figure 5.6c). The **medulla** (me-dool'ā) is the central axis of the hair; it consists of two or three layers of cells containing soft keratin. The **cortex** forms the bulk of the hair; it consists of cells containing hard keratin. The **cuticle** (kū'ti-kl) is a single layer of cells that forms the hair surface. The cuticle cells contain hard keratin, and the edges of the cuticle cells overlap like shingles on a roof.

Hard keratin contains more sulfur than does soft keratin. When hair burns, the sulfur combines with hydrogen to form hydrogen sulfide, which produces the unpleasant odor of rotten eggs. In some animals, such as sheep, the cuticle edges of the hair are raised; during textile manufacture, they catch each other and hold together to form threads.

The **hair follicle** consists of a **dermal root sheath** and an **epithelial root sheath**. The dermal root sheath is the portion of the dermis that surrounds the epithelial root sheath. The epithelial root sheath is divided into an external and an internal part (see figure 5.6b). At the opening of the follicle, the external epithelial root sheath has all the strata found in thin skin. Deeper in the hair follicle, the number of cells decreases until at the hair bulb only the stratum basale is present. This has important consequences for the repair of the skin. If the epidermis and the superficial part of the dermis are damaged, the undamaged part of the hair follicle that lies deep in the dermis can be a source of new epithelium. The internal epithelial root sheath has raised edges that mesh closely with the raised edges of the hair cuticle and hold the hair in place. When a hair is pulled out, the internal epithelial root sheath usually comes out as well and is plainly visible as whitish tissue around the root of the hair.

The hair bulb is an expanded knob at the base of the hair root (see figure 5.6a and b). Inside the hair bulb is a mass of undifferentiated epithelial cells, the **matrix**, which produces the hair and the internal epithelial root sheath. The dermis of the skin projects into the hair bulb as a **hair papilla**; it contains blood vessels that provide nourishment to the cells of the matrix.

Hair Growth

Hair is produced in cycles that involve a **growth stage** and a **resting stage**. During the growth stage, hair is formed by matrix cells that differentiate, become keratinized, and die. The hair grows longer as cells are added at the base of the hair root. Eventually, hair growth stops; the hair follicle shortens and holds the hair in place. A resting period follows, after which a new cycle begins and a new hair replaces the old hair, which falls out of the hair follicle. Thus, loss of hair normally means that the hair is being replaced. The length of each stage depends on the hair—eyelashes grow for approximately 30 days and rest for 105 days, whereas scalp hairs grow for 3 years and rest for 1–2 years. At any given time, an estimated 90% of the scalp hairs are in the growing stage, and loss of approximately 100 scalp hairs per day is normal.

The most common kind of permanent hair loss is “pattern baldness.” Hair follicles are lost, and the remaining hair follicles revert to producing vellus hair, which is very short, transparent,

FIGURE 5.6 Hair Follicle

(a) The hair follicle contains the hair and consists of a dermal and an epithelial root sheath. (b) Enlargement of the hair follicle wall and hair bulb. (c) Cross section of a hair within a hair follicle.

and for practical purposes invisible. Although more common and more pronounced in certain men, baldness can also occur in women. Genetic factors and the hormone testosterone are involved in causing pattern baldness.

The average rate of hair growth is approximately 0.3 mm per day, although hairs grow at different rates even in the same approximate location. Cutting, shaving, or plucking hair does not alter the growth rate or the character of the hair, but hair can feel coarse and bristly shortly after shaving because the short hairs are less flexible. Maximum hair length is determined

by the rate of hair growth and the length of the growing phase. For example, scalp hair can become very long, but eyelashes are short.

Hair Color

Melanin is produced by melanocytes within the hair bulb matrix and is passed to keratinocytes in the hair cortex and medulla. As with the skin, varying amounts and types of melanin cause different shades of hair color. Blonde hair has little black-brown melanin, whereas jet black hair has the most. Intermediate

CLINICAL FOCUS

Burns

A burn is injury to a tissue caused by heat, cold, friction, chemicals, electricity, or radiation. Burns are classified according to the extent of surface area involved and the depth of the burn. For an adult, the surface area that is burned can be conveniently estimated by “the rule of nines,” in which the body is divided into areas that are approximately 9%, or multiples of 9%, of the body surface area (BSA) (figure B). For younger patients, surface area relationships are different. For example, in an infant, the head and neck are 21% of BSA, whereas in an adult they are 9%. For burn victims younger than age 15, a table specifically developed for them should be consulted.

On the basis of depth, burns are classified as either partial-thickness or full-thickness burns (figure C). **Partial-thickness burns** are subdivided into first- and second-degree burns. **First-degree burns** involve only the epidermis and are red and painful, and slight edema (swelling) may occur. They can be caused by sunburn or brief exposure to hot or cold objects, and they heal in a week or so without scarring.

Second-degree burns damage the epidermis and the dermis. Minimal dermal damage causes redness, pain, edema, and blisters. Healing takes approximately 2 weeks, and no scarring results. If the burn goes deep into the dermis, however, the wound appears red, tan, or white; may take several months to heal; and might scar. In all second-degree burns, the epidermis regenerates from epithelial tissue in hair follicles and sweat glands, as well as from the edges of the wound.

FIGURE B The Rule of Nines

(a) In an adult, surface areas can be estimated using the rule of nines: Each major area of the body is 9%, or a multiple of 9%, of the total body surface area. (b) In infants and children, the head represents a larger proportion of surface area. The rule of nines is not as accurate for children, as can be seen in this 5-year-old child.

amounts of melanin account for different shades of brown. Red hair is caused by varying amounts of a red type of melanin. Hair sometimes contains both black-brown and red melanin. With age, the amount of melanin in hair can decrease, causing hair color to fade or become white (i.e., no melanin). Gray hair is usually a mixture of unfaded, faded, and white hairs. Hair color is controlled by several genes, and dark hair color is not necessarily dominant over light.

PREDICT 3

Marie Antoinette’s hair supposedly turned white overnight after hearing she would be sent to the guillotine. Explain why you believe or disbelieve this story.

Muscles

Associated with each hair follicle are smooth muscle cells, the **arrector pili** (ă-rek'tōr pī'lī), which extend from the dermal root sheath of the hair follicle to the papillary layer of the dermis (see figure 5.6a). Normally, the hair follicle and the hair inside it are at an oblique angle to the surface of the skin. When the arrector pili muscles contract, however, they pull the follicle into a position more perpendicular to the surface of the skin, causing the hair to “stand on end.” Movement of the hair follicles produces raised areas called “gooseflesh,” or “goose bumps.”

Contraction of the arrector pili muscles occurs in response to cold or to frightening situations, and in animals with fur the

Full-thickness burns are also called **third-degree burns**. The epidermis and dermis are completely destroyed, and deeper tissue may be involved. Third-degree burns are often surrounded by first- and second-degree burns. Although the areas that have first- and second-degree burns are painful, the region of third-degree burn is usually painless because of destruction of sensory receptors. Third-degree burns appear white, tan, brown, black, or deep cherry red in color. Skin can regenerate in a third-degree burn only from the edges, and skin grafts are often necessary.

The depth of burns and the percent of BSA affected by the burns can be combined with other criteria to classify the seriousness of burns. A **major burn** is a third-degree burn over 10% or more of the BSA; a second-degree burn over 25% or more of the BSA; or a second- or third-degree burn of the hands, feet, face, genitals, or anal region. Facial burns are often associated with damage to the respiratory tract, and burns of joints often heal with scar tissue formation that limits movement. A **moderate burn** is a third-degree burn of 2%–10% of the BSA or a second-degree burn of 15%–25% of the BSA. A **minor burn** is a third-degree burn of less than 2% or a second-degree burn of less than 15% of the BSA.

Deep partial-thickness and full-thickness burns take a long time to heal and form scar tissue with disfiguring and debilitating wound contracture. Skin grafts are performed to prevent these complications and to speed healing. In a split skin graft, the epidermis and part of the dermis are removed from another part of the body and are placed over the burn. Interstitial fluid from the burned area nourishes the graft until its dermis becomes vascularized. At the graft donation site, part of the dermis is

FIGURE C Burns

Parts of the skin damaged by burns of different degrees. Partial thickness burns are subdivided into first-degree burns (damage to only the epidermis) and second-degree burns (damage to the epidermis and part of the dermis). Full-thickness, or third-degree, burns destroy the epidermis, dermis, and sometimes deeper tissues.

still present. The deep parts of hair follicles and sweat gland ducts are in this remaining dermis. These hair follicles and sweat gland ducts are a source of epithelial cells, which form a new epidermis that covers the dermis. This is the same process of epidermis formation that occurs in superficial second-degree burns.

When it is not possible or practical to move skin from one part of the body to a burn site, artificial skin or grafts from human cadavers or

pigs are used. These techniques are often unsatisfactory because the body's immune system recognizes the graft as a foreign substance and rejects it. A solution to this problem is laboratory-grown skin. A piece of healthy skin from the burn victim is removed and placed into a flask with nutrients and hormones that stimulate rapid growth. The skin that is produced consists only of epidermis and does not contain glands or hair.

response increases the thickness of the fur. When the response results from cold temperatures, it is beneficial because the fur traps more air and thus becomes a better insulator. In a frightening situation, the animal appears larger and more ferocious, which might deter an attacker. It is unlikely that humans, with their sparse amount of hair, derive any important benefit from either response and probably retain this trait as an evolutionary holdover.

- 16** In what part of a hair does growth take place? What are the stages of hair growth?
- 17** What determines the different shades of hair color?
- 18** Explain the location and action of arrector pili muscles.

Glands

The major glands of the skin are the sebaceous glands and the sweat glands (figure 5.7).

FIGURE 5.7 Glands of the Skin

Sebaceous and apocrine sweat glands empty into the hair follicle. Merocrine sweat glands empty onto the surface of the skin.

Sebaceous Glands

Sebaceous (sē-bā'shūs) **glands**, located in the dermis, are simple or compound alveolar glands that produce **sebum** (sē'būm), an oily, white substance rich in lipids. Because sebum is released by the lysis and death of secretory cells, sebaceous glands are classified as holocrine glands (see chapter 4). Most sebaceous glands are connected by a duct to the upper part of the hair follicles, from which the sebum oils the hair and the skin surface. This prevents drying and protects against some bacteria. A few sebaceous glands located in the lips, in the eyelids (meibomian glands), and in the genitalia are not associated with hairs but open directly onto the skin surface.

Sweat Glands

There are two types of **sweat**, or **sudoriferous** (soo-dō-rif'er-ūs), **glands**, which are called merocrine and apocrine glands. At one time, it was believed that secretions were released in a merocrine fashion from merocrine glands and in an apocrine fashion from apocrine glands (see chapter 4). Accordingly, they were called merocrine and apocrine sweat glands. It is now known that apocrine sweat glands also release some of their secretions in a merocrine fashion, and possibly some in a holocrine fashion. Traditionally, they are still referred to as apocrine sweat glands.

Merocrine (mer'ō-krin, mer'ō-krīn, mer'ō-krēn), or **eccrine** (ek'rin), **sweat glands** are the most common type of sweat gland. They are simple, coiled, tubular glands that open directly onto the surface of the skin through sweat pores (see figure 5.7). Merocrine sweat glands can be divided into two parts: the deep coiled portion, which is located mostly in the dermis,

and the duct, which passes to the surface of the skin. The coiled part of the gland produces an isotonic fluid that is mostly water but also contains some salts (mainly sodium chloride) and small amounts of ammonia, urea, uric acid, and lactic acid. As this fluid moves through the duct, sodium chloride moves by active transport from the duct back into the body, thereby conserving salts. The resulting hypotonic fluid that leaves the duct is called **sweat**. When the body temperature starts to rise above normal levels, the sweat glands produce sweat, which evaporates and cools the body. Sweat also can be released in the palms, soles, and axillae as a result of emotional stress.

Detecting Lies

Emotional sweating is used in lie detector (polygraph) tests because sweat gland activity can increase when a person tells a lie. The sweat produced, even in small amounts, can be detected because the salt solution conducts electricity and lowers the electric resistance of the skin.

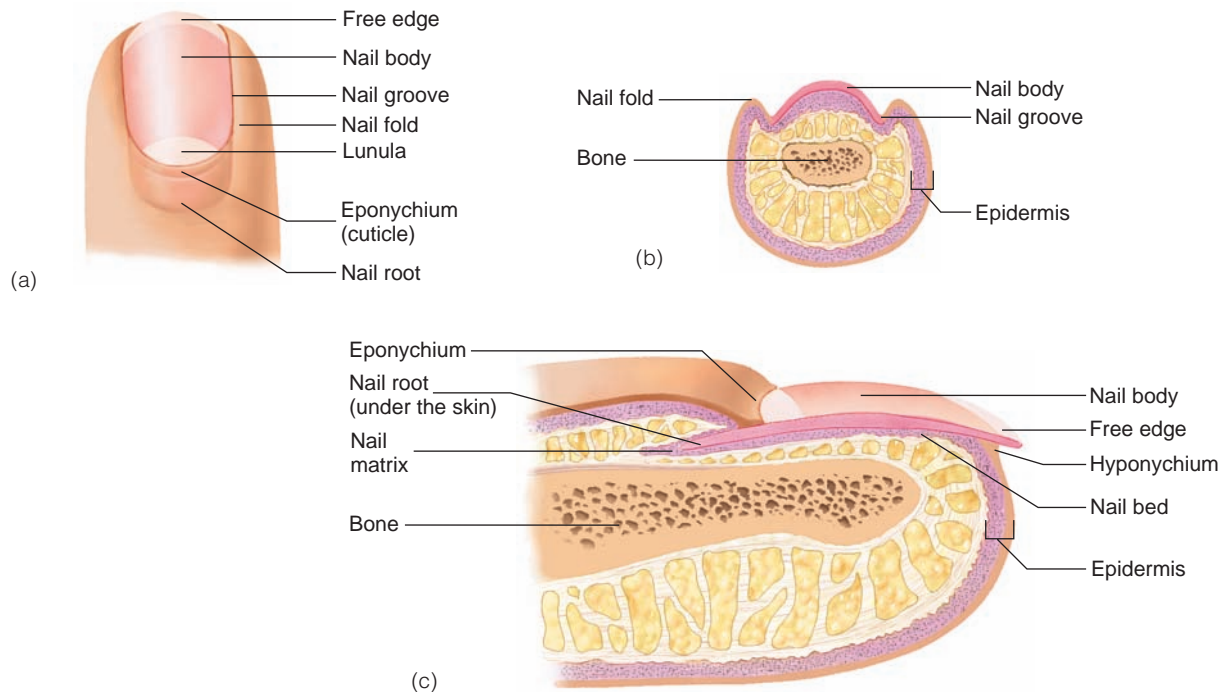

Merocrine sweat glands are most numerous in the palms of the hands and the soles of the feet but are absent from the margin of the lips, the labia minora, and the tips of the penis and clitoris. Only a few mammals, such as humans and horses, have merocrine sweat glands in hairy skin. Dogs, on the other hand, keep cool by water lost through panting instead of sweating.

Apocrine (ap'ō-krin) **sweat glands** are simple, coiled, tubular glands that usually open into hair follicles superficial to the opening of the sebaceous glands (see figure 5.7). In other mammals, these glands are widely distributed throughout the skin; they help regulate temperature. In humans, apocrine sweat glands are found in the axillae and genitalia (scrotum and labia majora) and around the anus, and they do not help regulate temperature. In humans, apocrine sweat glands become active at puberty as a result of the influence of sex hormones. Their secretions contain organic substances, such as 3-methyl-2-hexenoic acid, that are essentially odorless when first released but are quickly metabolized by bacteria to cause what commonly is known as body odor. Many mammals use scent as a means of communication, and it has been suggested that the activity of apocrine sweat glands may be a sign of sexual maturity.

Other Glands

Other skin glands include the ceruminous glands and the mammary glands. The **ceruminous** (sē-roo'mi-nūs) **glands** are modified merocrine sweat glands located in the ear canal (external auditory meatus). **Cerumen**, or earwax, is the combined secretions of ceruminous glands and sebaceous glands. Cerumen and hairs in the ear canal protect the eardrum by preventing the entry of dirt and small insects. An accumulation of cerumen, however, can block the ear canal and make hearing more difficult.

The **mammary glands** are modified apocrine sweat glands located in the breasts. They produce milk. The structure and regulation of mammary glands are discussed in chapters 28 and 29.

- 20** *Which glands of the skin are responsible for cooling the body? Which glands are involved with the production of body odor?*
- 21** *Where are ceruminous and mammary glands located, and what secretions do they produce?*

Nails

The distal ends of primate digits have nails, whereas most other mammals have claws or hooves. Nails protect the ends of the digits, aid in manipulation and grasping of small objects, and are used for scratching.

A **nail** consists of the proximal **nail root** and the distal **nail body** (figure 5.8a). The nail root is covered by skin, and the nail body is the visible portion of the nail. The lateral and proximal edges of the nail are covered by skin called the **nail fold**, and the edges are held in place by the **nail groove** (figure 5.8b). The stratum corneum of the nail fold grows onto the nail body as the **eponychium** (ep-ō-nik'ē-ŭm), or cuticle. Beneath the free edge of the nail body is the **hyponychium** (hī'pō-nik'ē-ŭm), a thickened region of the stratum corneum (figure 5.8c).

The nail root extends distally from the **nail matrix**. The nail also attaches to the underlying **nail bed**, which is located between the nail matrix and the hyponychium. The nail matrix and bed are epithelial tissue, with a stratum basale that gives rise to the cells that form the nail. The nail matrix is thicker than the nail bed and produces nearly all of the nail. The nail bed is visible through the clear nail and appears pink because of blood vessels in the dermis.

A small part of the nail matrix, the **lunula** (loo'noo-lā), is seen through the nail body as a whitish, crescent-shaped area at the base of the nail. The lunula, seen best on the thumb, appears white because the blood vessels cannot be seen through the thicker nail matrix.

The nail is stratum corneum. It contains a hard keratin, which makes the nail hard. As the nail is formed in the nail matrix and bed, it slides over the nail bed toward the distal end of the digit. Nails grow at an average rate of 0.5–1.2 mm per day, and fingernails grow more rapidly than toenails. Unlike hair, they grow continuously throughout life and do not have a resting phase.

- 22** *Name the parts of a nail. Which part produces most of the nail? What is the lunula?*
- 23** *What makes a nail hard? Do nails have growth stages?*

SUMMARY OF INTEGUMENTARY SYSTEM FUNCTIONS

Protection

The integumentary system is the body's fortress, defending it from harm. It performs many protective functions.

1. The skin protects underlying structures from mechanical damage. The dermis provides structural strength, preventing tearing of the skin. The stratified epithelium of the epidermis protects against abrasion. As the outer cells of the stratum

corneum are desquamated, they are replaced by cells from the stratum basale. Calluses develop in areas subject to heavy friction or pressure.

- The skin prevents the entry of microorganisms and other foreign substances into the body. Secretions from skin glands produce an environment unsuitable for some microorganisms. The skin contains components of the immune system that act against microorganisms (see chapter 22).
- Melanin absorbs ultraviolet light and protects underlying structures from its damaging effects.
- Hair provides protection in several ways. The hair on the head acts as a heat insulator and protects against ultraviolet light and abrasion. The eyebrows keep sweat out of the eyes, eyelashes protect the eyes from foreign objects, and hair in the nose and ears prevents the entry of dust and other materials. Axillary and pubic hair are a sign of sexual maturity and protect against abrasion.
- Nails protect the ends of the digits from damage and can be used in defense.
- The intact skin plays an important role in reducing water loss because its lipids act as a barrier to the diffusion of water.

Administering Medications Through the Skin

Some lipid-soluble substances readily pass through the epidermis. Lipid-soluble medications can be administered by applying them to the skin, after which the medication slowly diffuses through the skin into the blood. For example, nicotine patches are used to help reduce withdrawal symptoms in those attempting to quit smoking.

Sensation

The body feels pain, heat, and cold because the integumentary system has sensory receptors in all its layers. For example, the epidermis and dermal papillae are well supplied with touch receptors. The dermis and deeper tissues contain pain, heat, cold, touch, and pressure receptors. Hair follicles (but not the hair) are well innervated, and the movement of hair can be detected by sensory receptors surrounding the base of hair follicles. Sensory receptors are discussed in more detail in chapter 14.

Temperature Regulation

Body temperature is affected by blood flow through the skin. When blood vessels (arterioles) in the dermis dilate, there is increased flow of warm blood from deeper structures to the skin and heat loss increases (figure 5.9, steps 1 and 2). Body temperature tends to increase as a result of exercise, fever, or an increase in environmental temperature. Homeostasis is maintained by the loss of excess heat. To counteract environmental heat gain or to get rid of excess heat produced by the body, sweat is produced. The sweat spreads over the surface of the skin; as it evaporates, heat is lost from the body.

CASE STUDY

Frostbite

Billy was hiking in the mountains during the fall. Unexpectedly, a cold front moved in and the temperature dropped to well below freezing. Billy was unprepared for the temperature change, and he did not have a hat or ear muffs. As the temperature dropped, his ears and nose became pale in color. After a continued decrease in temperature and continued exposure to the cold, every 15–20 minutes his ears and nose turned red for 5–10 minutes, then became pale again. After several hours, Billy managed to hike back to the trail head. By then, he was very chilled and had no sensation in his ears or nose. As he looked in the rearview mirror of his car, he could see that the skin of his ears and nose had turned white. It took Billy 2 hours to drive to the nearest emergency room, where he was informed that the white-colored skin meant he had frostbite of his ears and nose. About 2 weeks later, the frostbitten skin peeled and, despite treatment with an antibiotic, Billy developed an infection of his right ear. Eventually, he recovered, but he lost part of his right ear.

PREDICT 4

Frostbite is the most common type of freezing injury. When skin temperature drops below 0°C (32°F), the skin freezes and ice crystal formation damages tissues.

- Using figure 5.9, describe the mechanism responsible for Billy's ears and nose becoming pale. How is this beneficial when the ambient temperature is decreasing?
- Explain what happened when Billy's ears and nose periodically turned red. How is this beneficial when the ambient temperature is very cold?
- What is the significance of Billy's ears and nose turning and staying white?
- Why is a person with frostbite likely to develop an infection of the affected part of the body?

When blood vessels in the dermis constrict, there is decreased flow of warm blood from deeper structures to the skin and heat loss decreases (figure 5.9, steps 3 and 4). If body temperature begins to drop below normal, heat can be conserved by a decrease in the diameter of dermal blood vessels.

Contraction of the arrector pili muscles causes hair to stand on end, but, with the sparse amount of hair covering the body, this does not significantly reduce heat loss in humans. Hair on the head, however, is an effective insulator. General temperature regulation is considered in chapter 25.

PROCESS FIGURE 5.9 Heat Exchange in the Skin

Vitamin D Production

Vitamin D functions as a hormone to stimulate the uptake of calcium and phosphate from the intestines, to promote their release from bones, and to reduce calcium loss from the kidneys, resulting in increased blood calcium and phosphate levels. Adequate levels of these minerals are necessary for normal bone metabolism (see chapter 6), and calcium is required for normal nerve and muscle function (see chapter 9).

Vitamin D synthesis begins in skin exposed to ultraviolet light, and humans can produce all the vitamin D they require by this process if enough ultraviolet light is available. Because humans live indoors and wear clothing, however, their exposure to ultraviolet light may not be adequate for the manufacture of sufficient vitamin D. This is especially likely for people living in cold climates because they remain indoors or are covered by warm clothing when outdoors. Fortunately, vitamin D can also be ingested and absorbed in the intestine. Natural sources of vitamin D are liver (especially fish liver), egg yolks, and dairy products (e.g., butter, cheese, and milk). In addition, the diet can be supplemented with vitamin D in fortified milk or vitamin pills.

Vitamin D synthesis begins when the precursor molecule 7-dehydrocholesterol (7-dē-hī'drō-kō-les'ter-ol) is exposed to ultraviolet light and is converted into cholecalciferol (kō'lē-kal-sif'er-ol). Cholecalciferol is released into the blood and modified by hydroxylation (hydroxide ions are added) in the liver and kidneys to form active vitamin D (calcitriol; kal-si-tri'ol).

Excretion

Excretion is the removal of waste products from the body. In addition to water and salts, sweat contains a small amount of waste products, such as urea, uric acid, and ammonia. Compared with the kidneys, however, the quantity of waste products eliminated in the sweat is insignificant, even when large amounts of sweat are lost.

- 24** *In what ways does the skin provide protection?*
- 25** *What kind of sensory receptors are found in the skin, and why are they important?*
- 26** *How does the skin help regulate body temperature?*
- 27** *Name the locations where cholecalciferol is produced and then modified into vitamin D. What are the functions of vitamin D?*
- 28** *What substances are excreted in sweat? Is the skin an important site of excretion?*

EFFECTS OF AGING ON THE INTEGUMENTARY SYSTEM

As the body ages, the skin is more easily damaged because the epidermis thins and the amount of collagen in the dermis decreases. Skin infections are more likely, and repair of the skin occurs more slowly. A decrease in the number of elastic fibers in the dermis and loss of fat from the hypodermis cause the skin to sag and wrinkle.

CLINICAL FOCUS

Clinical Disorders of the Integumentary System

THE INTEGUMENTARY SYSTEM AS A DIAGNOSTIC AID

The integumentary system can be used in diagnosis because it is easily observed and often reflects events occurring in other parts of the body. For example, **cyanosis** (sī-ă-nō'sis), a bluish color to the skin that results from decreased blood oxygen content, is an indication of impaired circulatory or respiratory function. When red blood cells wear out, they are broken down, and part of their contents is excreted by the liver as bile pigments into the intestine. **Jaundice** (jawn'dis), a yellowish skin color, occurs when excess bile pigments accumulate in the blood. If a disease, such as viral hepatitis, damages the liver, bile pigments are not excreted and accumulate in the blood.

Rashes and lesions in the skin can be symptomatic of problems elsewhere in the body. For example, scarlet fever results from a bacterial infection in the throat. The bacteria release a toxin into the blood that causes the pink-red rash for which this disease was named. In allergic reactions (see chapter 22), a release of histamine into the tissues produces swelling and reddening. The development of a rash (hives) in the skin can indicate an allergy to foods or drugs, such as penicillin.

The condition of the skin, hair, and nails is affected by nutritional status. In vitamin A deficiency, the skin produces excess keratin and assumes a characteristic sandpaper texture, whereas, in iron-deficiency anemia, the nails lose their normal contour and become flat or concave (spoon-shaped).

Hair concentrates many substances, which can be detected by laboratory analysis, and a comparison of a patient's hair with "normal" hair can be useful in certain diagnoses. For example, lead poisoning results in high levels of lead in the hair. The use of hair analysis as a screening test to determine the general health or nutritional status of an individual is unreliable, however.

BACTERIAL INFECTIONS

Staphylococcus aureus is commonly found in pimples, boils, and carbuncles and causes **impetigo** (im-pe-ti'gō), a disease of the skin that usually affects children. It is characterized by small blisters containing pus that easily rupture and form a thick, yellowish crust. *Streptococcus pyogenes* causes **erysipelas** (er-i-sip'ē-las), swollen red patches in the skin. Burns are often infected by *Pseudomonas aeruginosa*, which produces a characteristic blue-green pus caused by bacterial pigment.

Acne is a disorder of the hair follicles and sebaceous glands that affects almost everyone. Although the exact cause of acne is unknown, four factors are believed to be involved: hormones, sebum, abnormal keratinization within hair follicles, and the bacterium *Propionibacterium acnes*. Acne lesions apparently begin with a hyperproliferation of the hair follicle epidermis, and many cells are desquamated. These cells are abnormally sticky and adhere to one another to form a mass of cells mixed with sebum, which blocks the hair follicle. During puberty, hormones, especially testosterone, stimulate the sebaceous glands to increase sebum production. Because both the testes and the ovaries produce testosterone, the effect is seen in both males and females. An accumulation of sebum behind the blockage produces a whitehead, which may continue to develop into a blackhead or a pimple. A blackhead results if the opening of the hair follicle is pushed open by the accumulating cornified cells and sebum. Although it is generally agreed that dirt is not responsible for the black color of blackheads, its exact cause is disputed. Once the wall of the follicle ruptures, *P. acnes* and other microorganisms stimulate an inflammatory response, which results in the formation of a red pimple filled with pus. If tissue damage is extensive, scarring occurs.

The skin becomes drier with age as sebaceous gland activity decreases. A decrease in the activity of sweat glands and a decrease in the blood supply to the dermis result in a poor ability to regulate body temperature. Death from heat prostration can occur in elderly individuals who do not take proper precautions.

The number of functioning melanocytes generally decreases, but, in some localized areas, especially on the hands and the face, melanocytes increase in number to produce age spots. (Age spots are different from freckles, which are caused by an increase in melanin production, not an increase in melanocyte numbers.) White or gray hairs also occur because of a decrease in or lack of melanin production.

Skin that is exposed to sunlight appears to age more rapidly than nonexposed skin. This effect is observed on areas of the body, such as the face and hands, that receive sun exposure (figure 5.10). The effects of chronic sun exposure on the skin, however, are different from the effects of normal aging. In skin exposed to sunlight, normal elastic fibers are replaced by an interwoven mat of

thick, elasticlike material, the number of collagen fibers decreases, and the ability of keratinocytes to divide is impaired.

29 Compared with young skin, why is aged skin more likely to be damaged, wrinkled, and dry?

30 Why is heat potentially dangerous to the elderly?

31 Explain age spots and white hair.

32 What effect does exposure to sunlight have on skin?

Treatment of Skin Wrinkles

Retin-A (tretinoin; tret'i-nō-in) is a vitamin A derivative that is being used to treat skin wrinkles. It appears to be effective in treating fine wrinkles on the face, such as those caused by long-term exposure to the sun, but is not effective in treating deep lines. One ironic side effect of Retin-A use is increased sensitivity to the sun's ultraviolet rays. Doctors prescribing this cream caution their patients to always use a sunblock when they are going to be outdoors.

VIRAL INFECTIONS

Some of the well-known viral infections of the skin include **chicken pox** (varicella-zoster), **measles**, **German measles** (rubella), and **cold sores** (herpes simplex). **Warts**, which are caused by a viral infection of the epidermis, are generally harmless and usually disappear without treatment.

FUNGAL INFECTIONS

Ringworm is a fungal infection that affects the keratinized portion of the skin, hair, and nails and produces patchy scaling and an inflammatory response. The lesions are often circular with a raised edge, and in ancient times they were thought to be caused by worms. Several species of fungus cause ringworm in humans and are usually described by their location on the body; in the scalp, the condition is ringworm; in the groin, it is jock itch; in the feet, it is athlete's foot.

DECUBITUS ULCERS

Decubitus (dē-kū'bi-tūs) **ulcers**, also known as bedsores, or pressure sores, develop in patients who are immobile (e.g., bedridden or confined to a wheelchair). The weight of the body, especially in areas over bony projections, such as the hipbones and heels, compresses tissues and causes **ischemia** (is-kē'mē-ă), or reduced circulation. The consequence is destruction, or **necrosis** (ně-krō'sis), of the hypodermis

and deeper tissues, which is followed by necrosis of the skin. Once skin necrosis occurs, microorganisms gain entry to produce an infected ulcer.

BULLAE

Bullae (bul'ē), or blisters, are fluid-filled areas in the skin that develop when tissues are damaged and the resultant inflammatory response produces edema. Infections or physical injuries can cause bullae or lesions in different layers of the skin.

PSORIASIS

Psoriasis (sō-rī'ă-sis) is characterized by a thicker than normal stratum corneum that sloughs to produce large, silvery scales. If the scales are scraped away, bleeding occurs from the blood vessels at the top of the dermal papillae. These changes result from increased cell division in the stratum basale, abnormal keratin production, and elongation of the dermal papillae toward the skin surface. Evidence suggests that the disease has a genetic component and that the immune system stimulates the increased cell divisions. Psoriasis is a chronic disease that can be controlled with drugs and phototherapy (ultraviolet light) but as yet has no cure.

ECZEMA AND DERMATITIS

Eczema (ek'zē-mă, eg'zē-mă, eg-zē'mă) and **dermatitis** (der-mă-tī'tis) are general terms

used for inflammatory conditions of the skin. The cause of the inflammation can be an allergy, an infection, poor circulation, or exposure to physical factors, such as chemicals, heat, cold, or sunlight.

BIRTHMARKS

Birthmarks are congenital (present at birth) disorders of the capillaries in the dermis of the skin. Usually, they are of concern only for cosmetic reasons. A **strawberry birthmark** is a mass of soft, elevated tissue that appears bright red to deep purple. In 70% of patients, strawberry birthmarks disappear spontaneously by age 7. **Portwine stains** appear as flat, dull red or bluish patches that persist throughout life.

VITILIGO

Vitiligo (vit-i-lī'gō) is the development of patches of white skin because the melanocytes in the affected area are destroyed, apparently by an autoimmune response (see chapter 22).

MOLES

A **mole** is an elevation of the skin that is variable in size and is often pigmented and hairy. Histologically, a mole is an aggregation, or "nest," of melanocytes in the epidermis or dermis. They are a normal occurrence, and most people have 10–20 moles, which appear in childhood and enlarge until puberty.

FIGURE 5.10 Effects of Sunlight on Skin

SYSTEMS PATHOLOGY

Burns

Sam is a 23-year-old man who had difficulty falling asleep at night. He often stayed up late, watching television or reading, until he fell asleep. Sam was also a chain smoker. One night, he took several sleeping pills. Unfortunately, he fell asleep before putting out his cigarette, which started a fire. As a result, Sam was severely burned and received full-thickness and partial-thickness burns (figure Da). He was rushed to the emergency room and was eventually transferred to a burn unit.

For the first day after his accident, his condition was critical because he went into shock. Administration of large volumes of intravenous fluid stabilized his condition. As part of his treatment, Sam was also given a high-protein, high-calorie diet.

A week later, dead tissue was removed from the most serious burns (figure Db), and a skin graft was performed. Despite the use of topical antimicrobial drugs and sterile bandages, some of the burns became infected. An additional complication was the development of a venous thrombosis in his leg.

Although the burns were painful and the treatment was prolonged, Sam made a full recovery. He no longer smokes.

BACKGROUND INFORMATION

Major burns can cause systemic effects that can be life-threatening. One effect is on capillaries, which are the small blood vessels in which fluid, gases, nutrients, and waste products are normally exchanged between the blood and tissues. Within minutes of a major burn injury, capillaries become more permeable at the burn site and throughout the body. As a result, fluid and electrolytes (see chapter 2) are lost from the burn wound and into tissue spaces. The loss of fluid decreases blood volume, which decreases the heart's ability to pump blood. The resulting decrease in blood delivery to tissues can cause tissue damage, shock, and even death. Treatment consists of administering intravenous fluid at a faster rate than it leaks out of the capillaries. Although this can reverse the shock and prevent death, fluid continues to leak into tissue spaces, causing pronounced **edema**, a swelling of the tissues.

FIGURE D Burn Victim

(a) Partial and full-thickness burns. (b) Patient in a burn unit.

Typically, after 24 hours, capillary permeability returns to normal, and the amount of intravenous fluid administered can be greatly decreased. How burns result in capillary permeability changes is not well understood. It is clear, however, that, following a burn, immunologic and metabolic changes occur that affect not only capillaries but the rest of the body as well. For example, mediators of inflammation (see chapter 4), which are released in response to the tissue damage, contribute to changes in capillary permeability throughout the body.

Substances released from the burn may also play a role in causing cells to function abnormally. Burn injuries result in an almost

immediate hypermetabolic state, which persists until wound closure. Also contributing to the increased metabolism is a resetting of the temperature control center in the brain to a higher temperature and an increase in the hormones released by the endocrine system. For example, epinephrine and norepinephrine from the adrenal glands increase cell metabolism. Compared with a normal body temperature of approximately 37°C (98.6°F), a body temperature of 38.5°C (101.3°F) is typical in burn patients, despite the higher loss of water by evaporation from the burn.

In severe burns, the increased metabolic rate can result in weight loss as great as 30%–40% of the patient's preburn weight. To help

compensate, caloric intake may double or even triple. In addition, the need for protein, which is necessary for tissue repair, is greater.

The skin normally maintains homeostasis by preventing the entry of microorganisms. Because burns damage and even completely destroy the skin, microorganisms can cause infections. For this reason, burn patients are maintained in an aseptic environment, which attempts to prevent the entry of microorganisms into the wound. They are also given antimicrobial drugs, which kill microorganisms or suppress their growth. **Debridement** (dā-brēd-mon'), the removal of dead tissue from the burn, helps prevent infections by cleaning the wound and removing tissue in which infections could develop. Skin grafts,

performed within a week of the injury, also prevent infections by closing the wound and preventing the entry of microorganisms.

Despite these efforts, however, infections still are the major cause of death of burn victims. Depression of the immune system during the first or second week after the injury contributes to the high infection rate. The thermally altered tissue is recognized as a foreign substance, stimulating the immune system. As a result, the immune system is overwhelmed as its cells become less effective and the production of the chemicals that normally provide resistance to infections decreases (see chapter 22). The greater the magnitude of the burn, the greater the depression of the immune system, and the greater the risk of infection.

Venous thrombosis, the development of a clot in a vein, is also a complication of burns. Blood normally forms a clot when exposed to damaged tissue, such as at a burn site, but clotting can also occur elsewhere, such as in veins. Clots can block blood flow, resulting in tissue destruction. The concentration of chemicals in the blood that cause clotting increases for two reasons: an increased release of clotting factors from the liver and loss of fluid from the burn.

PREDICT 5

When Sam was first admitted to the burn unit, the nurses carefully monitored his urine output. Why does that make sense in light of his injuries?

SYSTEM INTERACTIONS	Effect of Burns on Other Systems
SYSTEM	INTERACTIONS
Skeletal	Red bone marrow replaces red blood cells destroyed in the burned skin.
Muscular	Loss of muscle mass results from the hypermetabolic state caused by the burn.
Nervous	Pain is sensed in the partial-thickness burns. The temperature-regulatory center in the brain is set to a higher temperature, which contributes to increased body temperature. Abnormal K^+ concentrations disturb normal nervous system activity: elevated levels are caused by the release of K^+ from damaged tissues; low levels can be caused by rapid loss of K^+ in fluid from the burn.
Endocrine	Increased secretion of epinephrine and norepinephrine from the adrenal gland in response to the injury contributes to increased body temperature by increasing cell metabolism.
Cardiovascular	Increased capillary permeability causes decreased blood volume, resulting in decreased blood delivery to tissues, edema, and shock. The heart's pumping effectiveness is impaired by electrolyte imbalance and substances released from the burn. Increased blood clotting causes venous thrombosis. Preferential delivery of blood to the injury promotes healing.
Lymphatic and immune	Inflammation increases in response to tissue damage. Later, depression of the immune system can result in infection.
Respiratory	Airway obstruction is caused by edema. Increased respiration rate is caused by increased metabolism and lactic acid buildup.
Digestive	Decreased blood delivery as a result of the burn causes degeneration of the intestinal lining and liver. Bacteria from the intestine can cause systemic infections. The liver releases blood clotting factors in response to the injury. Increased nutrients necessary to support increased metabolism and for repair of the integumentary system are absorbed.
Urinary	The kidneys compensate for the increased fluid loss caused by the burn by greatly reducing or even stopping urine production. Decreased blood volume causes decreased blood flow to the kidneys, which reduces urine output but can cause kidney tissue damage. Hemoglobin, released from red blood cells damaged in the burnt skin, can decrease urine production by blocking fluid movement from the blood into the urine.

SUMMARY

The integumentary system consists of the skin, hair, nails, and a variety of glands.

Overview of the Integumentary System (p. 150)

The integumentary system separates and protects us from the external environment. Other functions include sensation, temperature regulation, vitamin D production, and excretion of small amounts of waste products.

Skin (p. 150)

Epidermis

1. The epidermis is stratified squamous epithelium divided into five strata.
2. The stratum basale consists of keratinocytes, which produce the cells of the more superficial strata.
3. The stratum spinosum consists of several layers of cells held together by many desmosomes.
4. The stratum granulosum consists of cells filled with granules of keratohyalin. Cell death occurs in this stratum.
5. The stratum lucidum consists of a layer of dead, transparent cells.
6. The stratum corneum consists of many layers of dead squamous cells. The most superficial cells are desquamated.
7. Keratinization is the transformation of the living cells of the stratum basale into the dead squamous cells of the stratum corneum.
 - Keratinized cells are filled with keratin and have a protein envelope, both of which contribute to structural strength. The cells are also held together by many desmosomes.
 - Intercellular spaces are filled with lipids from the lamellae that contribute to the impermeability of the epidermis to water.
8. Soft keratin is found in skin and the inside of hairs, whereas hard keratin occurs in nails and the outside of hairs. Hard keratin makes cells more durable, and these cells do not desquamate.

Thick and Thin Skin

1. Thick skin has all five epithelial strata.
2. Thin skin contains fewer cell layers per stratum, and the stratum lucidum is usually absent. Hair is found only in thin skin.

Skin Color

1. Melanocytes produce melanin inside melanosomes and then transfer the melanin to keratinocytes. The size and distribution of melanosomes determine skin color. Melanin production is determined genetically but can be influenced by ultraviolet light (tanning) and hormones.
2. Carotene, an ingested plant pigment, can cause the skin to appear yellowish.
3. Increased blood flow produces a red skin color, whereas a decreased blood flow causes a pale skin. Decreased oxygen content in the blood results in a bluish color called cyanosis.

Dermis

1. The dermis is connective tissue divided into two layers.
2. The papillary layer has projections called dermal papillae and is loose connective tissue that is well supplied with capillaries.
3. The reticular layer is the main layer. It is dense irregular connective tissue consisting mostly of collagen.

Hypodermis (p. 157)

1. Located beneath the dermis, the hypodermis is loose connective tissue that contains collagen and elastin fibers.
2. The hypodermis attaches the skin to underlying structures and is a site of fat storage.

Accessory Skin Structures (p. 158)

Hair

1. Lanugo (fetal hair) is replaced near the time of birth by terminal hairs (scalp, eyelids, and eyebrows) and vellus hairs. At puberty, vellus hairs can be replaced with terminal hairs.
2. Hair is dead keratinized epithelial cells consisting of a central axis of cells with soft keratin, known as the medulla, which is surrounded by a cortex of cells with hard keratin. The cortex is covered by the cuticle, a single layer of cells filled with hard keratin.
3. A hair has three parts: shaft, root, and hair bulb.
4. The hair bulb produces the hair in cycles involving a growth stage and a resting stage.
5. Hair color is determined by the amount and kind of melanin present.
6. Contraction of the arrector pili muscles, which are smooth muscles, causes hair to “stand on end” and produces “gooseflesh.”

Glands

1. Sebaceous glands produce sebum, which oils the hair and the surface of the skin.
2. Merocrine sweat glands produce sweat, which cools the body. Apocrine sweat glands produce an organic secretion that can be broken down by bacteria to cause body odor.
3. Other skin glands include ceruminous glands, which make cerumen (earwax), and mammary glands, which produce milk.

Nails

1. The nail root is covered by skin, and the nail body is the visible part of the nail.
2. Nearly all of the nail is formed by the nail matrix, but the nail bed contributes.
3. The lunula is the part of the nail matrix visible through the nail body.
4. The nail is stratum corneum containing hard keratin.

Summary of Integumentary System Functions (p. 163)

Protection

1. The skin protects against abrasion and ultraviolet light, prevents the entry of microorganisms, helps regulate body temperature, and prevents water loss.
2. Hair protects against abrasion and ultraviolet light and is a heat insulator.
3. Nails protect the ends of the digits.

Sensation

The skin contains sensory receptors for pain, touch, hot, cold, and pressure that allow proper response to the environment.

Temperature Regulation

- Through dilation and constriction of blood vessels, the skin controls heat loss from the body.
- Sweat glands produce sweat, which evaporates and lowers body temperature.

Vitamin D Production

- Skin exposed to ultraviolet light produces cholecalciferol, which is modified in the liver and then in the kidneys to form active vitamin D.
- Vitamin D increases blood calcium levels by promoting calcium uptake from the intestine, the release of calcium from bone, and the reduction of calcium loss from the kidneys.

Excretion

Skin glands remove small amounts of waste products (e.g., urea, uric acid, and ammonia) but are not important in excretion.

Effects of Aging on the Integumentary System (p. 165)

- As the body ages, blood flow to the skin declines, the skin becomes thinner, and elasticity is lost.
- Sweat and sebaceous glands are less active, and the number of melanocytes decreases.

REVIEW AND COMPREHENSION

- A layer of skin (where mitosis occurs) that replaces cells lost from the outer layer of the epidermis is the
 - stratum corneum.
 - stratum basale.
 - stratum lucidum.
 - reticular layer.
 - hypodermis.
- If a splinter penetrates the skin of the palm of the hand to the second epidermal layer from the surface, the last layer damaged is the
 - stratum granulosum.
 - stratum basale.
 - stratum corneum.
 - stratum lucidum.
 - stratum spinosum.

For questions 3–7, match the layer of the epidermis with the correct description or function:

- | | |
|-----------------------|---------------------|
| a. stratum basale | d. stratum lucidum |
| b. stratum corneum | e. stratum spinosum |
| c. stratum granulosum | |
- Production of keratin fibers; formation of lamellar bodies; limited amount of cell division
 - Desquamation occurs; 25 or more layers of dead squamous cells
 - Production of cells; melanocytes produce and contribute melanin; hemidesmosomes present
 - Production of keratohyalin granules; lamellar bodies release lipids; cells die
 - Dispersion of keratohyalin around keratin fibers; layer appears transparent; cells dead
 - In which of these areas of the body is thick skin found?
 - back of the hand
 - abdomen
 - over the shin
 - bridge of the nose
 - heel of the foot
 - The function of melanin in the skin is to
 - lubricate the skin.
 - prevent skin infections.
 - protect the skin from ultraviolet light.
 - reduce water loss.
 - help regulate body temperature.
 - Concerning skin color, which of these statements is *not* correctly matched?
 - skin appears yellow—carotene present
 - no skin pigmentation (albinism)—genetic disorder
 - skin tans—increased melanin production
 - skin appears blue (cyanosis)—oxygenated blood
 - African-Americans darker than Caucasians—more melanin in African-American skin

For questions 11–14, match the layer of the dermis with the correct description or function:

- | | |
|--------------------|--------------------|
| a. papillary layer | b. reticular layer |
|--------------------|--------------------|
- Layer of dermis closest to the epidermis
 - Layer of dermis responsible for most of the structural strength of the skin
 - Layer of dermis responsible for fingerprints and footprints
 - Layer of dermis responsible for cleavage lines and striae
 - After birth, the type of hair on the scalp, eyelids, and eyebrows is
 - lanugo.
 - terminal hair.
 - vellus hair.
 - Hair
 - is produced by the dermal root sheath.
 - consists of living keratinized epithelial cells.
 - is colored by melanin.
 - contains mostly soft keratin.
 - grows from the tip.
 - Given these parts of a hair and hair follicle:
 - cortex
 - cuticle
 - dermal root sheath
 - epithelial root sheath
 - medulla

Arrange the structures in the correct order from the outside of the hair follicle to the center of the hair.

- | | | |
|--------------|--------------|--------------|
| a. 1,4,3,5,2 | c. 3,4,2,1,5 | e. 5,4,3,2,1 |
| b. 2,1,5,3,4 | d. 4,3,1,2,5 | |
- Concerning hair growth,
 - hair falls out of the hair follicle at the end of the growth stage.
 - most of the hair on the body grows continuously.
 - cutting or plucking the hair increases its growth rate and thickness.
 - genetic factors and the hormone testosterone are involved in “pattern baldness.”
 - eyebrows have a longer growth stage and resting stage than scalp hair.
 - Smooth muscles that produce “goose bumps” when they contract and are attached to hair follicles are called
 - external root sheaths.
 - arrector pili.
 - dermal papillae.
 - internal root sheaths.
 - hair bulbs.

For questions 20–22, match the type of gland with the correct description or function:

- | | |
|--------------------------|--------------------|
| a. apocrine sweat gland | c. sebaceous gland |
| b. merocrine sweat gland | |
20. Alveolar glands that produce a white, oily substance; usually open into hair follicles
 21. Coiled, tubular glands that secrete a hyposmotic fluid that cools the body; most numerous in the palms of the hands and soles of the feet
 22. Secretions from these coiled, tubular glands are broken down by bacteria to produce body odor; found in the axillae, in the genitalia, and around the anus
 23. The lunula of the nail appears white because
 - a. it lacks melanin.
 - b. blood vessels cannot be seen through the thick nail matrix.
 - c. the eponychium decreases blood flow to the area.
 - d. the nail root is much thicker than the nail body.
 - e. the hyponychium is thicker than the eponychium.
 24. The stratum corneum of the nail fold grows onto the nail body as the

a. eponychium.	c. lunula.	e. nail matrix.
b. hyponychium.	d. nail bed.	
 25. Most of the nail is produced by the

a. eponychium.	c. nail bed.	e. dermis.
b. hyponychium.	d. nail matrix.	
 26. The skin aids in maintaining the calcium and phosphate levels of the body at optimum levels by participating in the production of

a. vitamin A.	c. vitamin D.	e. keratin.
b. vitamin B.	d. melanin.	
 27. Which of these processes increase(s) heat loss from the body?

a. dilation of dermal arterioles	d. both a and c
b. constriction of dermal arterioles	e. both b and c
c. increased sweating	
 28. In third-degree (full-thickness) burns, both the epidermis and dermis of the skin are destroyed. Which of the following conditions does *not* occur as a result of a third-degree burn?

a. dehydration (increased water loss)
b. increased likelihood of infection
c. increased sweating
d. loss of sensation in the burned area
e. poor temperature regulation in the burned area

Answers in Appendix E

CRITICAL THINKING

1. The skin of infants is more easily penetrated and injured by abrasion than that of adults. Based on this fact, which stratum of the epidermis is probably much thinner in infants than that in adults?
2. Melanocytes are found primarily in the stratum basale of the epidermis. In reference to their function, why does this location make sense?
3. The rate of water loss from the skin of a hand was measured. Following the measurement, the hand was soaked in alcohol for 15 minutes. After all the alcohol had been removed from the hand, the rate of water loss was again measured. Compared with the rate of water loss before soaking the hand in alcohol, what difference, if any, would you expect in the rate of water loss after soaking the hand in alcohol?
4. It has been several weeks since Goodboy Player has competed in a tennis match. After the match, he discovers that a blister has formed beneath an old callus on his foot, and the callus has fallen off. When he examines the callus, he discovers that it appears yellow. Can you explain why?
5. Harry Fastfeet, a Caucasian man, jogs on a cold day. What color would you expect his skin to be (a) just before starting to run, (b) during the run, and (c) 5 minutes after the run?
6. A woman has stretch marks on her abdomen, yet she states that she has never been pregnant. Is this possible?
7. The lips are muscular folds forming the anterior boundary of the oral cavity. A mucous membrane covers the lips internally and the skin of the face covers them externally. The vermilion border, which is the red part of the lips, is covered by keratinized epithelium that is the transition between the epithelium of the mucous membrane and the facial skin. The vermilion border can become chapped (dry and cracked), whereas the mucous membrane and the facial skin do not. Propose as many reasons as you can to explain why the vermilion border is more prone to drying than the mucous membrane or facial skin.
8. Why are your eyelashes not a foot long? Your fingernails?
9. Pulling on hair can be quite painful, yet cutting hair is not painful. Explain.
10. Given what you know about the cause of acne, propose some ways to prevent or treat the disorder.
11. A patient has an ingrown toenail, a condition in which the nail grows into the nail fold. Would cutting the nail away from the nail fold permanently correct this condition? Why or why not?
12. Consider the following statement: Dark-skinned children are more susceptible to rickets (insufficient calcium in the bones) than fair-skinned children. Defend or refute this statement.

Answers in Appendix F

Skeletal System

Bones and Bone Tissue

6

Sitting, standing, walking, picking up a pencil, and taking a breath all involve the skeletal system. It is the structural framework that gives the body its shape and provides protection for internal organs and soft tissues. The term *skeleton* is derived from a Greek word meaning dried, indicating that the skeleton is the dried, hard parts left after the softer parts are removed. Even with the flesh and organs removed, the skeleton is easily recognized as human. Despite its association with death, however, the skeletal system actually consists of dynamic, living tissues that are capable of growth, adapt to stress, and undergo repair after injury.

This chapter describes the *functions of the skeletal system* (p. 174), provides an explanation of *cartilage* (p. 174), and examines *bone histology* (p. 175), *bone anatomy* (p. 180), *bone development* (p. 183), *bone growth* (p. 185), *bone remodeling* (p. 191), *bone repair* (p. 192), *calcium homeostasis* (p. 194), and the *effects of aging on the skeletal system* (p. 198).

Colorized scanning electron micrograph of an osteon. The large opening is the space through which blood vessels bring blood to the bone. The surrounding bone matrix is organized into circular layers.

FUNCTIONS OF THE SKELETAL SYSTEM

The skeletal system has four components: bones, cartilage, tendons, and ligaments. The skeletal system provides support and protection, allows body movements, stores minerals and fats, and is the site of blood cell production.

1. **Support.** Rigid, strong bone is well suited for bearing weight and is the major supporting tissue of the body. Cartilage provides a firm yet flexible support within certain structures, such as the nose, external ear, thoracic cage, and trachea. Ligaments are strong bands of fibrous connective tissue that attach to bones and hold them together.
2. **Protection.** Bone is hard and protects the organs it surrounds. For example, the skull encloses and protects the brain, and the vertebrae surround the spinal cord. The rib cage protects the heart, lungs, and other organs of the thorax.
3. **Movement.** Skeletal muscles attach to bones by tendons, which are strong bands of connective tissue. Contraction of the skeletal muscles moves the bones, producing body movements. Joints, which are formed where two or more bones come together, allow movement between bones. Smooth cartilage covers the ends of bones within some joints, allowing the bones to move freely. Ligaments allow some movement between bones but prevent excessive movements.
4. **Storage.** Some minerals in the blood are taken into bone and stored. Should blood levels of these minerals decrease, the minerals are released from bone into the blood. The principal minerals stored are calcium and phosphorus. Fat (adipose tissue) is also stored within bone cavities. If needed, the fats are released into the blood and used by other tissues as a source of energy.
5. **Blood cell production.** Many bones contain cavities filled with red bone marrow, which gives rise to blood cells and platelets (see chapter 19).

- 1 **Name the four components of the skeletal system. List the five functions of the skeletal system.**

CARTILAGE

Cartilage comes in three types: hyaline cartilage, fibrocartilage, and elastic cartilage (see chapter 4). Although each type of cartilage can provide support, hyaline cartilage is most intimately associated with bone. An understanding of hyaline cartilage is important because most of the bones in the body develop from it. In addition, the growth in length of bones and bone repair often involve the production of hyaline cartilage, followed by its replacement with bone.

Hyaline cartilage consists of specialized cells that produce a matrix surrounding the cells (figure 6.1). The cells that produce new cartilage matrix are **chondroblasts** (kon'drō-blastz; *chondro* is from the Greek word *chondrion*, cartilage). When matrix surrounds a chondroblast, it becomes a **chondrocyte** (kon'drō-sīt), which is a rounded cell that occupies a space called a **lacuna** (lä-koo'nă) within the matrix. The matrix contains collagen, which provides strength, and proteoglycans, which make cartilage resilient by trapping water (see chapter 4).

The **perichondrium** (per-i-kon'drē-ŭm) is a double-layered connective tissue sheath covering most cartilage (see figure 6.1). The outer layer of the perichondrium is dense irregular connective tissue containing fibroblasts. The inner, more delicate layer has fewer fibers and contains chondroblasts. Blood vessels and nerves penetrate the outer layer of the perichondrium but do not enter the cartilage matrix so that nutrients must diffuse through the cartilage matrix to reach the chondrocytes. **Articular cartilage**, which is the cartilage covering the ends of bones where they come together to form joints, has no perichondrium, blood vessels, or nerves.

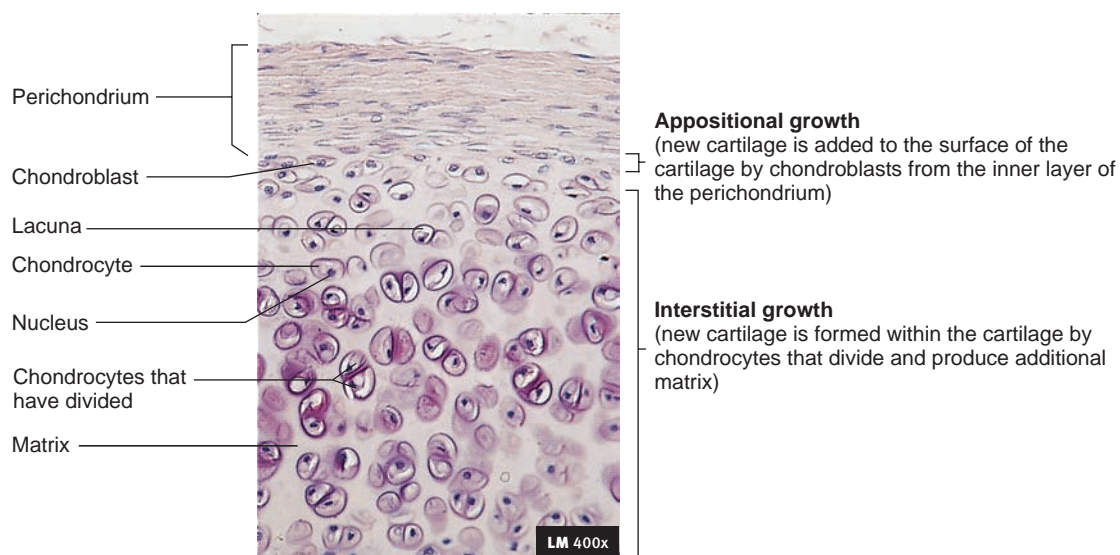

FIGURE 6.1 Hyaline Cartilage

Photomicrograph of hyaline cartilage covered by perichondrium. Chondrocytes within lacunae are surrounded by cartilage matrix.

PREDICT 1

Explain why damaged cartilage takes a long time to heal. What are the advantages of articular cartilage having no perichondrium, blood vessels, or nerves?

Cartilage grows in two ways. Through **appositional growth**, chondroblasts in the perichondrium lay down new matrix and add new chondrocytes to the outside of the tissue; through **interstitial growth**, chondrocytes within the tissue divide and add more matrix between the cells (see figure 6.1).

- 2 Describe the structure of hyaline cartilage. Name two types of cartilage cells. What is a lacuna?
- 3 Describe the connective tissue and cells found in both layers of the perichondrium. How do nutrients from blood vessels in the perichondrium reach the chondrocytes?
- 4 Describe appositional and interstitial growth of cartilage.

BONE HISTOLOGY

Bone consists of extracellular bone matrix and bone cells. The composition of the bone matrix is responsible for the characteristics of bone. The bone cells produce the bone matrix, become entrapped within it, and break it down so that new matrix can replace the old matrix.

Bone Matrix

By weight, mature bone matrix normally is approximately 35% organic and 65% inorganic material. The organic material consists primarily of collagen and proteoglycans. The inorganic material consists primarily of a calcium phosphate crystal called

hydroxyapatite (hī-drok'sē-ap-ă-tīt), which has the molecular formula $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$.

The collagen and mineral components are responsible for the major functional characteristics of bone. Bone matrix might be said to resemble reinforced concrete. Collagen, like reinforcing steel bars, lends flexible strength to the matrix, whereas the mineral components, like concrete, give the matrix compression (weight-bearing) strength.

If all the mineral is removed from a long bone, collagen becomes the primary constituent, and the bone becomes overly flexible. On the other hand, if the collagen is removed from the bone, the mineral component becomes the primary constituent, and the bone is very brittle (figure 6.2).

PREDICT 2

In general, the bones of elderly people break more easily than the bones of younger people. Give as many possible explanations as you can for this observation.

Bone Cells

Bone cells are categorized as osteoblasts, osteocytes, and osteoclasts, which have different functions and origins.

Osteoblasts

Osteoblasts (os'tē-ō-blastz) have an extensive endoplasmic reticulum and numerous ribosomes. They produce collagen and proteoglycans, which are packaged into vesicles by the Golgi apparatus and released from the cell by exocytosis. Osteoblasts also release **matrix vesicles**, which are membrane-bound sacs formed when the plasma membrane buds, or protrudes outward, and pinches off. The matrix vesicles concentrate Ca^{2+} and PO_4^{3-} and

FIGURE 6.2 Effects of Changing the Bone Matrix

(a) Normal bone. (b) Demineralized bone, in which collagen is the primary remaining component, can be bent without breaking. (c) When collagen is removed, mineral is the primary remaining component, thus making the bone so brittle that it is easily shattered.

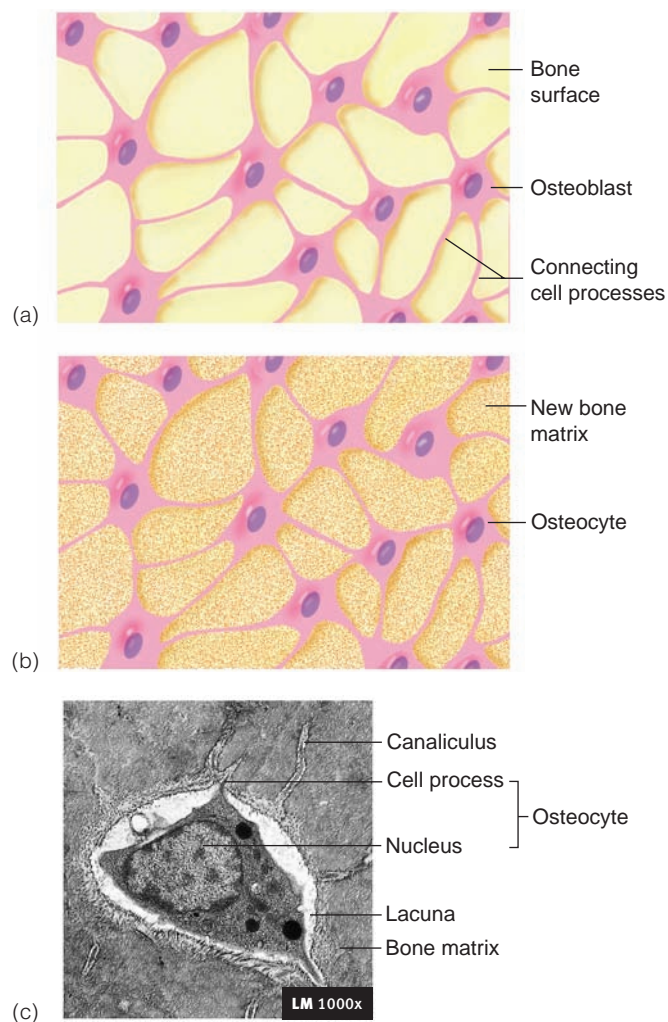

FIGURE 6.3 Ossification

(a) Osteoblasts on a preexisting surface, such as cartilage or bone. The cell processes of different osteoblasts join together. (b) Osteoblasts have produced bone matrix. The osteoblasts are now osteocytes. (c) Photomicrograph of an osteocyte in a lacuna with cell processes in the canaliculi.

form needlelike hydroxyapatite crystals. When the hydroxyapatite crystals are released from the matrix vesicles, they act as templates, or “seeds,” which stimulate further hydroxyapatite formation and mineralization of the matrix.

Ossification (os’i-fi-kā’shūn), or **osteogenesis** (os’tē-ō-jen’ĕ-sis), is the formation of bone by osteoblasts. Ossification occurs by appositional growth on the surface of previously existing bone or cartilage. For example, osteoblasts beneath the periosteum cover the surface of preexisting bone (figure 6.3). Elongated cell processes from osteoblasts connect to cell processes of other osteoblasts through gap junctions (see chapter 4). Bone matrix produced by the osteoblasts covers the older bone surface and surrounds the osteoblast cell bodies and processes. The result is a new layer of bone.

Osteocytes

Once an osteoblast becomes surrounded by bone matrix, it is a mature bone cell called an **osteocyte** (os’tē-ō-sīt). Osteocytes

become relatively inactive, compared with most osteoblasts, but it is possible for them to produce the components needed to maintain the bone matrix.

The spaces occupied by the osteocyte cell bodies are called **lacunae** (lă-koo’nē), and the spaces occupied by the osteocyte cell processes are called **canaliculi** (kan-ă-lik’ū-lī; little canals; see figure 6.3). In a sense, the cells and their processes form a “mold” around which the matrix is formed. Bone differs from cartilage in that the processes of bone cells are in contact with one another through the canaliculi. Instead of diffusing through the mineralized matrix, nutrients and gases can pass through the small amount of fluid surrounding the cells in the canaliculi and lacunae or pass from cell to cell through the gap junctions connecting the cell processes.

Osteoclasts

Osteoclasts (os’tē-ō-klastz) are large cells with several nuclei; they are responsible for the **resorption**, or breakdown, of bone. Where the plasma membrane of osteoclasts contacts bone matrix, it forms many projections called a **ruffled border**. Hydrogen ions are pumped across the ruffled border and produce an acid environment that causes decalcification of the bone matrix. The osteoclasts also release enzymes that digest the protein components of the matrix. Through the process of endocytosis, some of the breakdown products of bone resorption are taken into the osteoclast.

Osteoclasts break down bone best when they are in direct contact with mineralized bone matrix. Osteoblasts assist in the resorption of bone by osteoclasts by producing enzymes that break down the thin layer of unmineralized organic matrix normally covering bone. Removal of this layer by osteoblasts enables the osteoclasts to come into contact with the mineralized bone.

Origin of Bone Cells

Connective tissue develops embryologically from mesenchymal cells (see chapter 4). Some of the mesenchymal cells become **stem cells**, which can replicate and give rise to more specialized cell types. **Osteochondral progenitor cells** are stem cells that can become osteoblasts or chondroblasts. Osteochondral progenitor cells are located in the inner layer of the perichondrium, the inner layer of the periosteum, and the endosteum. From these locations, they are a potential source of new osteoblasts or chondroblasts.

Osteoblasts are derived from osteochondral progenitor cells, and osteocytes are derived from osteoblasts. Whether or not osteocytes freed from their surrounding bone matrix by resorption can revert to active osteoblasts is a debated issue. Osteoclasts are not derived from osteochondral progenitor cells but instead are derived from stem cells in red bone marrow (see chapter 19). The bone marrow stem cells that give rise to a type of white blood cell, called a monocyte, also are the source of osteoclasts. The multinucleated osteoclasts probably result from the fusion of many stem cell descendants.

- 5 **Name the components of bone matrix, and explain their contribution to bone flexibility and the ability of bones to bear weight.**
- 6 **What are the functions of osteoblasts, osteocytes, and osteoclasts?**

CLINICAL GENETICS

Osteogenesis Imperfecta

Collagen molecules consist of three polypeptide chains, called **collagen α -chains**, which wind around each other to form a ropelike helix. Collagen molecules combine to form collagen fibers (see chapter 4). Approximately 25 different collagen α -chains, each encoded by a separate gene, are known, and they combine to form approximately 20 types of collagen molecules. Type I collagen is the major collagen of bone, tendon, and skin. It consists of two collagen α -chains encoded by a gene on chromosome 17 called the COL1A1 gene (figure A) and a different collagen α -chain encoded by a gene on chromosome 7 called the COL1A2 gene.

Osteogenesis imperfecta (OI; os'tē-ō-jen'ē-sis im-per-fek'tā; imperfect bone forma-

tion) is a connective tissue disorder caused by mutations in either of these collagen genes. Consequently, less collagen than normal is produced. Depending on the type of osteogenesis imperfecta, the collagen can have a normal or an abnormal structure, resulting in bones with decreased flexibility and a tendency to break more easily than normal. OI is also known as brittle bone disorder.

In the United States, 20,000 to 50,000 people may have OI. Seven types of OI are recognized, and there is great variation in the appearance and severity of OI both between and within the types. Type I OI, the mildest form, is caused by too little formation of normal type I collagen. It may be characterized by any of the following: bones predisposed to fracture, especially before puberty; normal or near-normal stature; minimal or absent bone deformities; a tendency to develop spinal curvature; loose joints; brittle teeth; hearing loss; and a blue, purple, or gray tint to the whites of the eyes. The number of fractures over a lifetime can vary from a few to more than 100. The fractures usually heal normally without deformity. Children with mild type I OI may have few obvious clinical features, except for a history of broken bones. It is important for children with OI to be properly diagnosed because broken bones can be associated with child abuse.

The other types of OI are more severe than type I, and they result from a reduced amount of abnormal type I collagen. Type II is the most severe OI and most often is lethal within the first week of life. Death usually is caused by an inability to breathe because of a small thorax and rib fractures. Type III OI is characterized by bones that fracture very easily, often with fractures occurring before and during birth. Fractures of the extremities occurring before birth often heal in poor alignment, causing the limbs to be bent and short. Other characteristics of type III OI include short stature; severe bone deformities;

barrel-shaped rib cage; spinal curvature; loose joints; brittle teeth; hearing loss; and a blue, purple, or gray tint to the whites of the eyes. Types IV to VII OI are between types I and III in severity.

Almost all cases of OI are caused by autosomal-dominant mutations. The vast majority of type I OI cases result from mutations in the COL1A1 gene in which the normal nucleotide sequence is altered to produce a stop codon. Messenger RNA that codes for the collagen α -chain is not produced because transcription of the gene is prematurely stopped. Recall from chapter 3 that genes (alleles) occur in pairs on homologous chromosomes. In type I OI, one of the COL1A1 genes is mutated and nonfunctional, whereas the other is normal. A person with type I OI produces approximately half as much normal type I collagen as usual. Thus, type I OI is a collagen-deficiency disorder.

Other types of OI occur when mutated COL1A1 or COL1A2 genes are transcribed and the resulting mRNA codes for defective collagen α -chains. The more defective the collagen α -chains, the weaker the collagen fibers and the greater the severity of the disorder. In addition, bone cells produce less bone matrix because they are inefficient at making new bone matrix containing defective collagen α -chains. Thus, types II–VII OI are defective collagen *and* collagen-deficiency disorders.

There is a 50% chance that a child will inherit OI from an affected parent because it is an autosomal-dominant trait. However, because of the disorder's great variability, the child may be affected in different ways than the parent. For example, their tendency for fractures, bone deformity, and so on may be different. Approximately 25% of children with OI have parents who do not have the disorder. In these cases, a new mutation, which occurred during the formation of sperm cells or oocytes, is responsible.

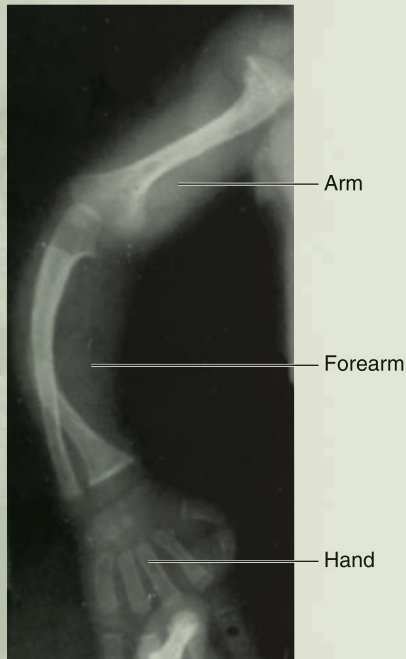

FIGURE A Osteogenesis imperfecta

 (b) Transverse section of a trabecula.

- 7** Describe the formation of new bone by appositional growth. Name the spaces that are occupied by osteocyte cell bodies and cell processes.
- 8** What cells give rise to osteochondral progenitor cells? What kinds of cells are derived from osteochondral progenitor cells? What types of cells give rise to osteoclasts?

Woven and Lamellar Bone

Bone tissue is classified as either woven or lamellar bone, according to the organization of collagen fibers within the bone matrix. In **woven bone**, the collagen fibers are randomly oriented in many directions. Woven bone is first formed during fetal development or during the repair of a fracture. After its formation, osteoclasts break down the woven bone and osteoblasts build new matrix. The process of removing old bone and adding new bone is called **remodeling**. It is an important process discussed later in this

chapter (see “Bone Remodeling,” p. 191). Woven bone is remodeled to form lamellar bone.

Lamellar bone is mature bone that is organized into thin sheets or layers approximately 3–7 micrometers (μm) thick called **lamellae** (lă-mel'ē). In general, the collagen fibers of one lamella lie parallel to one another, but at an angle to the collagen fibers in the adjacent lamellae. Osteocytes, within their lacunae, are arranged in layers sandwiched between lamellae.

Cancellous and Compact Bone

Bone, whether woven or lamellar, can be classified according to the amount of bone matrix relative to the amount of space present within the bone. Cancellous bone has less bone matrix and more space than compact bone, which has more bone matrix and less space than cancellous bone.

Cancellous bone (figure 6.4a) consists of interconnecting rods or plates of bone called **trabeculae** (trä-bek'ū-lē; beam). Between the trabeculae are spaces that, in life, are filled with bone marrow and blood vessels. Cancellous bone is sometimes called spongy bone because of its porous appearance.

Most trabeculae are thin (50–400 μm) and consist of several lamellae with osteocytes located in lacunae between the lamellae (figure 6.4b). Each osteocyte is associated with other osteocytes through canaliculi. Usually, no blood vessels penetrate the trabeculae, so osteocytes must obtain nutrients through their canaliculi. The surfaces of trabeculae are covered with a single layer of cells consisting mostly of osteoblasts with a few osteoclasts.

Trabeculae are oriented along the lines of stress within a bone (figure 6.5). If the stress on a bone is changed slightly (e.g., because

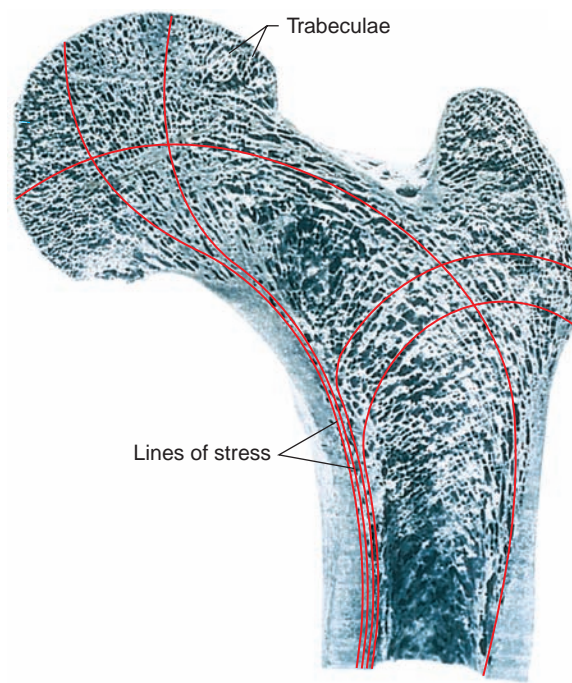

FIGURE 6.5 Trabeculae Oriented Along Lines of Stress

The proximal end of a long bone (femur) showing trabeculae oriented along lines of stress (red lines). The trabeculae bear weight and help bones resist bending and twisting.

FIGURE 6.6 Compact Bone

(a) Compact bone consists mainly of osteons, which are concentric lamellae surrounding blood vessels within central canals. The outer surface of the bone is formed by circumferential lamellae, and bone between the osteons consists of interstitial lamellae. (b) Photomicrograph of an osteon.

of a fracture that heals improperly), the trabecular pattern realigns with the new lines of stress.

Compact bone (figure 6.6) is denser and has fewer spaces than cancellous bone. Blood vessels enter the substance of the bone itself, and the lamellae of compact bone are primarily oriented around those blood vessels. Vessels that run parallel to the long axis of the bone are contained within **central**, or **Haversian** (ha-ver'shan), **canals**. Central canals are lined with endosteum and contain blood vessels, nerves, and loose connective tissue.

Concentric lamellae are circular layers of bone matrix that surround a common center, the central canal. An **osteon** (os'tē-on), or **Haversian system**, consists of a single central canal, its contents, and associated concentric lamellae and osteocytes. In cross section, an osteon resembles a circular target; the "bull's-eye" of the target is the central canal, and 4–20 concentric lamellae form the rings. Osteocytes are located in lacunae between the lamellar rings, and canaliculi radiate between lacunae across the lamellae, producing the appearance of minute cracks across the rings of the target.

The outer surfaces of compact bone are formed by **circumferential lamellae**, which are thin plates that extend around the bone (see figure 6.6). In some bones, such as certain bones of the face, the layer of compact bone can be so thin that no osteons exist, and the compact bone is composed of only circumferential lamellae. In between the osteons are **interstitial lamellae**, which are remnants of concentric or circumferential lamellae that were partially removed during bone remodeling.

Osteocytes receive nutrients and eliminate waste products through the canal system within compact bone. Blood vessels from the periosteum or medullary cavity enter the bone through **perforating**, or **Volkman's, canals**, which run perpendicular to the long axis of the bone (see figure 6.6). Perforating canals are not surrounded by concentric lamellae but pass through the concentric lamellae of osteons. The central canals receive blood vessels from perforating canals. Nutrients in the blood vessels enter the central canals, pass into the canaliculi, and move through the cytoplasm of the osteocytes that occupy the canaliculi and lacunae to the most peripheral cells within each osteon. Waste products are removed in the reverse direction.

- 9 **Distinguish between woven bone and lamellar bone. Where is woven bone found?**
- 10 **Describe the structure of cancellous bone. What are trabeculae, and what is their function? How do osteocytes within trabeculae obtain nutrients?**
- 11 **Describe the structure of compact bone. What is an osteon? Name three types of lamellae found in compact bone.**
- 12 **Trace the pathway nutrients must follow to go from blood vessels in the periosteum to osteocytes within osteons.**

PREDICT 3

Compact bone has perforating and central canals. Why isn't such a canal system necessary in cancellous bone?

BONE ANATOMY

Bone Shapes

Individual bones are classified according to their shape as long, short, flat, or irregular (figure 6.7). **Long bones** are longer than they are wide. Most of the bones of the upper and lower limbs are long bones. **Short bones** are about as broad as they are long. They are nearly cube-shaped or round and are exemplified by the bones of the wrist (carpals) and ankle (tarsals). **Flat bones** have a relatively thin, flattened shape and are usually curved. Examples of flat bones are certain skull bones, the ribs, the breastbone (sternum), and the shoulder blades (scapulae). **Irregular bones**, such as the vertebrae and facial bones, have shapes that do not fit readily into the other three categories.

Structure of a Long Bone

The **diaphysis** (dī-af'i-sis), or shaft, of a long bone is composed primarily of compact bone, but it can also contain some cancellous bone (figure 6.8c; table 6.1). The end of a long bone is mostly

FIGURE 6.7 Bone Shapes

cancellous bone, with an outer layer of compact bone. Within joints, the end of a long bone is covered with hyaline cartilage called **articular cartilage** (figure 6.8a and b).

During bone formation and growth, bones develop from centers of ossification (see “Bone Development,” p. 183). The primary ossification center is in the diaphysis. An **epiphysis** (e-pif'i-sis) is a part of a long bone that develops from a center of ossification distinct from that of the diaphysis. Each long bone of the arm, forearm, thigh (see figure 6.8a and b), and leg has one or more epiphyses (e-pif'i-sēz) on each end of the bone. Each long bone of the hand and foot has one epiphysis, which is located on the proximal or distal end of the bone.

The **epiphyseal** (ep-i-fiz'ē-āl), or **growth, plate** separates the epiphysis from the diaphysis (see figure 6.8a). Growth in bone length (see p. 186) occurs at the epiphyseal plate. Consequently, growth in length of the long bones of the arm, forearm, thigh, and leg occurs at both ends of the diaphysis, whereas growth in length of the hand and foot bones occurs at one end of the diaphysis. When bone stops growing in length, the epiphyseal plate becomes ossified and is called the **epiphyseal line** (see figure 6.8b).

In addition to the small spaces within cancellous bone and compact bone, the diaphysis of a long bone can have a large internal space called the **medullary cavity**. The cavities of cancellous bone and the medullary cavity are filled with marrow. **Red marrow** is

FIGURE 6.8 Long Bone

(a) Young long bone (the femur) showing epiphyses, epiphyseal plates, and diaphysis. The femur is unusual in that there are two epiphyses at the proximal end of the bone. (b) Adult long bone with epiphyseal lines. (c) Internal features of a portion of the diaphysis in (a).

the site of blood cell formation, and **yellow marrow** is mostly adipose tissue. In the fetus, the spaces within bones are filled with red marrow. The conversion of red marrow to yellow marrow begins just before birth and continues well into adulthood. Yellow marrow completely replaces the red marrow in the long bones of the limbs, except for some red marrow in the proximal part of the arm

and thigh bones. Elsewhere, varying proportions of yellow and red marrow are found. In some locations, red marrow is completely replaced by yellow marrow; in others, there is a mixture of red and yellow marrow. For example, part of the hip bone (ilium) may contain 50% red marrow and 50% yellow marrow. Marrow from the hip bone is used as a source for donating red bone marrow

TABLE 6.1 Gross Anatomy of a Long Bone

Part	Description	Part	Description
Diaphysis	Shaft of the bone	Epiphyseal plate	Area of hyaline cartilage between the diaphysis and epiphysis; cartilage growth followed by endochondral ossification results in bone growth in length
Epiphysis	End of a long bone that develops from a center of ossification distinct from the diaphysis	Cancellous (spongy) bone	Bone having many small spaces; found mainly in the epiphysis; arranged into trabeculae
Periosteum	Double-layered connective tissue membrane covering the outer surface of bone except where articular cartilage exists; ligaments and tendons attach to bone through the periosteum; blood vessels and nerves from the periosteum supply the bone; the periosteum is the site of bone growth in diameter	Compact bone	Dense bone with few internal spaces organized into osteons; forms the diaphysis and covers the cancellous bone of the epiphyses
Endosteum	Thin connective tissue membrane lining the inner cavities of bone	Medullary cavity	Large cavity within the diaphysis
Articular cartilage	Thin layer of hyaline cartilage covering a bone where it forms a joint (articulation) with another bone	Red marrow	Connective tissue in the spaces of cancellous bone or in the medullary cavity; the site of blood cell production
		Yellow marrow	Fat stored within the medullary cavity or in the spaces of cancellous bone

because it is a large bone with more marrow than smaller bones and it is accessed relatively easily.

The **periosteum** (per-ē-os'tē-ŭm) is a connective tissue membrane that covers the outer surface of a bone (figure 6.8c). The outer fibrous layer is dense irregular collagenous connective tissue that contains blood vessels and nerves. The inner layer is a single layer of bone cells, which includes osteoblasts, osteoclasts, and osteochondral progenitor cells (see “Bone Cells,” p. 175). Where tendons and ligaments attach to bone, the collagen fibers of the tendon or ligament become continuous with those of the periosteum. In addition, some of the collagen fibers of the tendons or ligaments penetrate the periosteum into the outer part of the bone. These bundles of collagen fibers are called **perforating**, or **Sharpey's, fibers**, and they strengthen the attachment of the tendons or ligaments to the bone.

The **endosteum** (en-dos'tē-ŭm) is a single layer of cells that lines the internal surfaces of all cavities within bones, such as the medullary cavity of the diaphysis and the smaller cavities in cancellous and compact bone (see figure 6.8c). The endosteum includes osteoblasts, osteoclasts, and osteochondral progenitor cells.

Structure of Flat, Short, and Irregular Bones

Flat bones contain an interior framework of cancellous bone sandwiched between two layers of compact bone (figure 6.9). Short and irregular bones have a composition similar to the epiphyses of long bones. They have compact bone surfaces that surround a cancellous bone center with small spaces that

usually are filled with marrow. Short and irregular bones are not elongated and have no diaphyses. Certain regions of these bones, however, such as the processes (projections) of irregular bones, possess epiphyseal growth plates and therefore have small epiphyses.

Some of the flat and irregular bones of the skull have air-filled spaces called **sinuses** (sī'nūs-ēz; see chapter 7), which are lined by mucous membranes.

- 13** List the four basic shapes of individual bones, and give an example of each.
- 14** Define the diaphysis, epiphysis, epiphyseal plate, and epiphyseal line of a long bone.
- 15** What are red marrow and yellow marrow? Where are they located in a child and in an adult?

**FIGURE 6.9** Structure of a Flat Bone

Outer layers of compact bone surround cancellous bone.

- 16** *Where are the periosteum and endosteum located? What types of cells are found in the periosteum and endosteum? What is the function of perforating (Sharpey's) fibers?*
- 17** *Compare the structure of long bones with the structure of flat, short, and irregular bones. How are compact bone and cancellous bone arranged in each?*

BONE DEVELOPMENT

During fetal development, bone formation occurs in two patterns—**intramembranous** and **endochondral ossification**. The terms describe the tissues in which bone formation takes place: intramembranous ossification in connective tissue membranes and endochondral ossification in cartilage. Both methods initially produce woven bone, which is then remodeled. After remodeling, bone formed by intramembranous ossification cannot be distinguished from bone formed by endochondral ossification. Table 6.2 compares the two types of ossification.

Intramembranous Ossification

At approximately the fifth week of development, embryonic mesenchyme condenses around the developing brain to form a membrane of connective tissue with randomly oriented, delicate collagen fibers. Intramembranous ossification of the membrane begins at approximately the eighth week of development and is completed by approximately 2 years of age. Many skull bones, part of the mandible (lower jaw), and the diaphyses of the clavicles (collarbones) develop by intramembranous ossification (figure 6.10).

Centers of ossification are the locations in the membrane where ossification begins. The centers of ossification expand to form a bone by gradually ossifying the membrane. Thus, the centers of ossification have the oldest bone and the expanding edges the youngest bone. The larger membrane-covered spaces

between the developing skull bones that have not yet been ossified are called **fontanels**, or soft spots (figure 6.11; see chapter 8). The bones eventually grow together, and all the fontanels have usually closed by 2 years of age.

1. Intramembranous ossification begins when some of the mesenchymal cells in the membrane become osteochondral progenitor cells, which specialize to become osteoblasts. The osteoblasts produce bone matrix that surrounds the collagen fibers of the connective tissue membrane, and the osteoblasts become osteocytes. As a result of this process, many tiny trabeculae of woven bone develop (see figure 6.10, step 1).
2. Additional osteoblasts gather on the surfaces of the trabeculae and produce more bone, thereby causing the trabeculae to become larger and longer (see figure 6.10, step 2). Cancellous bone forms as the trabeculae join together, resulting in an interconnected network of trabeculae separated by spaces.
3. Cells within the spaces of the cancellous bone specialize to form red bone marrow, and cells surrounding the developing bone specialize to form the periosteum. Osteoblasts from the periosteum lay down bone matrix to form an outer surface of compact bone (see figure 6.10, step 3).

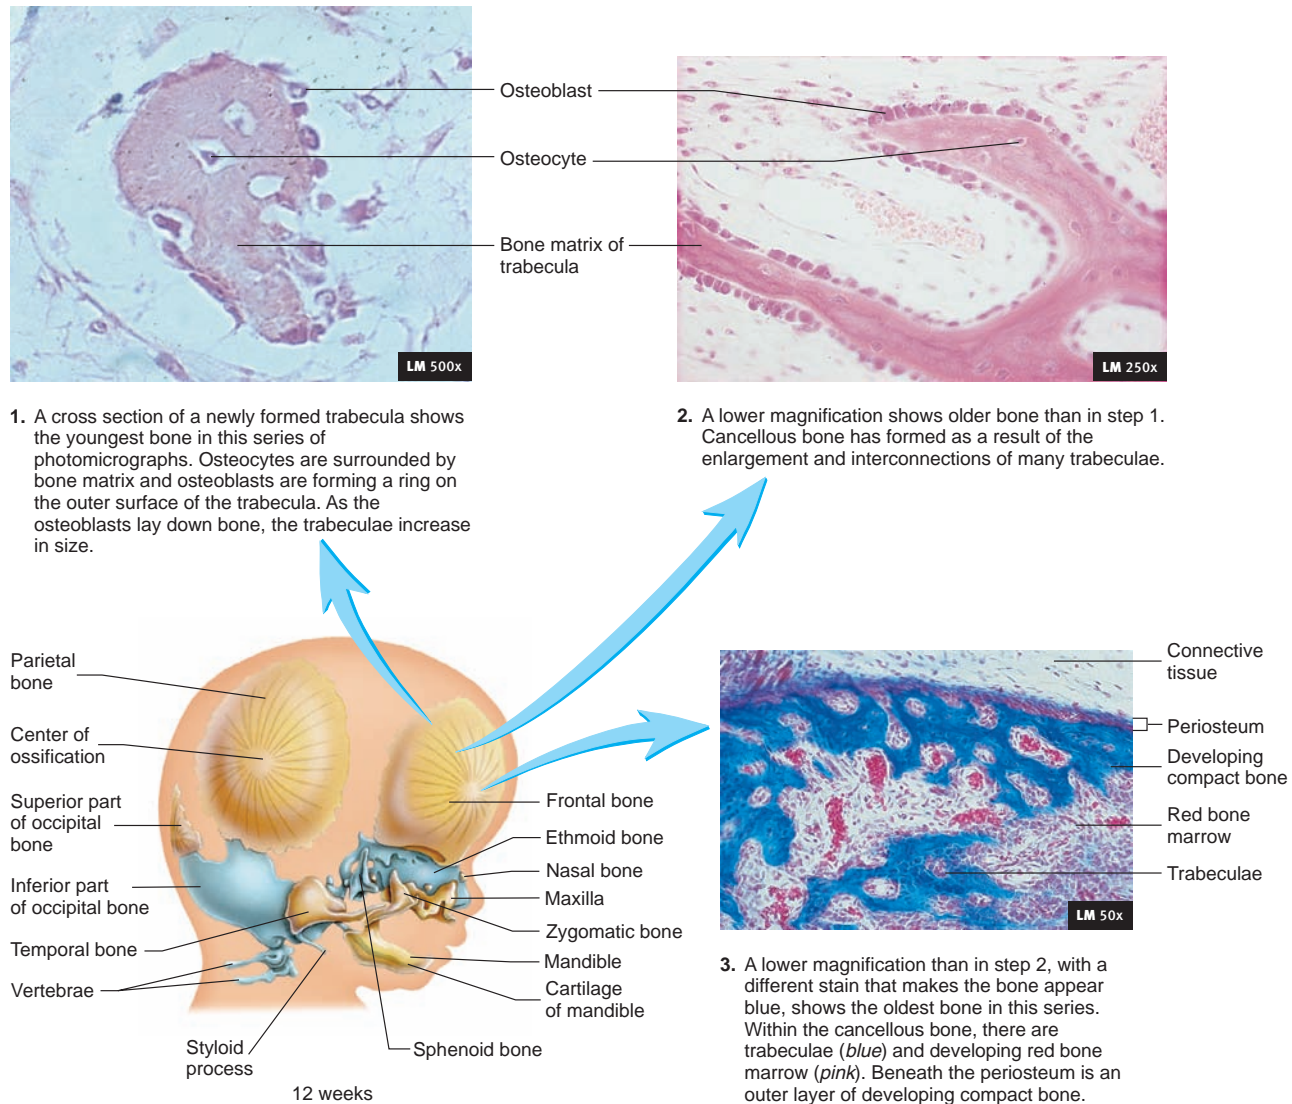

Thus, the end products of intramembranous bone formation are bones with outer compact bone surfaces and cancellous centers (see figure 6.9). Remodeling converts woven bone to lamellar bone and contributes to the final shape of the bone.

Endochondral Ossification

The formation of cartilage begins at approximately the end of the fourth week of development. Endochondral ossification of some of this cartilage starts at approximately the eighth week of development. Endochondral ossification of some cartilage might not begin until as late as age 18–20 years. Bones of the base of the skull, part of the mandible, the epiphyses of the clavicles, and most

TABLE 6.2 Comparison of Intramembranous and Endochondral Ossification

Intramembranous Ossification	Endochondral Ossification
Embryonic mesenchyme forms a collagen membrane containing osteochondral progenitor cells.	Embryonic mesenchymal cells become chondroblasts, which produce a cartilage template surrounded by the perichondrium.
No stage is comparable.	Chondrocytes hypertrophy, the cartilage, matrix becomes calcified, and the chondrocytes die.
Embryonic mesenchyme forms the periosteum, which contains osteoblasts.	The perichondrium becomes the periosteum when osteochondral progenitor cells within the periosteum become osteoblasts.
Osteochondral progenitor cells become osteoblasts at centers of ossification; internally, the osteoblasts form cancellous bone; externally, the periosteal osteoblasts form compact bone.	Blood vessels and osteoblasts from the periosteum invade the calcified cartilage template; internally, these osteoblasts form cancellous bone at primary ossification centers (and later at secondary ossification centers); externally, the periosteal osteoblasts form compact bone.
Intramembranous bone is remodeled and becomes indistinguishable from endochondral bone.	Endochondral bone is remodeled and becomes indistinguishable from intramembranous bone.

1. A cross section of a newly formed trabecula shows the youngest bone in this series of photomicrographs. Osteocytes are surrounded by bone matrix and osteoblasts are forming a ring on the outer surface of the trabecula. As the osteoblasts lay down bone, the trabeculae increase in size.

2. A lower magnification shows older bone than in step 1. Cancellous bone has formed as a result of the enlargement and interconnections of many trabeculae.

3. A lower magnification than in step 2, with a different stain that makes the bone appear blue, shows the oldest bone in this series. Within the cancellous bone, there are trabeculae (*blue*) and developing red bone marrow (*pink*). Beneath the periosteum is an outer layer of developing compact bone.

PROCESS FIGURE 6.10 Intramembranous Ossification

The inset shows a 12-week-old fetus. Bones formed by intramembranous ossification are *yellow* and bones formed by endochondral ossification are *blue*. Intramembranous ossification starts at a center of ossification and expands outward. Therefore, the youngest bone is at the edge of the expanding bone, and the oldest bone is at the center of ossification.

of the remaining skeletal system develop through the process of endochondral ossification (see figures 6.10 and 6.11).

1. Endochondral ossification begins as mesenchymal cells aggregate in regions of future bone formation. The mesenchymal cells become osteochondral progenitor cells that become chondroblasts. The chondroblasts produce a hyaline **cartilage model** having the approximate shape of the bone that will later be formed (figure 6.12, step 1). As the chondroblasts become surrounded by cartilage matrix, they become chondrocytes. The cartilage model is surrounded by perichondrium, except where a joint will form connecting one

bone to another bone. Not shown in figure 6.12, the perichondrium is continuous with tissue that will become the joint capsule (see chapter 8).

2. When blood vessels invade the perichondrium surrounding the cartilage model (figure 6.12, step 2), osteochondral progenitor cells within the perichondrium become osteoblasts. The perichondrium becomes the periosteum when the osteoblasts begin to produce bone. The osteoblasts produce compact bone on the surface of the cartilage model, forming a **bone collar**. Two other events are occurring at the same time that the bone collar is forming. First, the cartilage

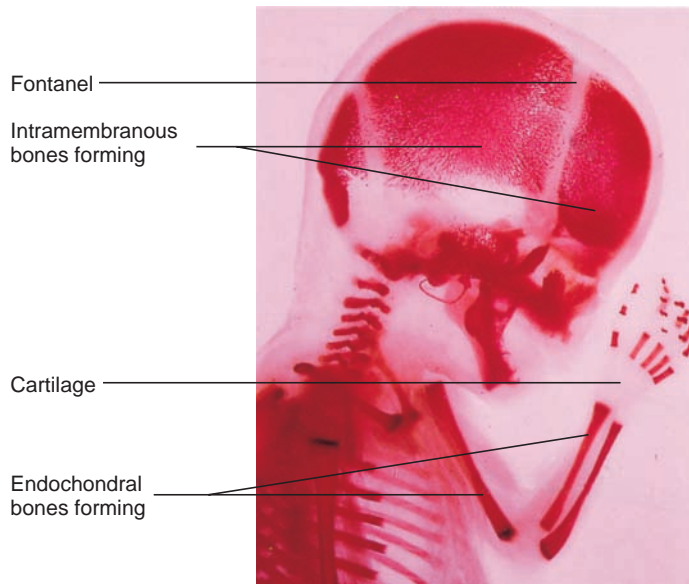

FIGURE 6.11 Bone Formation

Eighteen-week-old fetus showing intramembranous and endochondral ossification. Intramembranous ossification occurs at centers of ossification in the flat bones of the skull. Endochondral ossification has formed bones in the diaphyses of long bones. The epiphyses are still cartilage at this stage of development.

model increases in size as a result of interstitial and appositional cartilage growth. Second, the chondrocytes in the center of the cartilage model absorb some of the cartilage matrix and **hypertrophy** (hī-per'trō-fē), or enlarge. The chondrocytes also release matrix vesicles, which initiate the formation of hydroxyapatite crystals in the cartilage matrix. At this point, the cartilage is referred to as **calcified cartilage**. The chondrocytes in this calcified area eventually die, leaving enlarged lacunae with thin walls of calcified matrix.

3. Blood vessels grow into the enlarged lacunae of the calcified cartilage (figure 6.12, step 3). The connective tissue surrounding the blood vessels brings in osteoblasts and osteoclasts from the periosteum. The osteoblasts produce bone on the surface of the calcified cartilage, forming bone trabeculae, which changes the calcified cartilage of the diaphysis into cancellous bone. This area of bone formation is called the **primary ossification center**.
4. As bone development proceeds, the cartilage model continues to grow, more perichondrium becomes periosteum, the bone collar thickens and extends farther along the diaphysis, and additional cartilage within the diaphysis is calcified and transformed into cancellous bone (figure 6.12, step 4). Remodeling converts woven bone to lamellar bone and contributes to the final shape of the bone. Osteoclasts remove bone from the center of the diaphysis to form the medullary cavity, and cells within the medullary cavity specialize to form red bone marrow.

5. In long bones, the diaphysis is the primary ossification center, and additional sites of ossification, called **secondary ossification centers**, appear in the epiphyses (figure 6.12, step 5). The events occurring at the secondary ossification centers are the same as those occurring at the primary ossification centers, except that the spaces in the epiphyses do not enlarge to form a medullary cavity as in the diaphysis. Primary ossification centers appear during early fetal development, whereas secondary ossification centers appear in the proximal epiphysis of the femur, humerus, and tibia about 1 month before birth. A baby is considered full-term if one of these three ossification centers can be seen on radiographs at the time of birth. At about 18–20 years of age, the last secondary ossification center appears in the medial epiphysis of the clavicle.
6. Replacement of cartilage by bone continues in the cartilage model until all the cartilage, except that in the epiphyseal plate and on articular surfaces, has been replaced by bone (figure 6.12, step 6). The epiphyseal plate, which exists throughout an individual's growth, and the articular cartilage, which is a permanent structure, are derived from the original embryonic cartilage model.
7. In mature bone, cancellous and compact bone are fully developed and the epiphyseal plate has become the epiphyseal line. The only cartilage present is the articular cartilage at the ends of the bone (figure 6.12, step 7). All the original perichondrium that surrounded the cartilage model has become periosteum.

18 Describe the formation of cancellous and compact bone during intramembranous ossification. What are centers of ossification? What are fontanels?

19 For the process of endochondral ossification, describe the formation of these structures: cartilage model, bone collar, calcified cartilage, primary ossification center, medullary cavity, secondary ossification center, epiphyseal plate, epiphyseal line, and articular cartilage.

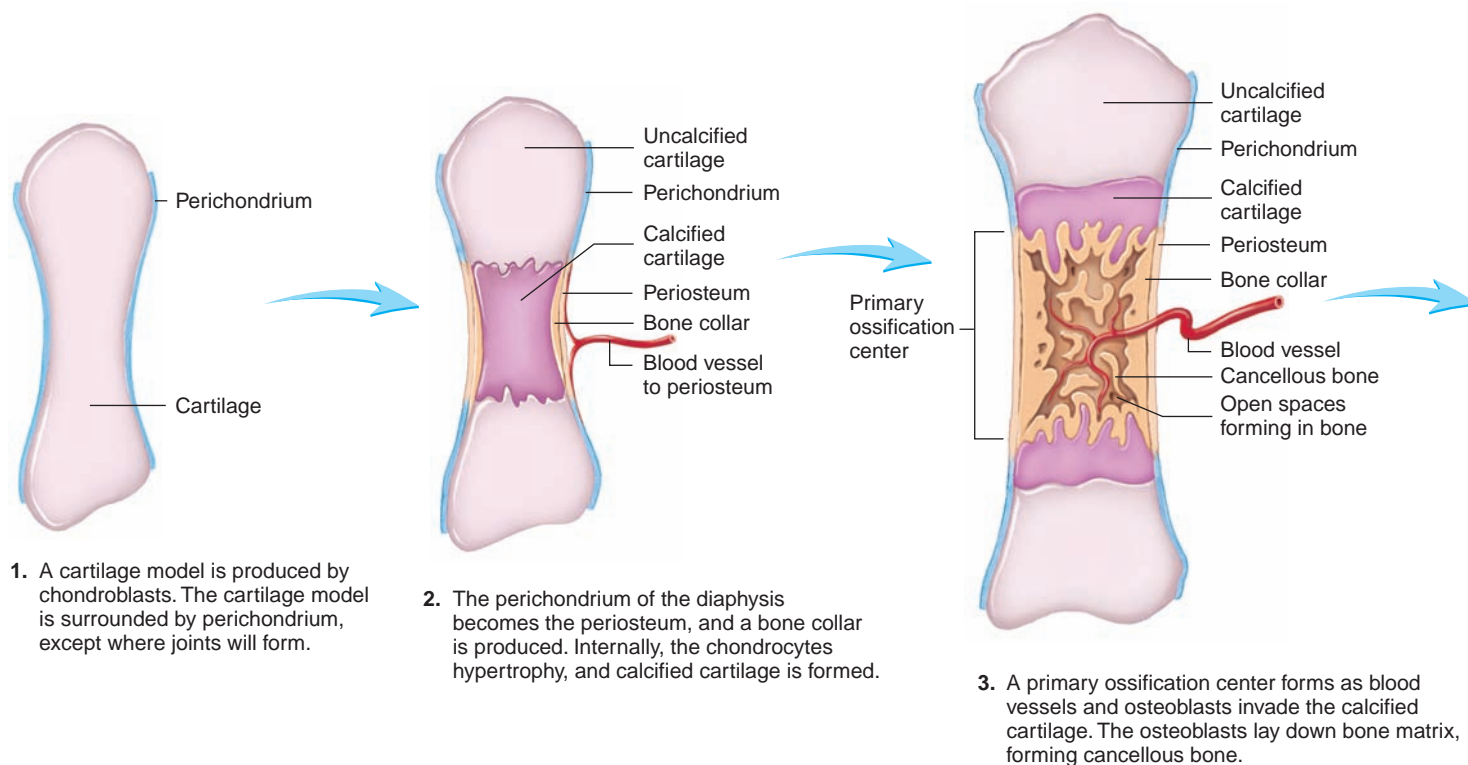

20 When do primary and secondary ossification centers appear during endochondral ossification?

PREDICT 4

During endochondral ossification, calcification of cartilage results in the death of chondrocytes. However, ossification of the bone matrix does not result in the death of osteocytes. Explain.

BONE GROWTH

Unlike cartilage, bones cannot grow by interstitial growth. Bones increase in size only by appositional growth, the formation of new bone on the surface of older bone or cartilage. For example, trabeculae grow in size by the deposition of new bone matrix by osteoblasts onto the surface of the trabeculae (see figure 6.10).

1. A cartilage model is produced by chondroblasts. The cartilage model is surrounded by perichondrium, except where joints will form.

2. The perichondrium of the diaphysis becomes the periosteum, and a bone collar is produced. Internally, the chondrocytes hypertrophy, and calcified cartilage is formed.

3. A primary ossification center forms as blood vessels and osteoblasts invade the calcified cartilage. The osteoblasts lay down bone matrix, forming cancellous bone.

PROCESS FIGURE 6.12 Endochondral Ossification

Endochondral ossification begins with the formation of a cartilage model. See successive steps as indicated by the blue arrows.

PREDICT 5

Explain why bones cannot undergo interstitial growth, as does cartilage.

Growth in Bone Length

Long bones and bony projections increase in length because of growth at the epiphyseal plate. In a long bone, the epiphyseal plate separates the epiphysis from the diaphysis (figure 6.13a). Long projections of bones, such as the processes of vertebrae (see chapter 7), also have epiphyseal plates.

Growth at the epiphyseal plate involves the formation of new cartilage by interstitial cartilage growth followed by appositional bone growth on the surface of the cartilage. The epiphyseal plate is organized into four zones (figure 6.13b). The **zone of resting cartilage** is nearest the epiphysis and contains randomly arranged chondrocytes that do not divide rapidly. The chondrocytes in the **zone of proliferation** produce new cartilage through interstitial cartilage growth. The chondrocytes divide and form columns resembling stacks of plates or coins. In the **zone of hypertrophy**, the chondrocytes produced in the zone of proliferation mature and enlarge. Thus, a maturation gradient exists in each column: The cells nearer the epiphysis

are younger and are actively proliferating, whereas the cells progressively nearer the diaphysis are older and are undergoing hypertrophy. The **zone of calcification** is very thin and contains hypertrophied chondrocytes and calcified cartilage matrix. The hypertrophied chondrocytes die, and blood vessels from the diaphysis grow into the area. The connective tissue surrounding the blood vessels contains osteoblasts from the endosteum. The osteoblasts line up on the surface of the calcified cartilage and, through appositional bone growth, deposit new bone matrix, which is later remodeled. The process of cartilage calcification and ossification in the epiphyseal plate occurs by the same basic process as the calcification and ossification of the cartilage model during endochondral bone formation.

As new cartilage cells form in the zone of proliferation, and as these cells enlarge in the zone of hypertrophy, the overall length of the diaphysis increases (figure 6.14). The thickness of the epiphyseal plate does not increase, however, because the rate of cartilage growth on the epiphyseal side of the plate is equal to the rate at which cartilage is replaced by bone on the diaphyseal side of the plate.

As the bones achieve normal adult size, growth in bone length ceases because the epiphyseal plate is ossified and becomes the epiphyseal line. This event, called closure of the epiphyseal plate, occurs between approximately 12 and 25 years of age, depending on the bone and the individual.

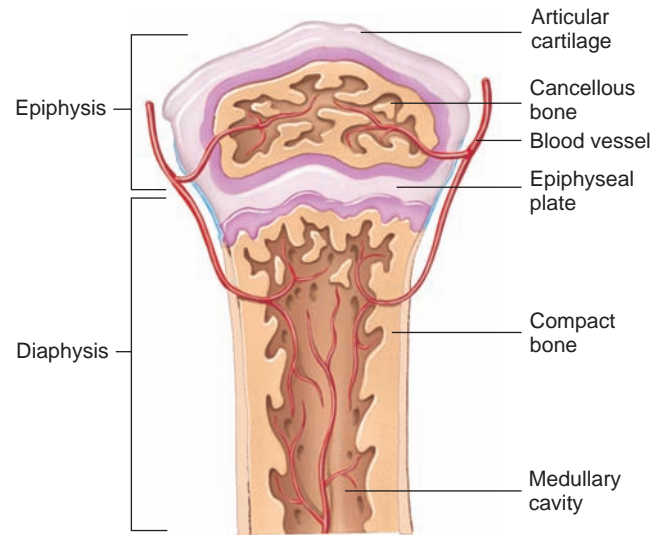

4. The process of bone collar formation, cartilage calcification, and cancellous bone production continues. Calcified cartilage begins to form in the epiphyses. A medullary cavity begins to form in the center of the diaphysis.

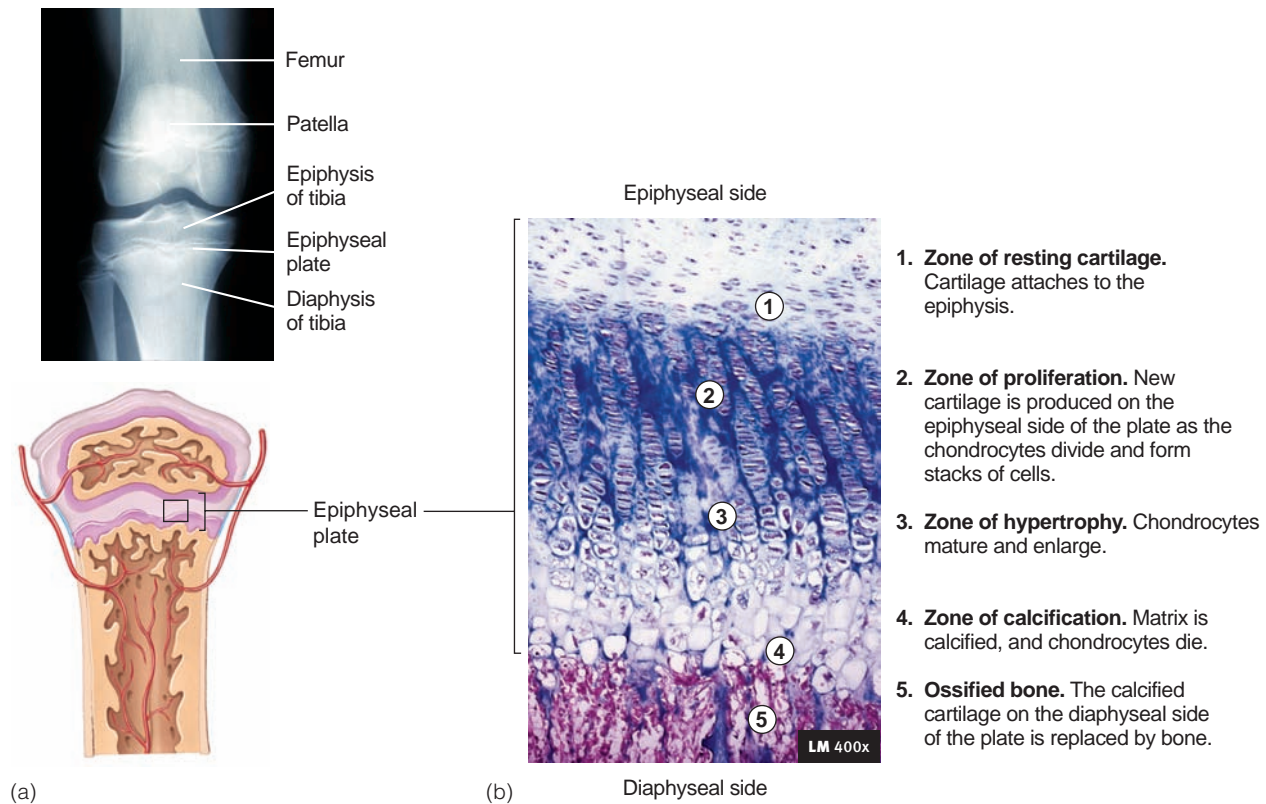

5. Secondary ossification centers form in the epiphyses of long bones.

7. In a mature bone, the epiphyseal plate has become the epiphyseal line and all the cartilage in the epiphysis, except the articular cartilage, has become bone.

6. The original cartilage model is almost completely ossified. Unossified cartilage becomes the epiphyseal plate and the articular cartilage.

PROCESS FIGURE 6.13 Epiphyseal Plate

(a) Radiograph of the knee, showing the epiphyseal plate of the tibia (shinbone). Because cartilage does not appear readily on x-ray film, the epiphyseal plate appears as a black area between the white diaphysis and the epiphyses. (b) Zones of the epiphyseal plate.

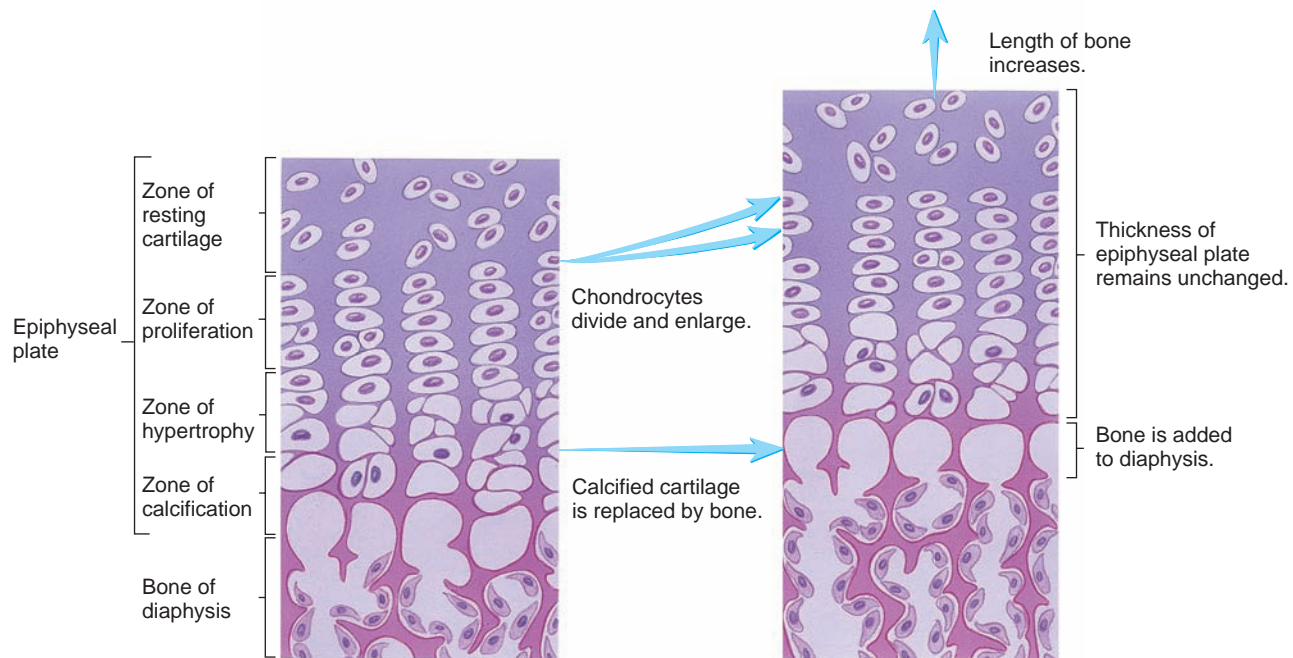

FIGURE 6.14 Bone Growth in Length at the Epiphyseal Plate

New cartilage is formed on the epiphyseal side of the plate at the same rate that new bone is formed on the diaphyseal side of the plate. Consequently, the epiphyseal plate remains the same thickness, but the length of the diaphysis increases.

FIGURE 6.15 Fracture of the Epiphyseal Plate

Radiograph of an adolescent's knee. The femur (thighbone) is separated from the tibia (leg bone) by a joint cavity. The epiphyseal plate of the femur is fractured, thereby separating the diaphysis from the epiphysis.

PREDICT 6

A 15-year-old football player is tackled during a game, and the epiphyseal plate of the left femur is damaged (figure 6.15). What are the results of such an injury, and why is recovery difficult?

Growth at Articular Cartilage

Epiphyses increase in size because of growth at the articular cartilage. In addition, growth at the articular cartilage increases the size of bones that do not have an epiphysis, such as short bones. The process of growth in articular cartilage is similar to that occurring in the epiphyseal plate, except that the chondrocyte columns are not as obvious. The chondrocytes near the surface of the articular cartilage are similar to those in the zone of resting cartilage of the epiphyseal plate. In the deepest part of the articular cartilage, nearer bone tissue, the cartilage is calcified and ossified to form new bone.

When the epiphyses reach their full size, the growth of cartilage and its replacement by bone cease. The articular cartilage, however, persists throughout life and does not become ossified as does the epiphyseal plate.

PREDICT 7

Growth at the epiphyseal plate stops when the epiphyseal cartilage becomes ossified. The articular cartilage, however, does not become ossified when growth of the epiphysis ceases. Explain why it is advantageous for the articular cartilage not to be ossified.

Growth in Bone Width

Long bones increase in width (diameter) and other bones increase in size or thickness because of appositional bone growth beneath the periosteum. When bone growth in width is rapid, as in young bones or during puberty, osteoblasts from the periosteum lay down bone to form a series of ridges with grooves between them (figure 6.16, step 1). The periosteum covers the bone ridges and extends down into the bottom of the grooves, and one or more blood vessels of the periosteum lie within each groove. As the osteoblasts continue to produce bone, the ridges increase in size, extend toward each other, and meet to change the groove into a tunnel (figure 6.16, step 2). The name of the periosteum in the tunnel changes to *endosteum* because the membrane now lines an internal bone surface. Osteoblasts from the endosteum lay down bone to form a concentric lamella (figure 6.16, step 3). The production of additional lamellae fills in the tunnel, encloses the blood vessel, and produces an osteon (figure 6.16, step 4).

When bone growth in width is slow, the surface of the bone becomes smooth as osteoblasts from the periosteum lay down even layers of bone to form circumferential lamellae. The circumferential lamellae are broken down during remodeling to form osteons (see “Bone Remodeling,” p. 191).

- 21** Name and describe the events occurring in the four zones of the epiphyseal plate. Explain how the epiphyseal plate remains the same thickness while the bone increases in length.
- 22** Describe the process of growth at the articular cartilage. What happens to the epiphyseal plate and the articular cartilage when bone growth ceases?
- 23** Describe how new osteons are produced as a bone increases in width.

Factors Affecting Bone Growth

The bones of an individual's skeleton usually reach a certain length, thickness, and shape through the processes described in the previous sections. The potential shape and size of a bone and an individual's final adult height are determined genetically, but factors such as nutrition and hormones can greatly modify the expression of those genetic factors.

Nutrition

Because bone growth requires chondroblast and osteoblast proliferation, any metabolic disorder that affects the rate of cell proliferation or the production of collagen and other matrix components affects bone growth, as does the availability of calcium or other minerals needed in the mineralization process.

The long bones of a child sometimes exhibit lines of arrested growth, which are transverse regions of greater bone density crossing an otherwise normal bone. These lines are caused by greater calcification below the epiphyseal plate of a bone, where it has grown at a slower rate during an illness or severe nutritional deprivation. They demonstrate that illness or malnutrition during the time of bone growth can cause a person to be shorter than he or she would have been otherwise.

Certain vitamins are important in very specific ways to bone growth. **Vitamin D** is necessary for the normal absorption of

PROCESS FIGURE 6.16 Bone Growth in Width

Bones can increase in width by the formation of new osteons beneath the periosteum.

calcium from the intestines (see chapters 5 and 24). The body can either synthesize or ingest vitamin D. Its rate of synthesis increases when the skin is exposed to sunlight.

Insufficient vitamin D in children causes **rickets**, a disease resulting from reduced mineralization of the bone matrix. Children with rickets can have bowed bones and inflamed joints. During the winter in northern climates, if children are not exposed to sufficient sunlight, they can take vitamin D as a dietary supplement to prevent rickets. The body's inability to absorb fats in which vitamin D is soluble can also result in vitamin D deficiency. This condition can occur in adults who suffer from digestive disorders and can be one cause of "adult rickets," or **osteomalacia** (os'tē-ō-mā-lā'shē-ă), which is a softening of the bones as a result of calcium depletion.

Vitamin C is necessary for collagen synthesis by osteoblasts. Normally, as old collagen breaks down, new collagen is synthesized to replace it. Vitamin C deficiency results in bones and cartilage that are deficient in collagen because collagen synthesis is impaired. In children, vitamin C deficiency can cause growth retardation. In children and adults, vitamin C deficiency can result in **scurvy**, which is marked by ulceration and hemorrhage in almost any area of the body because of a lack of normal collagen synthesis in connective tissues. Wound healing, which requires collagen synthesis, is hindered in patients with vitamin C deficiency. In extreme cases, the teeth can fall out because the ligaments that hold them in place break down.

Hormones

Hormones are very important in bone growth. **Growth hormone** from the anterior pituitary increases general tissue growth (see chapters 17 and 18), including overall bone growth, by stimulating interstitial cartilage growth and appositional bone growth. **Thyroid hormone** is also required for normal growth of all tissues, including cartilage; therefore, a decrease in this hormone can result in decreased size of the individual. **Sex hormones** also influence bone growth. Estrogen (a class of female sex hormones) and testosterone (a male sex hormone) initially stimulate bone growth, which accounts for the burst of growth at puberty, when production of these hormones increases. Both hormones also stimulate ossification of epiphyseal plates, however, and thus the cessation of growth. Females usually stop growing earlier than males because estrogens cause a quicker closure of the epiphyseal plate than does testosterone. Because their entire growth period is somewhat shorter, females usually do not reach the same height as males. Decreased levels of testosterone or estrogen can prolong the growth phase of the epiphyseal plates, even though the bones grow more slowly. Growth is very complex, however, and is influenced by many factors in addition to sex hormones, such as other hormones, genetics, and nutrition.

24 Explain how illness or malnutrition can affect bone growth. How do vitamins D and C affect bone growth?

25 What are the effects of growth hormone and thyroid hormone on bone growth?

26 What effects do estrogen and testosterone have on bone growth? How do these effects account for the average height difference observed in men and women?

PREDICT 8

A 12-year-old female has an adrenal tumor that produces large amounts of estrogen. If untreated, what effect will this condition have on her growth for the next 6 months? On her height when she is 18?

BONE REMODELING

Just as we renovate or remodel our homes when they become outdated, when bone becomes old it is replaced with new bone in a process called **bone remodeling**. In this process, osteoclasts remove old bone and osteoblasts deposit new bone. Bone remodeling converts woven bone into lamellar bone, and it is involved in bone growth, changes in bone shape, the adjustment of the bone to stress, bone repair, and calcium ion (Ca^{2+}) regulation in the body. For example, as a long bone increases in length and diameter, the size of the medullary cavity also increases (figure 6.17). Otherwise, the bone would consist of nearly solid bone matrix and would be very heavy. A cylinder with the same height, weight, and composition as a solid rod but with a greater diameter can support much more weight than the rod without bending. Bone therefore has a mechanical advantage as a cylinder rather than as a rod. The relative thickness of compact bone is maintained by the removal of bone on the inside by osteoclasts and the addition of bone to the outside by osteoblasts.

A **basic multicellular unit (BMU)** is a temporary assembly of osteoclasts and osteoblasts that travels through or across the surface of bone, removing old bone matrix and replacing it with new bone matrix. The average life span of a BMU is approximately 6 months, and BMU activity renews the entire skeleton every 10 years. In compact bone, the osteoclasts of a BMU break down bone matrix, forming a tunnel. Interstitial lamellae (see figure 6.6a) are remnants of osteons that were not completely removed when a BMU formed

a tunnel. Blood vessels grow into the tunnel and osteoblasts of the BMU move in and lay down a layer of bone on the tunnel wall, forming a concentric lamella. Additional concentric lamellae are produced, filling in the tunnel from the outside to the inside, until an osteon is formed in which the center of the tunnel becomes a central canal containing blood vessels. In cancellous bone, the BMU removes bone matrix from the surface of a trabecula, forming a cavity, which the BMU then fills in with new bone matrix.

**Mechanical Stress and Bone Strength**

Remodeling, the formation of additional bone, alteration in trabecular alignment to reinforce the scaffolding, or other changes can modify the strength of the bone in response to the amount of stress applied to it. Mechanical stress applied to bone increases osteoblast activity in bone tissue, and removal of mechanical stress decreases osteoblast activity. Under conditions of reduced stress, such as when a person is bedridden or paralyzed, osteoclast activity continues at a nearly normal rate, but osteoblast activity is reduced, resulting in a decrease in bone density. In addition, pressure in bone causes an electrical change that increases the activity of osteoblasts. Applying weight (pressure) to a broken bone therefore speeds the healing process. Weak pulses of electric current applied to a broken bone sometimes are used clinically to speed the healing process.

- 27** What cells are involved in bone remodeling? Describe how the medullary cavity of a long bone can increase in size as the width of the bone increases.
- 28** Explain two ways that remodeling is responsible for the formation of new osteons in compact bone.
- 29** How does bone adjust to stress? Describe the role of osteoblasts and osteoclasts in this process. What happens to bone that is not subjected to stress?

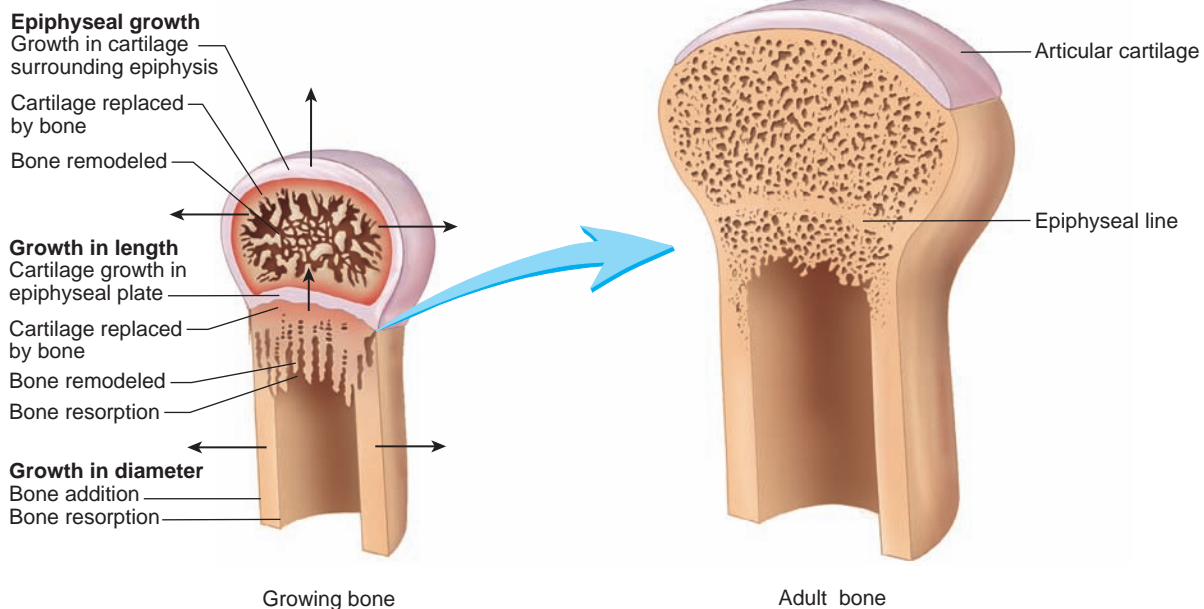

FIGURE 6.17 Remodeling of a Long Bone

The epiphysis enlarges and the diaphysis increases in length as new cartilage is formed and replaced by bone, which is remodeled. The diameter of the bone increases as a result of bone growth on the outside of the bone, and the size of the medullary cavity increases because of bone resorption.

CLINICAL FOCUS

Bone Disorders

GROWTH AND DEVELOPMENT DISORDERS

Giantism is a condition of abnormally increased height that usually results from excessive cartilage and bone formation at the epiphyseal plates of long bones (figure B). The most common type of giantism, **pituitary giantism**, results from excess secretion of pituitary growth hormone. The large stature of some individuals, however, can result from genetic factors rather than from abnormal levels of growth hormone. **Acromegaly** (ak-rō-meg'ă-lē) is also caused by excess pituitary growth hormone secretion; however, acromegaly involves the growth of connective tissue, including bones, after the epiphyseal plates have ossified. The effect mainly involves increased diameter of all bones and is most strikingly apparent in the face and hands. Many pituitary giants also develop acromegaly later in life.

Dwarfism, the condition in which a person is abnormally short, is the opposite of giantism (see figure B). **Pituitary dwarfism** results when abnormally low levels of pituitary growth hormone affect the whole body, thus producing a small person who is normally proportioned. **Achondroplasia** (ă-kon-drō-plă'zē-ă), or **achondroplastic** (ă-kon-drō-plas'tik) **dwarfism**, is the most common type of dwarfism; it produces a person with a nearly normal-sized trunk and head but shorter than normal limbs. Achondroplasia is an autosomal-dominant trait. Approximately 80% of cases result from a spontaneous mutation of the fibroblast growth factor receptor gene on chromosome 4 during the formation of sperm cells or oocytes. Thus, the parents of most achondroplastic dwarfs are of normal height and proportions. The normal effect of the gene is to slow bone

growth by inhibiting chondrocyte division at the epiphyseal plate. Mutation of the gene results in a “gain of function,” in which the

normal inhibitory effect is increased, resulting in severely reduced bone growth in length.

Giant and dwarf

FIGURE B Bone Disorders

BACTERIAL INFECTIONS

Osteomyelitis (os'tē-ō-mī-ě-lī'tis) is bone inflammation that often results from bacterial infection. It can lead to complete destruction of the bone. *Staphylococcus aureus*, often introduced into the body through wounds, is a common cause of osteomyelitis. Bone tuberculosis, a specific type of osteomyelitis, results from spread of the tubercular bacterium (*Mycobacterium tuberculosis*) from the initial site of infection, such as the lungs to the bones through the circulatory system.

TUMORS

Many types of tumors cause a wide range of resultant bone defects with varying prognoses. Tumors can be benign or malignant. Malignant bone tumors can metastasize to other parts of the body, or they can spread to bone from metastasizing tumors elsewhere in the body.

DECALCIFICATION

Osteomalacia (os't-ē-ō-mă-lă'shē-ă), or the softening of bones, results from calcium depletion from bones. If the body has an unusual need for calcium—such as during pregnancy, when growth of the fetus requires large amounts of calcium—it can be removed from the mother's bones, which become soft and weakened. **Osteoporosis**, which is a major disorder of decalcification, is discussed in the “Systems Pathology” section on p. 196.

BONE REPAIR

Bone is a living tissue that can undergo repair following damage to it. This process has four major steps.

1. **Hematoma formation** (figure 6.18, step 1). When bone is fractured, the blood vessels in the bone and surrounding

periosteum are damaged, and a hematoma forms. A **hematoma** (hē-mă-tō'mă, hem-ă-tō'mă) is a localized mass of blood released from blood vessels but confined within an organ or a space. Usually, the blood in a hematoma forms a clot, which consists of fibrous proteins that stop the bleeding. Disruption of blood vessels in the central canals results

PROCESS FIGURE 6.18 Bone Repair

in inadequate blood delivery to osteocytes, and bone tissue adjacent to the fracture site dies. Inflammation and swelling of tissues around the bone often occur following the injury.

2. **Callus formation** (figure 6.18, step 2). A **callus** (kal' ūs) is a mass of tissue that forms at a fracture site, connecting the broken ends of the bone. An **internal callus** forms *between* the ends of the broken bone, as well as in the marrow cavity if the fracture occurs in the diaphysis of a long bone. Several days after the fracture, blood vessels grow into the clot. As the clot dissolves (see chapter 19), macrophages clean up cell debris, osteoclasts break down dead bone tissue, and fibroblasts produce collagen and other extracellular materials to form granulation tissue (see chapter 4). As the fibroblasts continue to produce collagen fibers, a denser fibrous network, which helps hold the bone together, is produced. Chondroblasts derived from osteochondral progenitor cells of the periosteum and endosteum begin to produce cartilage in the fibrous network. As these events are occurring, osteochondral progenitor cells in the endosteum become osteoblasts and produce new bone that contributes to the internal callus.

The **external callus** forms a collar *around* the opposing ends of the bone fragments. Osteochondral progenitor cells from the periosteum become osteoblasts, which produce bone, and chondroblasts, which produce cartilage. Cartilage production is more rapid than bone production, and the cartilage from each side of the break eventually grows together. The external callus is a bone–cartilage collar that stabilizes the ends of the broken bone. In modern medical practice, stabilization of the bone is assisted with a cast or surgical implantation of metal supports.

3. **Callus ossification** (figure 6.18, step 3). Like the cartilage models formed during fetal development, the cartilage in the external callus is replaced by woven, cancellous bone through endochondral ossification. The result is a stronger external callus. Even as the internal callus is forming and replacing the hematoma, osteoblasts from the periosteum and endosteum enter the internal callus and begin to produce bone. Eventually, the fibers and cartilage of the internal callus are replaced by woven, cancellous bone, which further stabilizes the broken bone.
4. **Bone remodeling** (figure 6.18, step 4). Filling the gap between bone fragments with an internal callus of woven bone is not the end of the repair process because woven bone is not as structurally strong as the original lamellar bone. Repair is not complete until the woven bone of the internal callus and the dead bone adjacent to the fracture site are replaced by compact bone. In this compact bone, osteons from both sides of the break extend across the fracture line to “peg” the bone fragments together. This remodeling process takes time and may not be complete even after a year. As the internal callus is remodeled and becomes stronger, the external callus is reduced in size by osteoclast activity. Eventually, repair may be so complete that no evidence of the break remains; however, the repaired zone usually remains slightly thicker than the adjacent bone. If the fracture occurred in the diaphysis of a long bone, remodeling also restores the medullary cavity.

- 30 **How does breaking a bone result in hematoma formation?**
- 31 **Distinguish between the location and the composition of the internal and external callus.**
- 32 **Why is remodeling of the ossified callus necessary?**

Uniting Broken Bones

Before the formation of compact bone between the broken ends of a bone can take place, the appropriate substrate must be present. Normally, this is the woven, cancellous bone of the internal callus. If formation of the internal callus is prevented by infections, bone movements, or the nature of the injury, nonunion of the bone occurs. This condition can be treated by surgically implanting an appropriate substrate, such as living bone from another site in the body or dead bone from cadavers. Other substrates have also been used. For example, a specific marine coral calcium phosphate is converted into a predominantly hydroxyapatite biomatrix that is very much like cancellous bone.

CALCIUM HOMEOSTASIS

Bones play an important role in regulating blood Ca^{2+} levels, which must be maintained within narrow limits for functions such as muscle contraction and membrane potentials to occur normally (see chapters 9 and 11). Bone is the major storage site for calcium in the body, and movement of Ca^{2+} into and out of bone helps determine blood Ca^{2+} levels. Calcium ions move into bone as osteoblasts build new bone and out of bone as osteoclasts break down bone (figure 6.19). When osteoblast and osteoclast activity is balanced, the movement of Ca^{2+} into and out of a bone is equal.

When blood Ca^{2+} levels are too low, osteoclast activity increases. More Ca^{2+} are released by osteoclasts from bone into the blood than are removed by osteoblasts from the blood to make new bone. Consequently, a net movement of Ca^{2+} occurs from bone into

blood, and blood Ca^{2+} levels increase. Conversely, if blood Ca^{2+} levels are too high, osteoclast activity decreases. Fewer Ca^{2+} are released by osteoclasts from bone into the blood than are taken from the blood by osteoblasts to produce new bone. As a result, a net movement of Ca^{2+} occurs from the blood to bone, and blood Ca^{2+} levels decrease.

Parathyroid hormone (PTH) from the parathyroid glands (see figure 18.11) is the major regulator of blood Ca^{2+} levels. If the blood Ca^{2+} level decreases, the secretion of PTH increases, resulting in increased numbers of osteoclasts, which causes increased bone breakdown and increased blood Ca^{2+} levels (see figure 6.19). In addition, osteoblasts respond to PTH by releasing enzymes, resulting in the breakdown of the layer of unmineralized organic bone matrix covering bone, thereby making the mineralized bone matrix available to osteoclasts.

Osteoclast numbers are regulated by the interactions of osteoblasts, red bone marrow stromal (stem) cells, and osteoclast precursor cells. Osteoblasts and stromal cells have receptors for PTH. When PTH binds to these receptors, these cells respond by producing **receptor for activation of nuclear factor kappaB ligand (RANKL)**. RANKL is expressed on the surface of the osteoblasts and stromal cells and can combine with **receptor for activation of nuclear factor kappaB (RANK)** found on the cell surfaces of osteoclast precursor cells. In a cell-to-cell interaction, RANKL on osteoblasts or stromal cells binds to RANK on osteoclast precursor cells, stimulating them to become osteoclasts.

Osteoclast production is inhibited by **osteoprotegerin (OPG)**, which is secreted by osteoblasts and stromal cells. OPG inhibits osteoclast production by binding

1. Osteoclasts break down bone and release Ca^{2+} into the blood, and osteoblasts remove Ca^{2+} from the blood to make bone. (Blue arrows represent the movement of Ca^{2+} .) Parathyroid hormone (PTH) regulates blood Ca^{2+} levels by indirectly stimulating osteoclast activity, resulting in increased Ca^{2+} release into the blood. Calcitonin plays a minor role in Ca^{2+} maintenance by inhibiting osteoclast activity.
2. In the kidneys, PTH increases Ca^{2+} reabsorption from the urine.
3. In the kidneys, PTH also promotes the formation of active vitamin D (green arrows), which increases Ca^{2+} absorption from the small intestine.

PROCESS FIGURE 6.19 Calcium Homeostasis

CLINICAL FOCUS

Classification of Bone Fractures

Bone fractures are classified in several ways. The most commonly used classification involves the severity of the injury to the soft tissues surrounding the bone. An **open fracture** (formerly called compound) occurs when an open wound extends to the site of the fracture or when a fragment of bone protrudes through the skin. If the skin is not perforated, the fracture is called a **closed fracture** (formerly called simple). If the soft tissues around a closed fracture are damaged, the fracture is called a **complicated fracture**.

Two other terms to designate fractures are **incomplete**, in which the fracture does

not extend completely across the bone, and **complete**, in which the bone is broken into at least two fragments (figure Ca). An incomplete fracture that occurs on the convex side of the curve of the bone is a **greenstick fracture**. **Hairline fractures** are incomplete fractures in which the two sections of bone do not separate; they are common in skull fractures.

Comminuted (kom'i-noo-ted) fractures are complete fractures in which the bone breaks into more than two pieces—usually two major fragments and a smaller fragment (figure Cb). **Impacted fractures** are those in which one fragment is driven into

the cancellous portion of the other fragment (figure Cc).

Fractures are also classified according to the direction of the fracture within a bone. **Linear fractures** run parallel to the long axis of the bone, and **transverse fractures** are at right angles to the long axis (see figure Cb). **Spiral fractures** have a helical course around the bone, and **oblique fractures** run obliquely in relation to the long axis (figure Cd). **Dentate fractures** have rough, toothed, broken ends, and **stellate fractures** have breakage lines radiating from a central point.

FIGURE C Bone Fractures

(a) Complete and incomplete. (b) Transverse and comminuted. (c) Impacted. (d) Spiral and oblique.

to RANKL and preventing RANKL from binding to its receptor on osteoclast precursor cells. Increased PTH causes decreased secretion of OPG from osteoblasts and stromal cells. Thus, increased PTH promotes an increase in osteoclast numbers by increasing RANKL and decreasing OPG. The increased RANKL stimulates osteoclast precursor cells and the decreased OPG results in less inhibition of osteoclast precursor cells. Conversely, decreased PTH results in fewer osteoclasts by decreasing RANKL and increasing OPG.

PTH also regulates blood Ca^{2+} levels by increasing Ca^{2+} uptake in the small intestine (see figure 6.19). Increased PTH promotes the formation of vitamin D in the kidneys, and

vitamin D increases the absorption of Ca^{2+} from the small intestine. PTH also increases the reabsorption of Ca^{2+} from urine in the kidneys, which reduces Ca^{2+} lost in the urine.

Tumors that secrete large amounts of PTH can cause so much bone breakdown that bones become weakened and fracture easily. On the other hand, an increase in blood Ca^{2+} levels results in less PTH secretion, decreased osteoclast activity, reduced Ca^{2+} release from bone, and decreased blood Ca^{2+} levels.

Calcitonin (kal-si-tō'nin), secreted from the thyroid gland (see figure 18.8), decreases osteoclast activity (see figure 6.19) by binding to receptors on the osteoclasts. An increase in blood Ca^{2+} levels stimulates the thyroid gland to secrete calcitonin, which

SYSTEMS PATHOLOGY

Osteoporosis

Mrs. B is a 70-year-old grandmother. Since she was a teenager, she has been a heavy smoker. She is typically sedentary, seldom goes outside, has not had the best dietary habits, and is underweight. One of her favorite yearly events is the family picnic on the Fourth of July. During one picnic, misfortune struck when Mrs. B tripped on a lawn sprinkler and fell. She was unable to stand because of severe hip pain, so she was rushed to the hospital, where a radiograph revealed that her femur was broken (figure *Da*) and that she had osteoporosis (figure *Db*).

It was decided that hip replacement surgery was indicated. Before the surgery could be performed, however, a fat embolism from the fracture site lodged in her lungs, making it difficult for her to breathe. The surgery was postponed and the fracture immobilized until she recovered from the fat embolism. Three weeks after the accident, Mrs. B had a successful hip transplant and began physical therapy. She appeared to be on the road to recovery, but 6 weeks after the surgery she developed persistent pain and edema in her hip. A bone biopsy confirmed a postoperative infection, which was successfully treated with antibiotics.

BACKGROUND INFORMATION

Osteoporosis (os'tē-ō-pō-rō'sis), or porous bone, results from a reduction in the overall quantity of bone tissue. It occurs when the rate of bone resorption exceeds the rate of bone formation. The loss of bone mass makes bones so porous and weakened that they become deformed and prone to fracture. The occurrence of osteoporosis increases with age. In both men and women, bone mass starts to decrease at about age 35 and continually decreases thereafter. Women can eventually lose approximately half, and men a quarter, of their cancellous bone. Osteoporosis is two and a half times more common in women than in men.

Osteoporosis has a strong genetic component. It is estimated that approximately 60% of a person's peak bone mass is genetically determined and that 40% is attributed to environmental factors, such as diet and physical activity. A woman whose mother has osteopo-

rosis is more likely to develop osteoporosis than is a woman whose mother does not have the disorder. The genetic component of osteoporosis is complex and probably involves variations in a number of genes, such as those encoding vitamin D, calcitonin and estrogen receptors, collagen type I alpha 1 chain (COL1A1), and others.

In postmenopausal women, the decreased production of the female sex hormone estrogen can cause osteoporosis. Estrogen is secreted by the ovaries, and it normally contributes to the maintenance of normal bone mass by inhibiting the stimulatory effects of PTH on osteoclast activity. Following menopause, estrogen production decreases, resulting in degeneration of cancellous bone, especially in the vertebrae of the spine and the bones of the forearm. Collapse of the vertebrae can cause a decrease in height or, in more severe cases, can produce kyphosis, or a “dowager’s hump,” in the upper back.

Conditions that result in decreased estrogen levels, other than menopause, can also cause osteoporosis. Examples include removal of the ovaries before menopause, extreme exercise to the point of amenorrhea (lack of menstrual flow), anorexia nervosa (self-starvation), and cigarette smoking.

In males, reduction in testosterone levels can cause loss of bone tissue. Decreasing testosterone levels are usually less of a problem

for men than decreasing estrogen levels are for women for two reasons. First, because males have denser bones than females, a loss of some bone tissue has less of an effect. Second, testosterone levels generally do not decrease significantly until after age 65, and even then the rate of decrease is often slow.

Overproduction of PTH, which results in overstimulation of osteoclast activity, can also cause osteoporosis.

Inadequate dietary intake or absorption of calcium can contribute to osteoporosis. Absorption of calcium from the small intestine decreases with age, and individuals with osteoporosis often have insufficient intake of calcium or vitamin D. Drugs that interfere with calcium uptake or use can also increase the risk for osteoporosis.

Finally, osteoporosis can result from inadequate exercise or disuse caused by fractures or paralysis. Significant amounts of bone are lost after 8 weeks of immobilization.

Treatments for osteoporosis are designed to reduce bone loss, increase bone formation, or both. Increased dietary calcium and vitamin D can increase calcium uptake and promote bone formation. Daily doses of 1000–1500 mg of calcium and 800 IU (20 μg) of vitamin D are recommended. Exercise, such as walking or using light weights, also appears to be effective not only in reducing bone loss but in increasing bone mass as well.

FIGURE D Osteoporosis

(a) Radiograph of a “broken hip,” which is actually a break of the femur (thighbone) in the hip region. (b) Photomicrograph of normal bone and osteoporotic bone.

In postmenopausal women, **hormone replacement therapy (HRT)** with estrogen decreases osteoclast numbers by inhibiting the production of RANKL (see p. 194). This reduces bone loss but does not result in an increase in bone mass because osteoclast activity still exceeds osteoblast activity. However, the use of HRT to prevent bone loss is now discouraged because of the results of a study sponsored by the Women's Health Initiative. The study examined HRT in over 16,000 women, and found that HRT increased the risk for breast cancer, uterine cancer, heart attacks, strokes, and blood clots but decreased the risk for hip fractures and colorectal cancer. **Selective estrogen receptor modulators (SERMs)** are a class of drugs that bind to estrogen receptors. They may be able to protect against bone loss without increasing the risk of breast cancer. For example, raloxifene (ral-ox'ī-fēn) stimulates estrogen receptors

in bone but inhibits them in the breast and uterus.

Osteoprotegerin, which prevents RANKL from binding to its receptors, is under consideration as a treatment for osteoporosis. Calcitonin (Miacalcin), which inhibits osteoclast activity, is now available as a nasal spray. Calcitonin can be used to treat osteoporosis in men and women and has been shown to produce a slight increase in bone mass. **Statins** (stat'ins) are drugs that inhibit cholesterol synthesis; they also stimulate osteoblast activity, and there is some evidence that statins can reduce the risk for fractures. Alendronate (Fosamax) belongs to a class of drugs called **bisphosphonates** (bis-fos'fō-nāts). Bisphosphonates concentrate in bone; when osteoclasts break down bone, the bisphosphonates are taken up by the osteoclasts. The bisphosphonates interfere with certain enzymes, leading to inactiva-

tion and lysis of the osteoclasts. Alendronate increases bone mass and reduces fracture rates even more effectively than calcitonin. Slow-releasing sodium fluoride (Slow Fluoride) in combination with calcium citrate (Citracal) also appears to increase bone mass.

Early diagnosis of osteoporosis may lead to the use of more preventive treatments. Instruments that measure the absorption of photons (particles of light) by bone are currently used, of which dual-energy x-ray absorptiometry (DEXA) is considered the best.

PREDICT 9

What advice should Mrs. B give to her granddaughter so that the granddaughter will be less likely to develop osteoporosis when she is Mrs. B's age?

SYSTEM INTERACTIONS	The Effects of Osteoporosis on Other Systems
SYSTEM	INTERACTIONS
Integumentary	Decreased exposure to sunlight because of an indoor lifestyle reduces vitamin D production and decreases Ca^{2+} absorption. Surgical wounds through the skin can allow the entry of bacteria, resulting in postoperative infections.
Muscular	A sedentary lifestyle and decreased body weight reduces stress on bone and contributes to osteoporosis. Muscle atrophy and weakness make it difficult to maintain balance, which increases the likelihood of falling and injury. Following hip replacement surgery, physical therapy places stress on the bones and improves muscular strength.
Nervous	Pain sensations following the injury and during rehabilitation help prevent further injury.
Endocrine	Although not a factor in this case of osteoporosis, elevated PTH (usually from a benign parathyroid tumor) or elevated thyroid hormone (Graves disease) can result in excessive osteoclast activity. Calcitonin is being used to treat osteoporosis.
Cardiovascular	Blood clotting following the injury starts the process of tissue repair. Blood cells are carried to the injury site to fight infections and remove cell debris. Blood vessels grow into the recovering tissue, providing nutrients and removing waste products.
Lymphatic and Immune	Immune cells resist infections and release chemicals that promote tissue repair. New immune cells are produced in bone marrow.
Respiratory	Excessive smoking lowers estrogen levels, which increases bone loss. A fat embolism from a fractured bone can impair respiration.
Digestive	Inadequate calcium and vitamin D in the inadequate calcium absorption by the digestive system can contribute to osteoporosis.
Urinary	Calcium ions released from the bones are excreted through the urinary system.
Reproductive	Decreased estrogen levels following menopause contribute to osteoporosis.

inhibits osteoclast activity. PTH and calcitonin are described more fully in chapters 18 and 27.

33 Name the hormone that is the major regulator of Ca^{2+} levels in the body. What stimulates the secretion of this hormone?

34 Describe how PTH controls the number of osteoclasts. What are the effects of PTH on the formation of vitamin D, Ca^{2+} uptake in the small intestine, and reabsorption of Ca^{2+} from urine?

35 What stimulates calcitonin secretion? How does calcitonin affect osteoclast activity?

CASE STUDY

Henry is a 65-year-old man who was admitted to the emergency room after a fall. A radiograph confirmed that he had fractured the proximal part of his arm bone (surgical neck of the humerus). The radiograph also revealed that his bone matrix was not as dense as it should be for a man his age. A test for blood Ca^{2+} levels was normal. On questioning, Henry confessed that he is a junk food addict with poor eating habits. He

eats few vegetables and never consumes dairy products. In addition, Henry never exercises and seldom goes outdoors except at night.

PREDICT 10

Use your knowledge of bone physiology and figure 6.19 to answer the following questions.

- Why is Henry more likely than most men his age to break a bone?
- How has Henry's eating habits contributed to his low bone density?
- Would Henry's PTH levels be lower than normal, normal, or higher than normal?
- What effect has Henry's nocturnal lifestyle had on his bone density?
- How has lack of exercise affected his bone density?

EFFECTS OF AGING ON THE SKELETAL SYSTEM

The most significant age-related changes in the skeletal system affect the quality and quantity of bone matrix. Recall that a mineral (hydroxyapatite) in the bone matrix gives bone compression (weight-bearing) strength, but collagen fibers make the bone flexible. The bone matrix in an older bone is more brittle than in a younger bone because decreased collagen production results in a matrix that has relatively more mineral and fewer collagen fibers. With aging, the amount of matrix also decreases because the rate of matrix formation by osteoblasts becomes slower than the rate of matrix breakdown by osteoclasts.

Bone mass is at its highest around age 30, and men generally have denser bones than women because of the effects of testosterone and greater body weight. Race also affects bone mass. African-Americans and Hispanics have higher bone masses than Caucasians and Asians. After age 35, both men and women have an age-related loss of bone of 0.3%–0.5% a year. This loss can increase by 10 times in women after menopause, and women can have a bone loss of 3%–5% a year for approximately 5–7 years (see “Osteoporosis,” p. 196).

Cancellous bone is lost at first as the trabeculae become thinner and weaker. The ability of the trabeculae to provide support also decreases as they become disconnected from each other. Eventually, some of the trabeculae completely disappear.

Trabecular bone loss is greatest in the trabeculae that are under the least stress.

A slow loss of compact bone begins about age 40 and increases after age 45. The rate of compact bone loss, however, is approximately half the rate of trabecular bone loss. Bones become thinner, but their outer dimensions change little, because most loss of compact bone occurs under the endosteum on the inner surfaces of bones. In addition, the remaining compact bone becomes weaker as a result of incomplete bone remodeling. In a young bone, when osteons are removed, the resulting spaces are filled with new osteons. With aging, the new osteons fail to completely fill in the spaces produced when the older osteons are removed.

Significant loss of bone increases the likelihood of having bone fractures. For example, loss of trabeculae greatly increases the risk of compression fractures of the vertebrae (backbones) because the weight-bearing body of the vertebrae consists mostly of cancellous bone. In addition, loss of bone can cause deformity, loss of height, pain, and stiffness. For example, compression fractures of the vertebrae can cause an exaggerated curvature of the spine, resulting in a bent-forward, stooped posture. Loss of bone from the jaws can also lead to tooth loss.

36 What effect does aging have on the quality and quantity of bone matrix?

37 Describe how cancellous and compact bone change with age. How do these changes affect a person's health?

SUMMARY

Functions of the Skeletal System (p. 174)

1. The skeletal system consists of bones, cartilage, tendons, and ligaments.
2. The skeletal system supports the body, protects the organs it surrounds, allows body movements, stores minerals and fats, and is the site of blood cell production.

Cartilage (p. 174)

1. Chondroblasts produce cartilage and become chondrocytes. Chondrocytes are located in lacunae surrounded by matrix.
2. The matrix of cartilage contains collagen fibers (for strength) and proteoglycans (trap water).
3. The perichondrium surrounds cartilage.
 - The outer layer contains fibroblasts.
 - The inner layer contains chondroblasts.
4. Cartilage grows by appositional and interstitial growth.

Bone Histology (p. 175)

Bone Matrix

1. Collagen provides flexible strength.
2. Hydroxyapatite provides compressional strength.

Bone Cells

1. Osteoblasts produce bone matrix and become osteocytes.
 - Osteoblasts connect to one another through cell processes and surround themselves with bone matrix to become osteocytes.
 - Osteocytes are located in lacunae and are connected to one another through canaliculi.
2. Osteoclasts break down bone (with assistance from osteoblasts).
3. Osteoblasts originate from osteochondral progenitor cells, whereas osteoclasts originate from stem cells in red bone marrow.
4. Ossification, the formation of bone, occurs through appositional growth.

Woven and Lamellar Bone

1. Woven bone has collagen fibers oriented in many different directions. It is remodeled to form lamellar bone.
2. Lamellar bone is arranged in thin layers, called lamellae, which have collagen fibers oriented parallel to one another.

Cancellous and Compact Bone

1. Cancellous bone has many spaces.
 - Lamellae combine to form trabeculae, beams of bone that interconnect to form a latticelike structure with spaces filled with bone marrow and blood vessels.
 - The trabeculae are oriented along lines of stress and provide structural strength.
2. Compact bone is dense with few spaces.
 - Compact bone consists of organized lamellae: Circumferential lamellae form the outer surface of compact bones; concentric lamellae surround central canals, forming osteons; interstitial lamellae are remnants of lamellae left after bone remodeling.
 - Canals within compact bone provide a means for the exchange of gases, nutrients, and waste products. From the periosteum or endosteum, perforating canals carry blood vessels to central canals, and canaliculi connect central canals to osteocytes.

Bone Anatomy (p. 180)

Bone Shapes

Individual bones can be classified as long, short, flat, or irregular.

Structure of a Long Bone

1. The diaphysis is the shaft of a long bone, and the epiphyses are the ends.
2. The epiphyseal plate is the site of bone growth in length.
3. The medullary cavity is a space within the diaphysis.
4. Red marrow is the site of blood cell production, and yellow marrow consists of fat.
5. The periosteum covers the outer surface of bone.
 - The outer layer contains blood vessels and nerves.
 - The inner layer contains osteoblasts, osteoclasts, and osteochondral progenitor cells.
 - Perforating fibers hold the periosteum, ligaments, and tendons in place.
6. The endosteum lines cavities inside bone and contains osteoblasts, osteoclasts, and osteochondral progenitor cells.

Structure of Flat, Short, and Irregular Bones

Flat, short, and irregular bones have an outer covering of compact bone surrounding cancellous bone.

Bone Development (p. 183)

Intramembranous Ossification

1. Some skull bones, part of the mandible, and the diaphyses of the clavicles develop from membranes.
2. Within the membrane at centers of ossification, osteoblasts produce bone along the membrane fibers to form cancellous bone.
3. Beneath the periosteum, osteoblasts lay down compact bone to form the outer surface of the bone.
4. Fontanelles are areas of membrane that are not ossified at birth.

Endochondral Ossification

1. Most bones develop from a cartilage model.
2. The cartilage matrix is calcified, and chondrocytes die. Osteoblasts form bone on the calcified cartilage matrix, producing cancellous bone.
3. Osteoblasts build an outer surface of compact bone beneath the periosteum.
4. Primary ossification centers form in the diaphysis during fetal development. Secondary ossification centers form in the epiphyses.
5. Articular cartilage on the ends of bones and the epiphyseal plate is cartilage that does not ossify.

Bone Growth (p. 185)

1. Bones increase in size only by appositional growth, the adding of new bone on the surface of older bone or cartilage.
2. Trabeculae grow by appositional growth.

Growth in Bone Length

1. Epiphyseal plate growth involves the interstitial growth of cartilage followed by appositional bone growth on the cartilage.
2. Epiphyseal plate growth results in an increase in the length of the diaphysis and bony processes. Bone growth in length ceases when the epiphyseal plate becomes ossified and forms the epiphyseal line.

Growth at Articular Cartilage

1. Articular cartilage growth involves the interstitial growth of cartilage followed by appositional bone growth on the cartilage.
2. Articular cartilage growth results in larger epiphyses and an increase in the size of bones that do not have epiphyseal plates.

Growth in Bone Width

1. Appositional bone growth beneath the periosteum increases the diameter of long bones and the size of other bones.
2. Osteoblasts from the periosteum form ridges with grooves between them. The ridges grow together, converting the grooves into tunnels filled with concentric lamellae to form osteons.
3. Osteoblasts from the periosteum lay down circumferential lamellae, which can be remodeled.

Factors Affecting Bone Growth

1. Genetic factors determine bone shape and size. The expression of genetic factors can be modified.
2. Factors that alter the mineralization process or the production of organic matrix, such as deficiencies in vitamins D and C, can affect bone growth.
3. Growth hormone, thyroid hormone, estrogen, and testosterone stimulate bone growth.
4. Estrogen and testosterone cause increased bone growth and closure of the epiphyseal plate.

Bone Remodeling (p. 191)

1. Remodeling converts woven bone to lamellar bone and allows bone to change shape, adjust to stress, repair itself, and regulate body calcium levels.

2. Bone adjusts to stress by adding new bone and by realigning bone through remodeling.

Bone Repair (p. 192)

1. Fracture repair begins with the formation of a hematoma.
2. The hematoma is replaced by an internal callus consisting of fibers and cartilage.
3. The external callus is a bone–cartilage collar that stabilizes the ends of the broken bone.
4. The internal and external calluses are ossified to become woven bone.
5. Woven bone is remodeled.

Calcium Homeostasis (p. 194)

PTH increases blood Ca^{2+} levels by increasing bone breakdown, Ca^{2+} absorption from the small intestine, and reabsorption of Ca^{2+} from the urine. Calcitonin decreases blood Ca^{2+} by decreasing bone breakdown.

Effects of Aging on the Skeletal System (p. 198)

1. With aging, bone matrix is lost and the matrix becomes more brittle.
2. Cancellous bone loss results from a thinning and a loss of trabeculae. Compact bone loss mainly occurs from the inner surface of bones and involves less osteon formation.
3. Loss of bone increases the risk for fractures and causes deformity, loss of height, pain, stiffness, and loss of teeth.

REVIEW AND COMPREHENSION

1. Which of these is *not* a function of bone?
 - a. internal support and protection
 - b. attachment for the muscles
 - c. calcium and phosphate storage
 - d. blood cell production
 - e. vitamin D storage
2. The extracellular matrix for hyaline cartilage
 - a. is produced by chondroblasts.
 - b. contains collagen.
 - c. contains proteoglycans.
 - d. is usually covered by the perichondrium.
 - e. all of the above.
3. Chondrocytes are mature cartilage cells found within the _____, and they are derived from _____.
 - a. perichondrium, fibroblasts
 - b. perichondrium, chondroblasts
 - c. lacunae, fibroblasts
 - d. lacunae, chondroblasts
4. Which of these statements concerning cartilage is correct?
 - a. Cartilage often occurs in thin plates or sheets.
 - b. Chondrocytes receive nutrients and oxygen from blood vessels in the matrix.
 - c. Articular cartilage has a thick perichondrium layer.
 - d. The perichondrium has both chondrocytes and osteocytes.
 - e. Appositional growth of cartilage occurs when chondrocytes within the tissue add more matrix from the inside.
5. Which of these substances makes up the major portion of bone?
 - a. collagen
 - b. hydroxyapatite
 - c. proteoglycan aggregates
 - d. osteocytes
 - e. osteoblasts
6. The flexible strength of bone occurs because of
 - a. osteoclasts.
 - b. ligaments.
 - c. hydroxyapatite.
 - d. collagen fibers.
 - e. periosteum.
7. The prime function of osteoclasts is to
 - a. prevent osteoblasts from forming.
 - b. become osteocytes.
 - c. break down bone.
 - d. secrete calcium salts and collagen fibers.
 - e. form the periosteum.
8. Osteochondral progenitor cells
 - a. can become osteoblasts or chondroblasts.
 - b. are derived from mesenchymal stem cells.
 - c. are located in the perichondrium, periosteum, and endosteum.
 - d. do not produce osteoclasts.
 - e. all of the above.
9. Lamellar bone
 - a. is mature bone.
 - b. is remodeled to form woven bone.
 - c. is the first type of bone formed during early fetal development.
 - d. has collagen fibers randomly oriented in many directions.
 - e. all of the above.

10. Central canals
 a. connect perforating canals to canaliculi.
 b. connect cancellous bone to compact bone.
 c. are where blood cells are produced.
 d. are found only in cancellous bone.
 e. are lined with periosteum.
11. The type of lamellae found in osteons is _____ lamellae.
 a. circumferential b. concentric c. interstitial
12. Cancellous bone consists of interconnecting rods or plates of bone called
 a. osteons. d. a haversian system.
 b. canaliculi. e. trabeculae.
 c. circumferential lamellae.
13. A fracture in the shaft of a bone is a break in the
 a. epiphysis. c. diaphysis.
 b. perichondrium. d. articular cartilage.
14. Yellow marrow is
 a. found mostly in children's bones.
 b. found in the epiphyseal plate.
 c. important for blood cell production.
 d. mostly adipose tissue.
15. The periosteum
 a. is an epithelial tissue membrane.
 b. covers the outer and internal surfaces of bone.
 c. contains only osteoblasts.
 d. becomes continuous with collagen fibers of tendons or ligaments.
 e. has a single fibrous layer.
16. Given these events:
 1. Osteochondral progenitor cells become osteoblasts.
 2. Connective tissue membrane is formed.
 3. Osteoblasts produce woven bone.
 Which sequence best describes intramembranous bone formation?
 a. 1,2,3 b. 1,3,2 c. 2,1,3 d. 2,3,1 e. 3,2,1
17. Given these processes:
 1. Chondrocytes die.
 2. Cartilage matrix calcifies.
 3. Chondrocytes hypertrophy.
 4. Osteoblasts deposit bone.
 5. Blood vessels grow into lacunae.
 Which sequence best represents the order in which they occur during endochondral bone formation?
 a. 3,2,1,4,5 c. 5,2,3,4,1 e. 3,5,2,4,1
 b. 3,2,1,5,4 d. 3,2,5,1,4
18. Intramembranous bone formation
 a. occurs at the epiphyseal plate.
 b. is responsible for growth in diameter of a bone.
 c. gives rise to the flat bones of the skull.
 d. occurs within a hyaline cartilage model.
 e. produces articular cartilage in the long bones.
19. The ossification regions formed during early fetal development
 a. are secondary ossification centers.
 b. become articular cartilage.
 c. become medullary cavities.
 d. become the epiphyses.
 e. are primary ossification centers.
20. Growth in the length of a long bone occurs
 a. at the primary ossification center. d. at the epiphyseal plate.
 b. beneath the periosteum. e. at the epiphyseal line.
 c. at the center of the diaphysis.
21. During growth in length of a long bone, cartilage is formed and then ossified. The location of the ossification is the zone of
 a. calcification. c. proliferation.
 b. hypertrophy. d. resting cartilage.
22. Given these processes:
 1. An osteon is produced.
 2. Osteoblasts from the periosteum form a series of ridges.
 3. The periosteum becomes the endosteum.
 4. Osteoblasts lay down bone to produce a concentric lamella.
 5. Grooves are changed into tunnels.
 Which sequence best represents the order in which these processes occur during growth in width of a long bone?
 a. 1,4,2,3,5 c. 3,4,2,1,5 e. 5,4,2,1,3
 b. 2,5,3,4,1 d. 4,2,1,5,3
23. Chronic vitamin D deficiency results in which of these consequences?
 a. Bones become brittle.
 b. The percentage of bone composed of hydroxyapatite increases.
 c. Bones become soft and pliable.
 d. Scurvy occurs.
 e. both a and b
24. Osteomalacia occurs as a result of a deficiency of
 a. growth hormone. c. thyroid hormone. e. vitamin D.
 b. sex hormones. d. vitamin C.
25. Estrogen
 a. stimulates a burst of growth at puberty.
 b. causes a later closure of the epiphyseal plate than does testosterone.
 c. causes a longer growth period in females than testosterone causes in males.
 d. tends to prolong the growth phase of the epiphyseal plates.
 e. all of the above.
26. Bone remodeling can occur
 a. when woven bone is converted into lamellar bone.
 b. as bones are subjected to varying patterns of stress.
 c. as a long bone increases in diameter.
 d. when new osteons are formed in compact bone.
 e. all of the above.
27. Given these processes:
 1. cartilage ossification
 2. external callus formation
 3. hematoma formation
 4. internal callus formation
 5. remodeling of woven bone into compact bone
 Which sequence best represents the order in which the processes occur during repair of a fracture?
 a. 1,2,3,4,5 c. 3,4,2,1,5 e. 5,3,4,2,1
 b. 2,4,3,1,5 d. 4,1,5,2,3
28. Which of these processes during bone repair requires the longest period of time?
 a. cartilage ossification
 b. external callus formation
 c. hematoma formation
 d. internal callus formation
 e. remodeling of woven bone into compact bone
29. If the secretion of parathyroid hormone (PTH) increases, osteoclast activity _____, and blood Ca^{2+} levels _____.
 a. decreases, decrease c. increases, decrease
 b. decreases, increase d. increases, increase
30. Osteoclast activity is inhibited by
 a. calcitonin. c. parathyroid hormone. e. thyroid hormone.
 b. growth hormone. d. sex hormones.

CRITICAL THINKING

1. When a person develops Paget disease, for unknown reasons the collagen fibers in the bone matrix run randomly in all directions. In addition, the amount of trabecular bone decreases. What symptoms would you expect to observe?
2. When closure of the epiphyseal plate occurs, the cartilage of the plate is replaced by bone. Does this occur from the epiphyseal side of the plate or the diaphyseal side?
3. Assume that two patients have identical breaks in the femur (thigh-bone). If one is bedridden and the other has a walking cast, which patient's fracture heals faster? Explain.
4. Explain why running helps prevent osteoporosis in the elderly. Does the benefit include all bones or mainly those of the legs and spine?
5. Astronauts can experience a dramatic decrease in bone density while in a weightless environment. Explain how this happens, and suggest a way to slow the loss of bone tissue.
6. Would a patient suffering from kidney failure be more likely to develop osteomalacia or osteoporosis? Explain.
7. In some cultures, eunuchs were responsible for guarding harems, which are the collective wives of one male. Eunuchs are males who were castrated as boys. Castration removes the testes, the major site of testosterone production in males. Because testosterone is responsible for the sex drive in males, the reason for castration is obvious. As a side effect of this procedure, the eunuchs grew to above-normal heights. Can you explain why?
8. When a long bone is broken, blood vessels at the fracture line are severed. The formation of blood clots stops the bleeding. Within a few days, bone tissue on both sides of the fracture site dies. The bone only dies back a certain distance from the fracture line, however. Explain.
9. A patient has hyperparathyroidism because of a tumor in the parathyroid gland that produces excessive amounts of PTH. What effect does this hormone have on bone? Would administration of large doses of vitamin D help the situation? Explain.

Skeletal System

Gross Anatomy

7

If the body had no skeleton, it would look somewhat like a poorly stuffed rag doll. Without a skeletal system, we would have no framework to help maintain shape and we would not be able to move normally. Most muscles act on bones to produce movement, often pulling on the bones with considerable force. Without the skeleton, muscles would not make the body move. Human bones are very strong and can resist tremendous bending and compression forces without breaking. Nonetheless, each year nearly 2 million Americans break a bone.

The skeletal system includes the bones, cartilage, ligaments, and tendons. To study skeletal gross anatomy, however, dried, prepared bones are used. This allows the major features of individual bones to be seen clearly without being obstructed by associated soft tissues, such as muscles, tendons, ligaments, cartilage, nerves, and blood vessels. As a consequence, however, it is easy to ignore the important relationships among bones and soft tissues and the fact that living bones have soft tissue, such as the periosteum (see chapter 6).

This chapter includes a discussion of *general considerations* (p. 204). It then discusses the two categories of the named bones: the *axial skeleton* (p. 206) and the *appendicular skeleton* (p. 233).

Colorized SEM of bone trabeculae.

GENERAL CONSIDERATIONS

The average adult skeleton has 206 bones (table 7.1 and figure 7.1). Although this is the traditional number, the actual number of bones varies from person to person and decreases with age as some bones become fused.

Many of the anatomical terms used to describe the features of bones are listed in table 7.2. Most of these features are based on the relationship between the bones and associated soft tissues. If a bone possesses a **tubercle** (too'ber-kl; lump) or **process** (projection), such structures usually exist because a ligament or tendon was attached to that tubercle or process during life. If a bone has

TABLE 7.1 Number of Named Bones Listed by Category

Bones	Number	Bones	Number
Axial Skeleton		Appendicular Skeleton	
<i>Skull (Cranium)</i>		<i>Pectoral Girdle</i>	
Neurocranium (braincase)		Scapula	2
Paired	Parietal 2	Clavicle	2
	Temporal 2	<i>Upper Limb</i>	
Unpaired	Frontal 1	Humerus	2
	Sphenoid 1	Ulna	2
	Occipital 1	Radius	2
	Ethmoid 1	Carpals	16
Viscerocranium (face)		Metacarpals	10
Paired	Maxilla 2	Phalanges	28
	Zygomatic 2	Total upper limb and girdle	64
	Palatine 2	<i>Pelvic Girdle</i>	
	Lacrimal 2	Coxal bone	2
	Nasal 2	<i>Lower Limb</i>	
	Inferior nasal concha 2	Femur	2

TABLE 7.2 General Anatomical Terms for Various Features of Bones

Term	Description
Body	Main part
Head	Enlarged (often rounded) end
Neck	Constriction between head and body
Margin or border	Edge
Angle	Bend
Ramus	Branch off the body (beyond the angle)
Condyle	Smooth, rounded articular surface
Facet	Small, flattened articular surface
Ridges	
Line or linea	Low ridge
Crest or crista	Prominent ridge
Spine	Very high ridge
Projections	
Process	Prominent projection
Tubercle	Small, rounded bump
Tuberosity or tuber	Knob; larger than a tubercle
Trochanter	Tuberosities on the proximal femur
Epicondyle	Upon a condyle
Lingula	Flat, tongue-shaped process
Hamulus	Hook-shaped process
Cornu	Horn-shaped process
Openings	
Foramen	Hole
Canal or meatus	Tunnel
Fissure	Cleft
Sinus or labyrinth	Cavity
Depressions	
Fossa	General term for a depression
Notch	Depression in the margin of a bone
Fovea	Little pit
Groove or sulcus	Deeper, narrow depression

a smooth, articular surface, that surface was part of a joint and was covered with articular cartilage. If the bone has a **foramen** (fō-rā'men; pl. *foramina*; fō-ram'i-nā; a hole) in it, that foramen was occupied by something such as a nerve or blood vessel. Some skull bones contain mucous membrane-lined air spaces called **sinuses**. Regions of some skull bones are composed of paper-thin, translucent compact bone only and have little or no cancellous center (see chapter 6).

1 How many bones are in an average adult skeleton?

2 How are lumps, projections, and openings in bones related to soft tissues?

AXIAL SKELETON

The **axial skeleton** is divided into the skull, auditory ossicles, hyoid bone, vertebral column, and thoracic cage, or rib cage. The axial skeleton forms the upright axis of the body. It protects the brain, the spinal cord, and the vital organs housed within the thorax.

3 List the parts of the axial skeleton and its functions.

Skull

The **skull**, or **cranium** (krā'nē-ŭm), protects the brain; supports the organs of vision, hearing, smell, and taste; and provides a foundation for the structures that take air, food, and water into the body. When the skull is disassembled, the mandible is easily separated from the rest of the skull, which remains intact. Special effort is needed to separate the other bones. For this reason, it is convenient to think of the skull, except for the mandible, as a single unit. The top of the skull is called the **calvaria** (kal-vā'rē-ă), or skullcap. It is usually cut off to reveal the skull's interior. The exterior and interior of the skull have ridges, lines, processes, and plates. These structures are important for the attachment of muscles or for articulations between the bones of the skull. Selected features of the intact skull are listed in table 7.3.

Superior View of the Skull

The skull appears quite simple when viewed from above. Only four bones are seen from this view: the frontal bone, two parietal bones, and a small part of the occipital bone. The paired **parietal bones** are joined at the midline by the **sagittal suture**, and the parietal bones are connected to the **frontal bone** by the **coronal suture** (figure 7.2).

Posterior View of the Skull

The parietal and occipital bones are the major structures seen from the posterior view (figure 7.3). The parietal bones are joined to the **occipital bone** by the **lambdoid** (lam'doyd; the shape resembles the Greek letter lambda) **suture**. Occasionally, extra small bones called **sutural** (soo'choor-ăl), or wormian, **bones** form along the lambdoid suture.

PREDICT 1

Explain the basis for the names *sagittal* and *coronal sutures*.

Inca Bone

Sutural bones are usually small, bilateral, and apparently genetically determined. A large midline bone, called an Inca bone, may form at the junction of the lambdoid and sagittal sutures. The bone was common in the skulls of Incas and is still present in their Andean descendants.

An **external occipital protuberance** is present on the posterior surface of the occipital bone (see figure 7.3). It can be felt through the scalp at the base of the head and varies considerably in size from person to person. The external occipital protuberance is the site of attachment of the **ligamentum nuchae** (noo'kē; nape of neck),

TABLE 7.3 Processes and Other Features of the Skull

Feature	Bone on Which Feature is Found	Description
External Features		
Alveolar process	Mandible, maxilla	Ridges on the mandible and maxilla containing the teeth
Angle	Mandible	The posterior, inferior corner of the mandible
Coronoid process	Mandible	Attachment point for the temporalis muscle
Genu	Mandible	Chin (resembles a bent knee)
Horizontal plate	Palatine	The posterior third of the hard palate
Mandibular condyle	Mandible	Region where the mandible articulates with the skull
Mandibular fossa	Temporal	Depression where the mandible articulates with the skull
Mastoid process	Temporal	Enlargement posterior to the ear; attachment site for several muscles that move the head
Nuchal lines	Occipital	Attachment points for several posterior neck muscles
Occipital condyle	Occipital	Point of articulation between the skull and the vertebral column
Palatine process	Maxilla	Anterior two-thirds of the hard palate
Pterygoid hamulus	Sphenoid	Hooked process on the inferior end of the medial pterygoid plate, around which the tendon of one palatine muscle passes; an important dental landmark
Pterygoid plates (medial and lateral)	Sphenoid	Bony plates on the inferior aspect of the sphenoid bone; the lateral pterygoid plate is the site of attachment for two muscles of mastication (chewing)
Ramus	Mandible	Portion of the mandible superior to the angle
Styloid process	Temporal	Attachment site for three muscles (to the tongue, pharynx, and hyoid bone) and some ligaments
Temporal lines	Parietal	Where the temporalis muscle, which closes the jaw, attaches
Internal Features		
Crista galli	Ethmoid	Process in the anterior part of the cranial vault to which one of the connective tissue coverings of the brain (dura mater) connects
Petrous portion	Temporal	Thick, interior part of temporal bone containing the middle and inner ears and the auditory ossicles
Sella turcica	Sphenoid	Bony structure resembling a saddle in which the pituitary gland is located

**FIGURE 7.2** Skull as Seen from the Superior View

The names of the bones are bolded.

FIGURE 7.3 Skull as Seen from the Posterior View

The names of the bones are bolded.

an elastic ligament that extends down the neck and helps keep the head erect by pulling on the occipital region of the skull. **Nuchal lines** are a set of small ridges that extend laterally from the protuberance and are the points of attachment for several neck muscles.

Nuchal Lines

The ligamentum nuchae and neck muscles in humans are not as strong as comparable structures in other animals; therefore, the human bony prominence and lines of the posterior skull are not as well developed as they are in those animals. The location of the human foramen magnum allows the skull to balance above the vertebral column and allows for an upright posture. Thus human skulls require less ligamental and muscular effort to balance the head on the spinal column than do the skulls of other animals, including other primates, such as chimpanzees, whose skulls are not balanced over the vertebral column. The presence of small nuchal lines in hominids (i.e., animals with an upright stance, such as humans) reflects this decreased musculature and is one way paleontologists establish probable upright posture in hominids.

Lateral View of the Skull

The parietal bone and the squamous part of the temporal bone form a large part of the side of the head (figure 7.4). The term *temporal* means related to time, and the temporal bone

is so named because the hair of the temples is often the first to turn white, indicating the passage of time. The **squamous suture** joins these bones. A prominent feature of the temporal bone is a large hole, the **external acoustic**, or **auditory, meatus** (mē-ā'tūs; passageway or tunnel), which transmits sound waves toward the eardrum. The external ear, or auricle, surrounds the meatus. Just posterior and inferior to the external auditory meatus is a large inferior projection, the **mastoid** (mas'toyd; resembling a breast) **process**. The process can be seen and felt as a prominent lump just posterior to the ear. The process is not solid bone but is filled with cavities called **mastoid air cells**, which are connected to the middle ear. Important neck muscles involved in rotation of the head attach to the mastoid process. The superior and inferior **temporal lines**, which are attachment points of the temporalis muscle, one of the major muscles of mastication, arch across the lateral surface of the parietal bone.

Temporal Lines

The temporal lines are important to anthropologists because a heavy temporal line suggests a strong temporalis muscle supporting a heavy jaw. In a male gorilla, the temporalis muscles are so large that the temporal lines meet in the midline of the skull to form a heavy sagittal crest. The temporal lines are much smaller in humans.

FIGURE 7.4 Lateral View of the Skull as Seen from the Right Side

The names of the bones are bolded.

The lateral surface of the **greater wing** of the **sphenoid** (sfē'noyd; wedge-shaped) **bone** is immediately anterior to the temporal bone (see figure 7.4). Although appearing to be two bones, one on each side of the skull, the sphenoid bone is actually a single bone that extends completely across the skull. Anterior to the sphenoid bone is the **zygomatic** (zī'gō-mat'ik; a bar or yoke) **bone**, or cheekbone, which can be easily seen and felt on the face (figure 7.5).

The **zygomatic arch**, which consists of joined processes from the temporal and zygomatic bones, forms a bridge across the side of the skull (see figure 7.4). The zygomatic arch is easily felt on the side of the face, and the muscles on each side of the arch can be felt as the jaws are opened and closed (see figure 7.5).

The **maxilla** (mak-sil'ā; upper jaw) is anterior and inferior to the zygomatic bone to which it is joined. The **mandible** (lower jaw) is inferior to the maxilla and articulates posteriorly with the temporal bone (see figure 7.4). The mandible consists of two main portions: the **body**, which extends anteroposteriorly, and the **ramus** (branch), which extends superiorly from the body toward the temporal bone. The superior end of the ramus has a mandibular **condyle**, which articulates with the mandibular fossa of the temporal bone, and the **coronoid** (kōr'ō-noyd; shaped like a crow's beak) **process**, to which the powerful

temporalis muscle, one of the chewing muscles, attaches. The alveolar process of the maxilla contains the superior set of teeth, and the alveolar process of the mandible contains the inferior teeth.

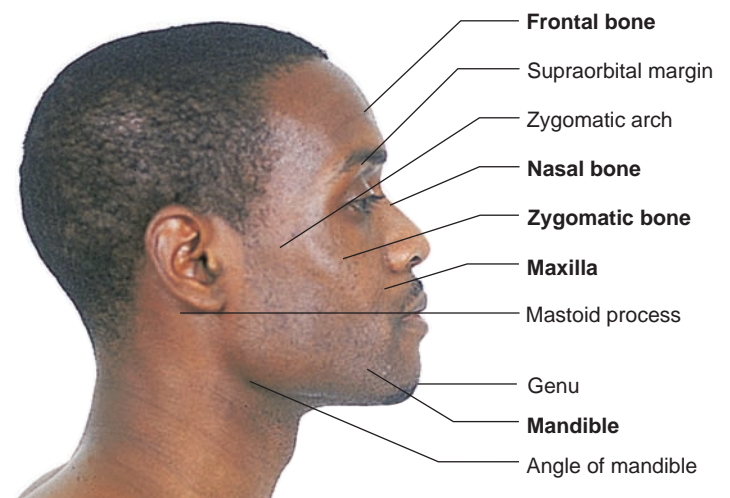

FIGURE 7.5 Lateral View of Bony Landmarks on the Face

FIGURE 7.6 Skull as Seen from the Anterior View

The names of the bones are bolded.

Anterior View of the Skull

The major structures seen from the anterior view are the frontal bone (forehead), the zygomatic bones (cheekbones), the maxillae, and the mandible (figure 7.6). The teeth, which are very prominent in this view, are discussed in chapter 24. Many bones of the face can be easily felt through the skin of the face (figure 7.7).

From this view, the most prominent openings into the skull are the orbits and the nasal cavity. The **orbits** are cone-shaped fossae with their apices directed posteriorly (see figure 7.6; figure 7.8). They are called orbits because of the rotation of the eyes within the fossae. The bones of the orbits provide both protection for the eyes and attachment points for the muscles that move the eyes. The major portion of each eyeball is within the orbit, and the portion of the eye visible from the outside is relatively small. Each orbit contains blood vessels, nerves, and fat, as well as the eyeball and the muscles that move it. The bones forming the orbit are listed in table 7.4.

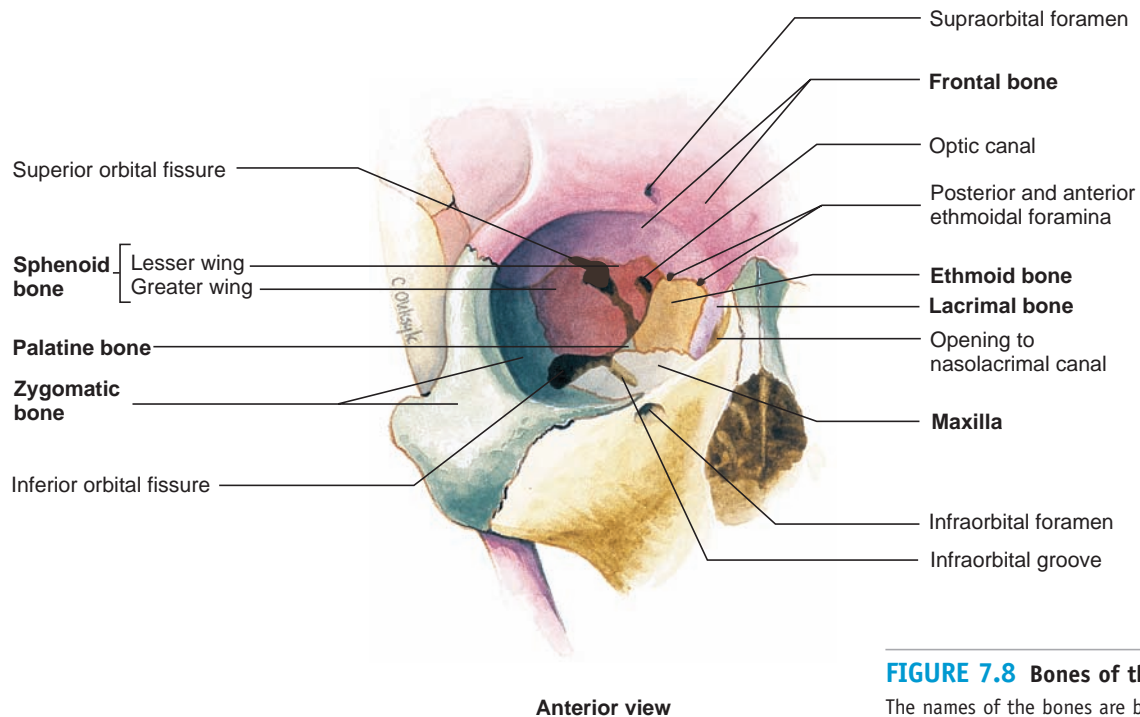

FIGURE 7.7 Anterior View of Bony Landmarks on the Face

The names of the bones are bolded.

**FIGURE 7.8** Bones of the Right Orbit

The names of the bones are bolded.

**Orbit Weak Point**

The superolateral corner of the orbit, where the zygomatic and frontal bones join, is a weak point in the skull that is easily fractured by a blow to that region of the head. The bone tends to collapse into the orbit, resulting in an injury that is difficult to repair.

The orbit has several openings through which structures communicate between the orbit and other cavities. The nasolacrimal duct passes from the orbit into the nasal cavity through the **nasolacrimal canal**, carrying tears from the eyes to the nasal cavity. The optic nerve for the sense of vision passes from the eye through the **optic canal** at the posterior apex of the orbit and enters the cranial cavity. Superior and inferior fissures in the posterior region of the orbit provide openings through which nerves and blood vessels communicate with structures in the orbit or pass to the face.

TABLE 7.4 Bones Forming the Orbit (See Figures 7.6 and 7.8)

Bone	Part of Orbit
Frontal	Roof
Sphenoid	Roof and posterolateral wall
Zygomatic	Lateral wall
Maxilla	Floor
Lacrimal	Medial wall
Ethmoid	Medial wall
Palatine	Medial wall

**Deviated Nasal Septum**

The nasal septum usually is located in the midsagittal plane until a person is 7 years old. Thereafter, it tends to deviate, or bulge slightly to one side. The septum can also deviate abnormally at birth or, more commonly, as a result of injury. Deviations can be severe enough to block one side of the nasal passage and interfere with normal breathing. The repair of severe deviations requires surgery.

TABLE 7.5 Bones Forming the Nasal Cavity (See Figures 7.6 and 7.9)

Bone	Part of Nasal Cavity
Frontal	Roof
Nasal	Roof
Sphenoid	Roof
Ethmoid	Roof, septum, lateral wall
Inferior nasal concha	Lateral wall
Lacrimal	Lateral wall
Maxilla	Floor
Palatine	Floor and lateral wall
Vomer	Septum

FIGURE 7.9 Bones of the Nasal Cavity

The names of the bones are bolded. (a) Nasal septum as seen from the left nasal cavity. (b) Right lateral nasal wall as seen from inside the nasal cavity (nasal septum removed).

The external part of the nose, formed mostly of hyaline cartilage, is almost entirely absent in the dried skeleton and is represented mainly by the nasal bones and the frontal processes of the maxillary bones, which form the bridge of the nose.

PREDICT 2

A direct blow to the nose may result in a “broken nose.” List at least three bones that may be broken.

The lateral wall of the nasal cavity has three bony shelves, the **nasal conchae** (kon’kē; resembling a conch shell), which are directed inferiorly (see figure 7.9). The inferior nasal concha is a

separate bone, and the middle and superior nasal conchae are projections from the ethmoid bone. The conchae increase the surface area in the nasal cavity, thereby facilitating moistening, the removal of particles, and warming of the air inhaled through the nose.

Several of the bones associated with the nasal cavity have large cavities within them called the **paranasal sinuses**, which open into the nasal cavity (figure 7.10). The sinuses decrease the weight of the skull and act as resonating chambers during voice production. Compare a normal voice with the voice of a person who has a cold and whose sinuses are “stopped up.” The sinuses are named for the bones in which they are located and include the frontal, maxillary, and sphenoidal sinuses. The cavities within

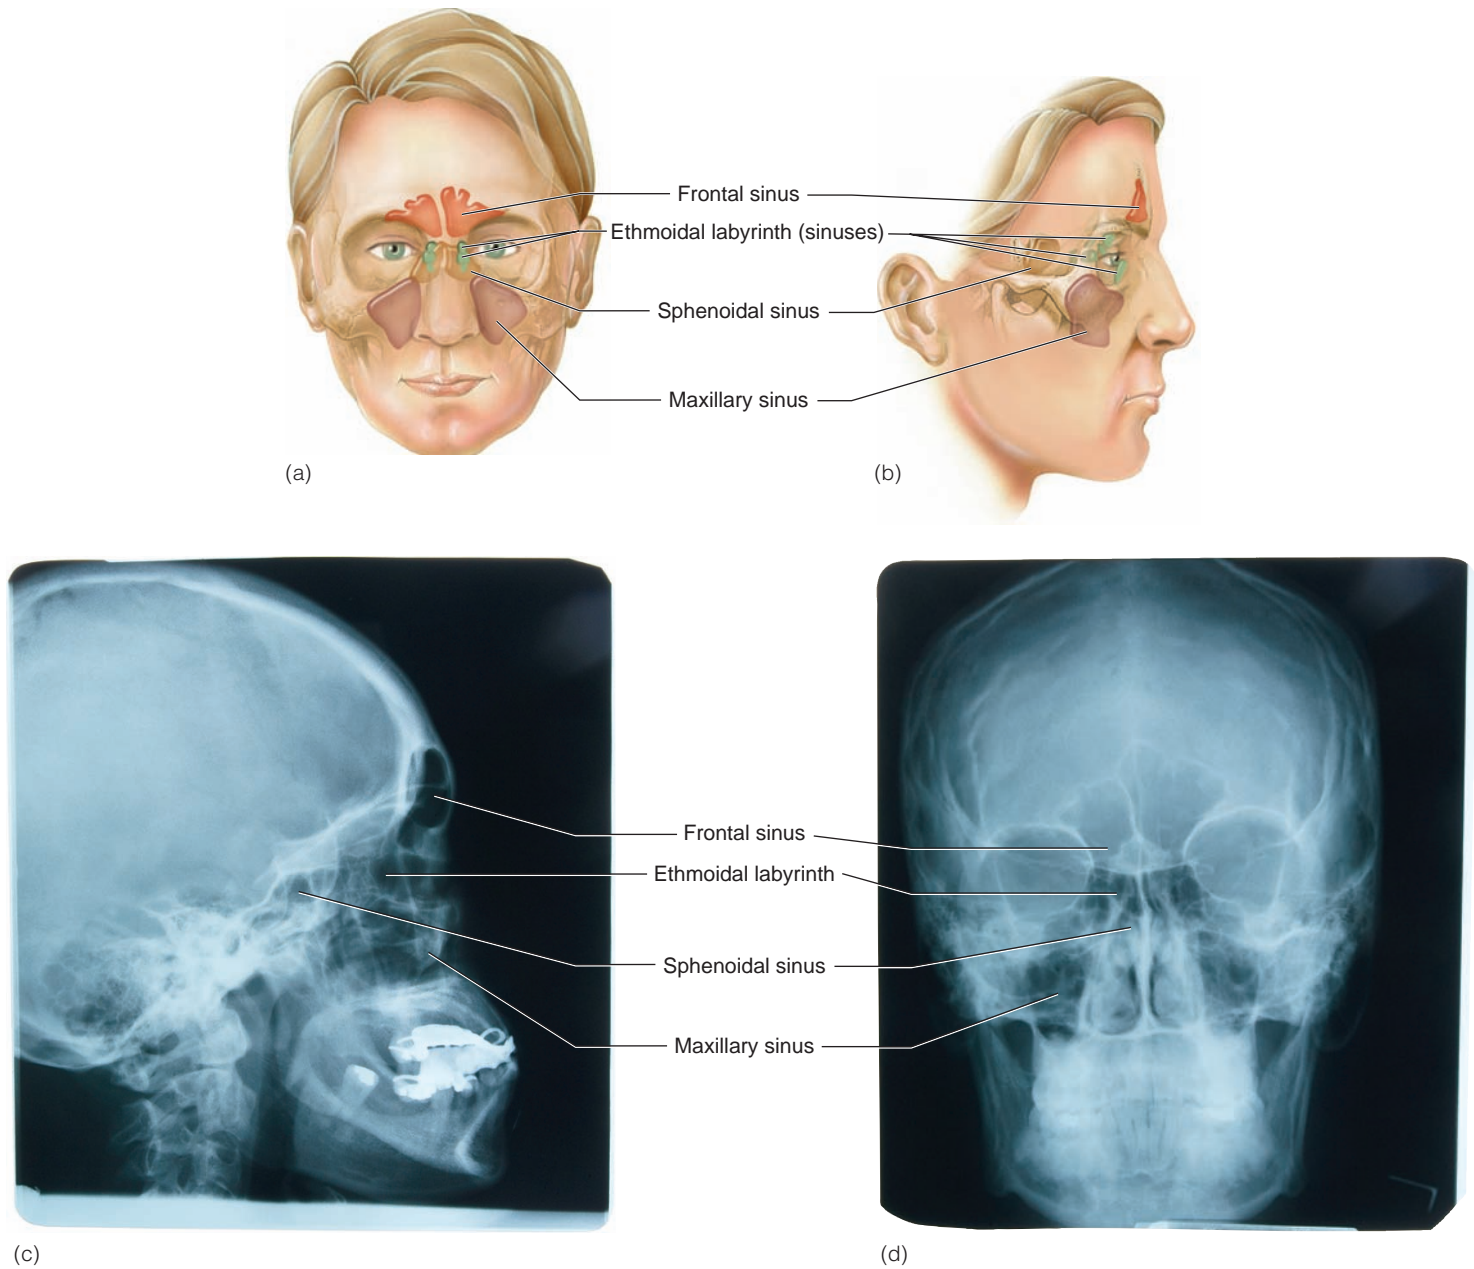

FIGURE 7.10 Paranasal Sinuses

(a) Lateral view. (b) Anterior view. (c) X-ray of the sinuses, lateral view. (d) X-ray of the sinuses, anterior view.

each ethmoid bone are collectively called the ethmoidal labyrinth because it consists of a maze of interconnected ethmoidal air cells. The ethmoidal labyrinth is often referred to as the ethmoidal sinuses.

Interior of the Cranial Cavity

The **cranial cavity** is the cavity in the skull occupied by the brain. The cranial cavity can be exposed by cutting away the calvaria, the upper, domelike portion of the skull. With the calvaria removed, the floor of the cranial cavity can be seen (figure 7.11). That floor

can be divided roughly into anterior, middle, and posterior cranial fossae, which are formed as the developing neurocranium conforms to the shape of the brain.

A prominent ridge, the **crista galli** (kris'tă gäl'ē; rooster's comb), is located in the center of the anterior fossa. The crista galli is a point of attachment for one of the **meninges** (mĕ-nin'jĕz), a thick connective tissue membrane that supports and protects the brain (see chapter 13). On each side of the crista galli is an olfactory fossa. An olfactory bulb rests in each fossa and receives the olfactory nerves for the sense of smell. The **cribriform** (krib'ri-fōrm; sievelike) **plate** of the ethmoid bone forms the floor of each olfactory fossa. The olfactory

FIGURE 7.11 Floor of the Cranial Cavity

The names of the bones are bolded. The roof of the skull has been removed, and the floor is seen from a superior view.

nerves extend from the cranial cavity into the roof of the nasal cavity through sievelike perforations in the cribriform plate called **olfactory foramina** (see figure 7.9a and chapter 15).

Fracture of the Cribriform Plate

The cribriform plate may be fractured in an automobile accident involving a car without air bags, if the driver's nose strikes the steering wheel. Cerebrospinal (ser'ě-brō-spī-nāl, sě-rě'brō-spī-nāl) fluid from the cranial cavity may leak through the fracture into the nose. This leakage is a dangerous sign and requires immediate medical attention because risk of infection is very high.

The body of the sphenoid bone forms a central prominence located within the floor of the cranial cavity. This prominence is modified into a structure resembling a saddle, the **sella turcica** (sel'ă tür'si-kă; Turkish saddle), which is occupied by the pituitary gland. An **optic canal** is located on each side just anterior to the sella turcica. The lesser wings of the sphenoid bone form a ridge to each side of the optic canals. This ridge separates the **anterior cranial fossa** from the **middle cranial fossa**.

The petrous (rocky) part of the temporal bone extends posterolaterally from each side of the sella turcica. This thick, bony ridge is

hollow and contains the middle and inner ears. The petrous ridge separates the middle cranial fossa from the **posterior cranial fossa**.

The **superior orbital fissure**, **foramen rotundum**, **foramen ovale**, **foramen spinosum**, and internal opening of the **carotid canal** are all important openings in the floor of the middle cranial fossa (table 7.6). The **foramen lacerum** (lă-ser'um), in the floor of the carotid canal, is an artifact of the dried skull. In life, it is filled with cartilage.

The prominent **foramen magnum**, through which the spinal cord and brain are connected, is located in the posterior fossa. A **hypoglossal canal** is located on the anterolateral sides of the foramen magnum. **Jugular** (jüg'ū-lar, throat) **foramina** are located on each side of the foramen magnum near the base of the petrous ridge. An **internal acoustic meatus** is located about midway up the face of each ridge (see table 7.6).

Inferior View of the Skull

Seen from below with the mandible removed, the base of the skull is complex, with a number of foramina and specialized surfaces (figure 7.12). The foramen magnum passes through the occipital bone just slightly posterior to the center of the skull base. **Occipital condyles**, smooth points of articulation between the skull and the

TABLE 7.6 Skull Foramina, Fissures, and Canals (See Figures 7.11 and 7.12)

Opening	Bone Containing the Opening	Structures Passing Through Openings
Carotid canal	Temporal	Carotid artery and carotid sympathetic nerve plexus
Ethmoidal foramina, anterior and posterior	Between frontal and ethmoid	Anterior and posterior ethmoidal nerves
External acoustic meatus	Temporal	Sound waves enroute to the eardrum
Foramen lacerum	Between temporal, occipital, and sphenoid	The foramen is filled with cartilage during life; the carotid canal and pterygoid canal cross its superior part but do not actually pass through it
Foramen magnum	Occipital	Spinal cord, accessory nerves, and vertebral arteries
Foramen ovale	Sphenoid	Mandibular division of trigeminal nerve
Foramen rotundum	Sphenoid	Maxillary division of trigeminal nerve
Foramen spinosum	Sphenoid	Middle meningeal artery
Hypoglossal canal	Occipital	Hypoglossal nerve
Incisive foramen (canal)	Between maxillae	Incisive nerve
Inferior orbital fissure	Between sphenoid and maxilla	Infraorbital nerve and blood vessels and zygomatic nerve
Infraorbital foramen	Maxilla	Infraorbital nerve
Internal acoustic meatus	Temporal	Facial nerve and vestibulocochlear nerve
Jugular foramen	Between temporal and occipital	Internal jugular vein, glossopharyngeal nerve, vagus nerve, and accessory nerve
Mandibular foramen	Mandible	Inferior alveolar nerve to the mandibular teeth
Mental foramen	Mandible	Mental nerve
Nasolacrimal canal	Between lacrimal and maxilla	Nasolacrimal (tear) duct
Olfactory foramina	Ethmoid	Olfactory nerves
Optic canal	Sphenoid	Optic nerve and ophthalmic artery
Palatine foramina, anterior and posterior	Palatine	Palatine nerves
Pterygoid canal	Sphenoid	Sympathetic and parasympathetic nerves to the face
Sphenopalatine foramen	Between palatine and sphenoid	Nasopalatine nerve and sphenopalatine blood vessels
Stylomastoid foramen	Temporal	Facial nerve
Superior orbital fissures	Sphenoid	Oculomotor nerve, trochlear nerve, ophthalmic division of trigeminal nerve, abducens nerve, and ophthalmic veins
Supraorbital foramen or notch	Frontal	Supraorbital nerve and vessels
Zygomatofacial foramen	Zygomatic	Zygomatofacial nerve
Zygomatotemporal foramen	Zygomatic	Zygomatotemporal nerve

vertebral column, are located on the lateral and anterior margins of the foramen magnum.

The major entry and exit points for blood vessels that supply the brain can be seen from this view. Blood reaches the brain through the internal carotid arteries, which pass through the **carotid** (ka-rot'id; put to sleep) **canals**, and the vertebral arteries, which pass through the foramen magnum. An internal carotid artery enters the inferior opening of each carotid canal (see figure 7.11) and passes through the carotid canal, which runs anteriomedially through the temporal bone. A thin plate of bone separates the carotid canal from the middle ear, making it possible for a person to hear his or her own heartbeat—for example, when frightened or after running. Most blood leaves the brain through the internal jugular veins, which exit through the jugular foramina located lateral to the occipital condyles.

Two long, pointed **styloid** (sti'loid; stylus- or pen-shaped) **processes** project from the floor of the temporal bone (see figures 7.4 and 7.12). Three muscles involved in movement of the tongue, hyoid bone, and pharynx attach to each process. The **mandibular fossa**, where the mandible articulates with the rest of the skull, is anterior to the mastoid process at the base of the zygomatic arch.

The posterior opening of the nasal cavity is bounded on each side by the vertical bony plates of the sphenoid bone: the **medial pterygoid** (ter'i-goyd; wing-shaped) **plate** and the **lateral pterygoid plate**. The medial and lateral pterygoid muscles, which help move the mandible, attach to the lateral plate (see chapter 10). The **vomer** forms most of the posterior portion of the nasal septum and can be seen between the medial pterygoid plates in the center of the nasal cavity.

The **hard palate**, or **bony palate**, forms the floor of the nasal cavity. Sutures join four bones to form the hard palate; the palatine

FIGURE 7.12 Inferior View of the Skull

The names of the bones are bolded.

processes of the two maxillary bones form the anterior two-thirds of the palate, and the horizontal plates of the two palatine bones form the posterior one-third of the palate. The tissues of the soft palate extend posteriorly from the hard palate. The hard and soft palates separate the nasal cavity from the mouth, enabling humans to chew and breathe at the same time.

Cleft Lip or Palate

During development, the facial bones sometimes fail to fuse with one another. A **cleft lip** results if the maxillae do not form normally, and a **cleft palate** occurs when the palatine processes of the maxillae do not fuse with one another. A cleft palate produces an opening between the nasal and oral cavities, making it difficult to eat or drink or to speak distinctly. An artificial palate may be inserted into a newborn's mouth until the palate can be repaired. Approximately 1 in 700 babies in the United States is born with a facial cleft. A cleft lip alone, or cleft lip and palate, occurs approximately once in every 1000 births and is more common in males than in females. A cleft palate alone occurs approximately once in every 2000 births and is more common in females than in males. A cleft lip and cleft palate may also occur in the same person.

- 4 List the seven bones that form the orbit of the eye.
- 5 Describe the bones and cartilage found in the nasal septum.
- 6 What is a sinus? What are the functions of sinuses? Give the location of the paranasal sinuses.
- 7 Name the bones that form the hard palate. What is the function of the hard palate?
- 8 Through what foramen does the brainstem connect to the spinal cord? Name the foramina that contain nerves for the senses of vision (optic nerve), smell (olfactory nerves), and hearing (vestibulocochlear nerve).
- 9 Name the foramina through which the major blood vessels enter and exit the skull.
- 10 List the places where these muscles attach to the skull: neck muscles, throat muscles, muscles of mastication, muscles of facial expression, and muscles that move the eyeballs.

Bones of the Skull

The skull, or cranium, is composed of 22 separate bones (see table 7.1; table 7.7). In addition, the skull contains six **auditory ossicles**, which function in hearing (see chapter 15). Each

TABLE 7.7 Skull Bones

Styloid process

Stylomastoid foramen (shown in figure 7.12)

Zygomatic process

Special Features

Contains the middle and inner ear and the mastoid air cells

Place where the mandible articulates with the rest of the skull

Description

Canal through which the internal carotid artery enters the cranial cavity

External canal of the ear; carries sound to the ear

Opening through which the facial (cranial nerve VII) and vestibulocochlear (cranial nerve VIII) nerves enter the petrous portion of the temporal bone

Foramen through which the internal jugular vein exits the cranial cavity

Articulation point between the mandible and skull

Attachment point for muscles moving the head and for a hyoid muscle

Depression in the floor of the cranial cavity formed by the temporal lobes of the brain

Thick, "rocky" portion of the temporal bone

Flat, lateral portion of the temporal bone

Attachment for muscles of the tongue, throat, and hyoid bone

Foramen through which the facial nerve (cranial nerve VII) exits the skull

Helps form the bony bridge from the cheek to just anterior to the ear; attachment for a muscle moving the mandible

TABLE 7.7 Skull Bones—Continued

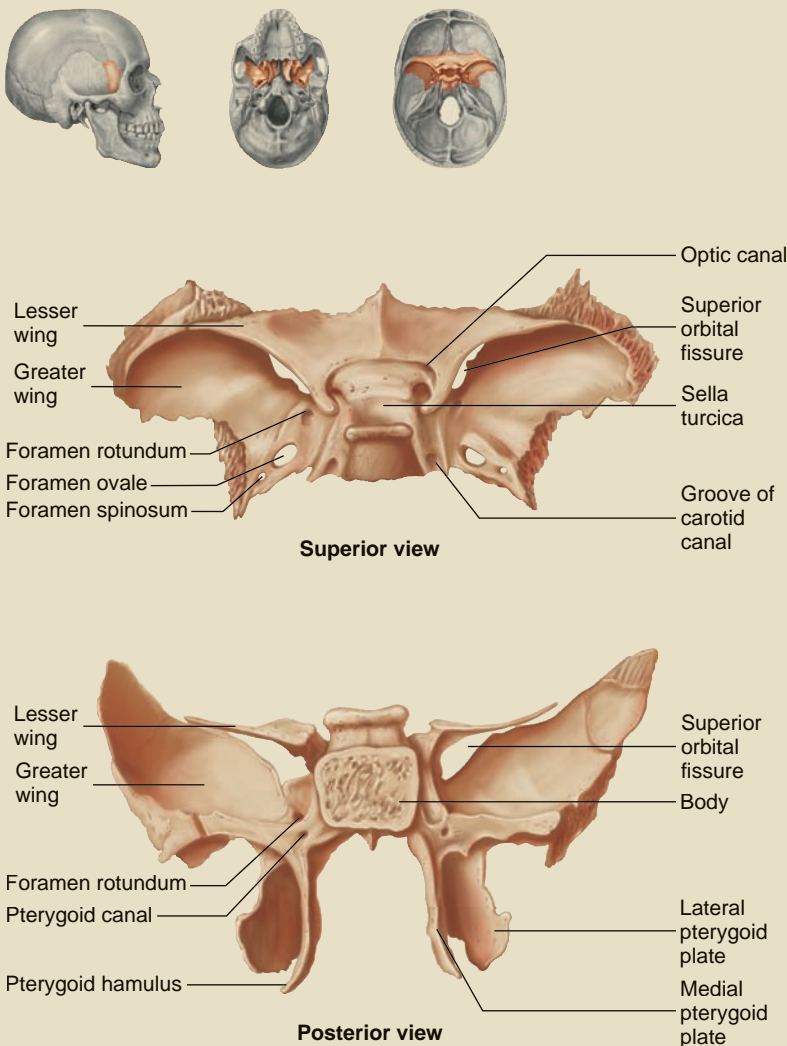

(c) Frontal Bone—Anterior View

Landmark	Description
Glabella	Area between the supraorbital margins
Nasal spine	Superior part of the nasal bridge
Orbital plate	Roof of the orbit
Supraorbital foramen	Opening through which nerves and vessels exit the skull to the skin of the forehead
Supraorbital margin	Ridge forming the anterior superior border of the orbit
Zygomatic process	Connects to the zygomatic bone; helps form the lateral margin of the orbit

Special Features
 Forms the forehead and roof of the orbit
 Contains the frontal sinus

(d) Sphenoid Bone—Superior and Posterior Views

Landmark	Description
Body	Thickest part of the bone which articulates with the occipital bone
Foramen ovale	Opening through which a branch of the trigeminal nerve (cranial nerve V) exits the cranial cavity
Foramen rotundum	Opening through which a branch of the trigeminal nerve (cranial nerve V) exits the cranial cavity
Foramen spinosum	Opening through which a major artery to the meninges (membranes around the brain) enters the cranial cavity
Greater wing	Forms the floor of the middle cranial fossa; several foramina pass through this wing
Lateral pterygoid plate	Attachment point for muscles of mastication (chewing)
Lesser wing	Superior border of the superior orbital fissure
Medial pterygoid plate	Posterolateral walls of the nasal cavity
Optic canal	Opening through which the optic nerve (cranial nerve II) passes from the orbit to the cranial cavity
Pterygoid canal	Opening through which nerves and vessels exit the cranial cavity
Pterygoid hamulus	Process around which the tendon from a muscle to the soft palate passes
Sella turcica	Fossa containing the pituitary gland
Superior orbital fissure	Opening through which nerves and vessels enter the orbit from the cranial cavity

Special Feature
 Contains the sphenoidal sinus

TABLE 7.7 Skull Bones—Continued

(e) Occipital Bone—Inferior View

Landmark	Description
Condyle	Articulation point between the skull and first vertebra
External occipital protuberance	Attachment point for a strong ligament (nuchal ligament) in the back of the neck
Foramen magnum	Opening around the point where the brain and spinal cord connect
Hypoglossal canal (shown in figure 7.11)	Opening through which the hypoglossal nerve (cranial nerve XII) passes
Inferior nuchal line	Attachment point for neck muscles
Posterior cranial fossa (shown in figure 7.11)	Depression in the posterior of the cranial cavity formed by the cerebellum
Superior nuchal line	Attachment point for neck muscles
Special Feature	
	Forms the base of the skull

(f) Zygomatic Bone (Right)—Lateral View

Landmark	Description
Frontal process	Connection to the frontal bone; helps form the lateral margin of the orbit
Infraorbital margin	Ridge forming the inferior border of the orbit
Temporal process	Helps form the bony bridge from the cheek to just anterior to the ear
Zygomaticofacial foramen	Opening through which a nerve and vessels exit the orbit to the face
Special Features	
	Forms the prominence of the cheek
	Forms the anterolateral wall of the orbit

TABLE 7.7 Skull Bones—Continued

(g) Ethmoid Bone—Superior, Lateral, and Anterior Views

Landmark	Description
Cribriform plate	Contains numerous olfactory foramina through which branches of the olfactory nerve (cranial nerve I) enter the cranial cavity from the nasal cavity
Crista galli	Attachment for meninges (membranes around brain)
Ethmoidal foramina (shown in figure 7.8)	Openings through which nerves and vessels pass from the orbit to the nasal cavity
Middle nasal concha	Ridge extending into the nasal cavity; increases surface area, helps warm and moisten air in the cavity
Orbital plate	Forms the medial wall of the orbit
Perpendicular plate	Forms the superior portion of the nasal septum
Superior nasal concha	Ridge extending into the nasal cavity; increases surface area, helps warm and moisten air in the cavity

Special Features

Forms part of the nasal septum and part of the lateral walls and roof of the nasal cavity

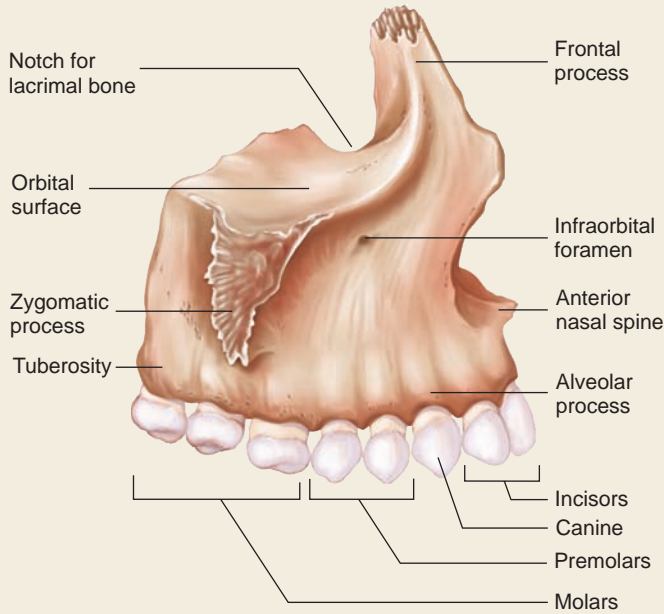

Contains the ethmoidal labyrinth, or ethmoidal sinuses. The labyrinth is divided into anterior, middle, and posterior ethmoidal cells.

TABLE 7.7 Skull Bones—Continued

TABLE 7.7 Skull Bones—Continued

(l) Mandible (Right Half)—Medial and Lateral Views

Landmark	Description
Alveolar process	Ridge containing the teeth
Angle	Corner between the body and ramus
Body	Major, horizontal portion of the bone
Condylar process	Extension containing the mandibular condyle
Coronoid process	Attachment for a muscle of mastication
Mandibular condyle	Helps form the temporomandibular joint (the point of articulation between the mandible and the rest of the skull)
Mandibular foramen	Opening through which nerves and vessels to the mandibular teeth enter the bone
Mandibular notch	Depression between the condylar process and the coronoid process
Mental foramen	Opening through which a nerve and vessels exit the mandible to the skin of the chin
Mylohyoid line	Attachment point of the mylohyoid muscle
Oblique line	Ridge from the anterior edge of the ramus onto the body of the mandible
Ramus	Major, nearly vertical portion of the bone

Special Features
 The only bone in the skull that is freely movable relative to the rest of the skull bones
 Holds the lower teeth

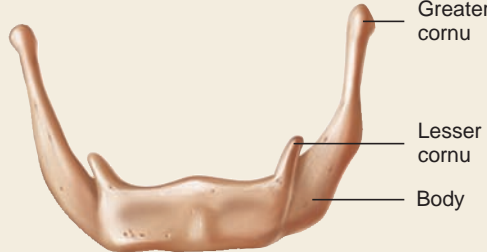

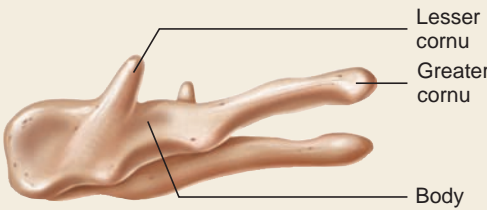

(m) Vomer—Anterior and Lateral Views

temporal bone holds one set of auditory ossicles, which consists of the malleus, incus, and stapes. These bones cannot be observed unless the temporal bones are cut open.

The 22 bones of the skull are divided into two portions: the neurocranium and the viscerocranium. The **neurocranium**, or **braincase**, consists of 8 bones that immediately surround and protect the brain. They include the paired parietal and temporal bones and the unpaired frontal, occipital, sphenoid, and ethmoid bones.

The 14 bones of the **viscerocranium**, or **facial bones**, form the structure of the face in the anterior skull. They are the maxilla (2), zygomatic (2), palatine (2), lacrimal (2), nasal (2), inferior nasal concha (2), mandible (1), and vomer (1) bones. The frontal and ethmoid bones, which are part of the neurocranium, also contribute to the face. The mandible is often listed as a facial bone, even though it is not part of the intact skull.

The facial bones protect the major sensory organs located in the face: the eyes, nose, and tongue. The bones of the face also provide attachment points for the muscles involved in **mastication** (mas-ti-kā'shūn; chewing), facial expression, and eye movement. The jaws (mandible and maxillae) possess **alveolar** (al-vē'ō-lār)

processes with sockets for the attachment of the teeth. The bones of the face and their associated soft tissues determine the unique facial features of each individual.

11 Name the bones of the neurocranium and viscerocranium. What functions are accomplished by each group?

Hyoid Bone

The **hyoid bone** (table 7.8), which is unpaired, is often listed as part of the viscerocranium because it has a common developmental origin with the bones of the face. It is not, however, part of the adult skull (see table 7.1). The hyoid bone has no direct bony attachment to the skull. Instead, muscles and ligaments attach it to the skull, so the hyoid “floats” in the superior aspect of the neck just below the mandible. The hyoid bone provides an attachment point for some tongue muscles, and it is an attachment point for important neck muscles that elevate the larynx during speech or swallowing.

12 Where is the hyoid bone located and what does it do?

Vertebral Column

The **vertebral column** usually consists of 26 bones, which can be divided into five regions (figure 7.13). Seven **cervical vertebrae** (ver'tě-brē), 12 **thoracic vertebrae**, 5 **lumbar vertebrae**, 1 **sacral bone**, and 1 **coccygeal** (kok-sij'ē-äl) bone make up the vertebral column. The cervical vertebrae are designated “C,” thoracic “T,” and lumbar “L.” A number after the letter indicates the number of the vertebra, from superior to inferior, within each vertebral region. The developing embryo has about 33–34 vertebrae, but the 5 sacral vertebrae fuse to form 1 bone, and the 4 or 5 coccygeal bones usually fuse to form 1 bone.

The five regions of the adult vertebral column have four major curvatures (see figure 7.13). Two of the curves appear during embryonic development and reflect the C-shaped curve of the embryo and fetus within the uterus. When the infant raises its head in the first few months after birth, a secondary curve, which is convex anteriorly, develops in the neck. Later, when the infant learns to sit and then walk, the lumbar portion of the column also becomes convex anteriorly. Thus, in the adult vertebral column, the cervical region is convex anteriorly, the thoracic region is concave anteriorly, the lumbar region is convex anteriorly, and the sacral and coccygeal regions together are concave anteriorly.

Abnormal Spinal Curvatures

Lordosis (lōr-dō'sis; hollow back) is an exaggeration of the convex curve of the lumbar region. **Kyphosis** (kī-fō'sis; hump back) is an exaggeration of the concave curve of the thoracic region. **Scoliosis** (skō'lē-ō'sis) is an abnormal lateral and rotational curvature of the vertebral column, which is often accompanied by secondary abnormal curvatures, such as kyphosis (figure A).

FIGURE A Scoliosis

FIGURE 7.13 Complete Vertebral Column Viewed from the Left Side

TABLE 7.9 General Structure of a Vertebra

Feature	Description
Body	Disk-shaped; usually the largest part with flat surfaces directed superiorly and inferiorly; forms the anterior wall of the vertebral foramen; intervertebral disks are located between the bodies
Vertebral foramen	Hole in each vertebra through which the spinal cord passes; adjacent vertebral foramina form the vertebral canal
Vertebral arch	Forms the lateral and posterior walls of the vertebral foramen; possesses several processes and articular surfaces
Pedicle	Foot of the arch with one on each side; forms the lateral walls of the vertebral foramen
Lamina	Posterior part of the arch; forms the posterior wall of the vertebral foramen
Transverse process	Process projecting laterally from the junction of the lamina and pedicle; a site of muscle attachment
Spinous process	Process projecting posteriorly at the point where the two laminae join; a site of muscle attachment; strengthens the vertebral column and allows for movement
Articular processes	Superior and inferior projections containing articular facets where vertebrae articulate with each other; strengthen the vertebral column and allow for movement
Intervertebral notches	Form intervertebral foramina between two adjacent vertebrae through which spinal nerves exit the vertebral canal

(d) Posterior view

General Plan of the Vertebrae

The vertebral column performs five major functions: (1) It supports the weight of the head and trunk, (2) it protects the spinal cord, (3) it allows spinal nerves to exit the spinal cord, (4) it provides a site for muscle attachment, and (5) it permits movement of the head and trunk. The general structure of a vertebra is outlined

in table 7.9. Each vertebra consists of a body, an arch, and various processes. The weight-bearing portion of the vertebra is a bony disk called the **body**.

The **vertebral arch** projects posteriorly from the body. The arch is divided into left and right halves, and each half has two parts: the **pedicle** (ped'i-kl; foot), which is attached to the body, and the **lamina**

(lam'i-na; thin plate), which joins the lamina from the opposite half of the arch. The vertebral arch and the posterior part of the body surround a large opening called the **vertebral foramen**. The vertebral foramina of adjacent vertebrae combine to form the **vertebral canal**, which contains the spinal cord or cauda equina (see figure 12.1). The vertebral arches and bodies protect the spinal cord.

A **transverse process** extends laterally from each side of the arch between the lamina and pedicle, and a single **spinous process** is present at the junction between the two laminae. The spinous processes can be seen and felt as a series of lumps down the midline of the back (figure 7.14). Much vertebral movement is accomplished by the contraction of the skeletal muscles attached to the transverse and spinous processes (see chapter 10).

Spinal nerves exit the spinal cord through the **intervertebral foramina** (see table 7.9 and figure 7.13). Each intervertebral foramen is formed by **intervertebral notches** in the pedicles of adjacent vertebrae.

Movement and additional support of the vertebral column are made possible by the vertebral processes. Each vertebra has two **superior** and two **inferior articular processes**, with the superior processes of one vertebra articulating with the inferior processes of the next superior vertebra (see table 7.9c & d). Overlap of these processes increases the rigidity of the vertebral column. The region of overlap and articulation between the superior and inferior articular processes creates a smooth **articular facet** (fas'et; little face) on each articular process.

FIGURE 7.14 Surface View of the Back Showing the Scapula and Vertebral Spinous Processes

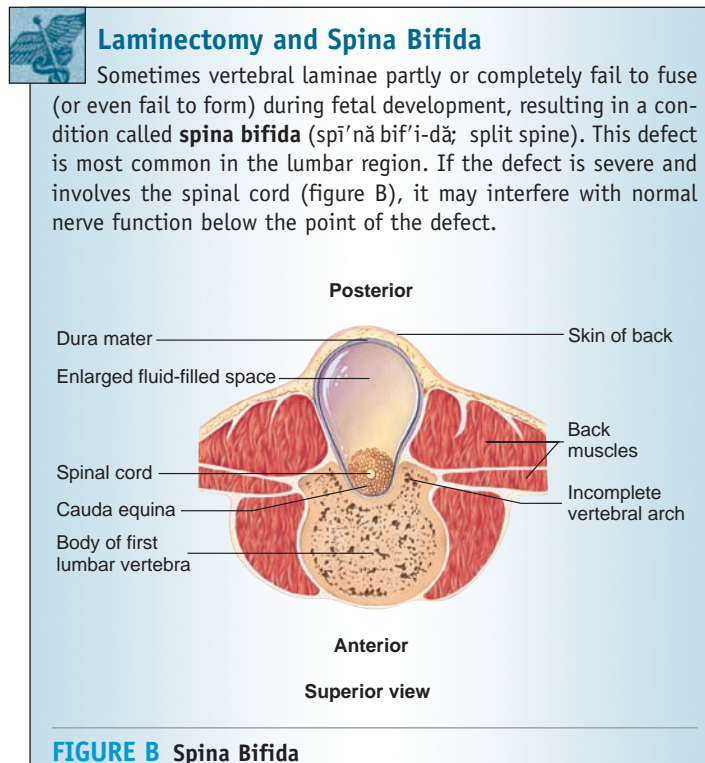

FIGURE B Spina Bifida

Intervertebral Disks

During life, **intervertebral disks** of fibrocartilage, which are located between the bodies of adjacent vertebrae (see table 7.9, figure 7.13; figure 7.15), provide additional support and prevent the vertebral

(a) Lateral view

(b) Superior view

FIGURE 7.15 Intervertebral Disk

Herniated, or Ruptured, Intervertebral Disk

A **herniated**, or **ruptured**, **disk** results from the breakage or ballooning of the annulus fibrosus with a partial or complete release of the nucleus pulposus (figure C). The herniated part of the disk may push against and compress the spinal cord, cauda equina, or spinal nerves, compromising their normal function and producing pain. Herniation of the inferior lumbar intervertebral disks is most common, but herniation of the inferior cervical disks is almost as common.

Herniated, or ruptured, disks can be repaired in one of several ways. One procedure uses prolonged bed rest and is based on the tendency for the herniated part of the disk to recede and the annulus fibrosus to repair itself. In many cases, however, surgery is required. A **laminectomy** is the removal of a vertebral lamina, or vertebral arch. A **hemilaminectomy** is the removal of a portion of a vertebral lamina. These procedures are performed to reduce the compression of the spinal nerve or spinal cord. **Fenestration** involves removal of the nucleus pulposus, leaving the annulus fibrosus intact. In extreme cases, the entire damaged disk is removed. To enhance the stability of the vertebral column, a piece of hipbone is sometimes inserted into the space previously occupied by the disk, and the adjacent vertebrae become fused by bone across the gap.

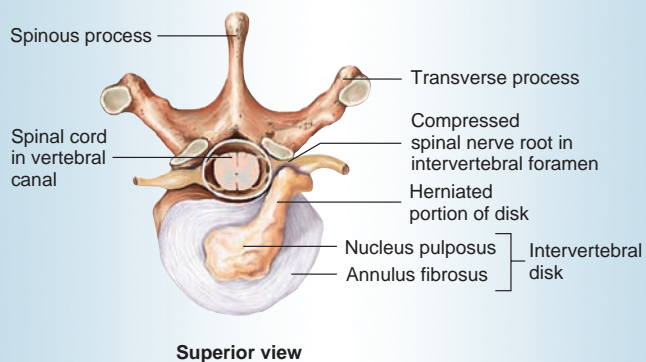

FIGURE C Herniated Disk

Part of the annulus fibrosus has been removed to reveal the nucleus pulposus in the center of the disk and in the intervertebral foramen.

bodies from rubbing against each other. The intervertebral disks consist of an external **annulus fibrosus** (an'ū-lūs fī-brō'sūs; fibrous ring) and an internal, gelatinous **nucleus pulposus** (pūlpō'sūs; pulp). The disk becomes more compressed with increasing age so that the distance between vertebrae and therefore the overall height of the individual decreases. The annulus fibrosus also becomes weaker with age and more susceptible to herniation.

Regional Differences in Vertebrae

The vertebrae of each region of the vertebral column have specific characteristics that tend to blend at the boundaries between regions (table 7.10). The **cervical vertebrae** (see figure 7.13; figure 7.16a–g) have very small bodies; most have **bifid** (bi'fid; split) **spinous processes**, and a **transverse foramen** in each transverse process through which the vertebral arteries extend toward the head. Only cervical vertebrae have transverse foramina.

The first cervical vertebra is called the **atlas** (see figure 7.16a) because it holds up the head, just as Atlas in classical mythology held up the world. The atlas vertebra has no body and no spinous process, but it has large superior articular facets, where it articulates with the occipital condyles on the base of the skull. This joint allows the head to move in a “yes” motion or to tilt from side to side. The second cervical vertebra is called the **axis** (figure 7.16c and d) because a considerable amount of rotation occurs at this vertebra to produce a “no” motion of the head. The axis has a highly modified process on the superior side of its small body called the **dens**, or **odontoid** (ō-don'toyd; tooth-shaped), **process** (both *dens* and *odontoid* mean tooth-shaped). The dens fits into the enlarged vertebral foramen of the atlas, and the latter rotates around this process. The spinous process of the seventh cervical vertebra, which is not bifid, is quite pronounced and often can be seen and felt as a lump between the shoulders (see figure 7.14). The most prominent spinous process in this area is called the **vertebral prominens**. This is usually the spinous process of the seventh cervical vertebra, but it may be that of the sixth cervical

TABLE 7.10 Comparison of Vertebral Regions

Feature	Cervical	Thoracic	Lumbar
Body	Absent in C1, small in others	Medium-sized with articular facets for ribs	Large
Transverse process	Transverse foramen	Articular facets for ribs, except T11 and T12	Square
Spinous process	Absent in C1, bifid in others, except C7	Long, angled inferiorly	Square
Articular facets	Face superior/inferior	Face obliquely	Face medial/lateral

(f) Fifth cervical vertebra, lateral view. (g) Cervical vertebrae together from an anterolateral view.

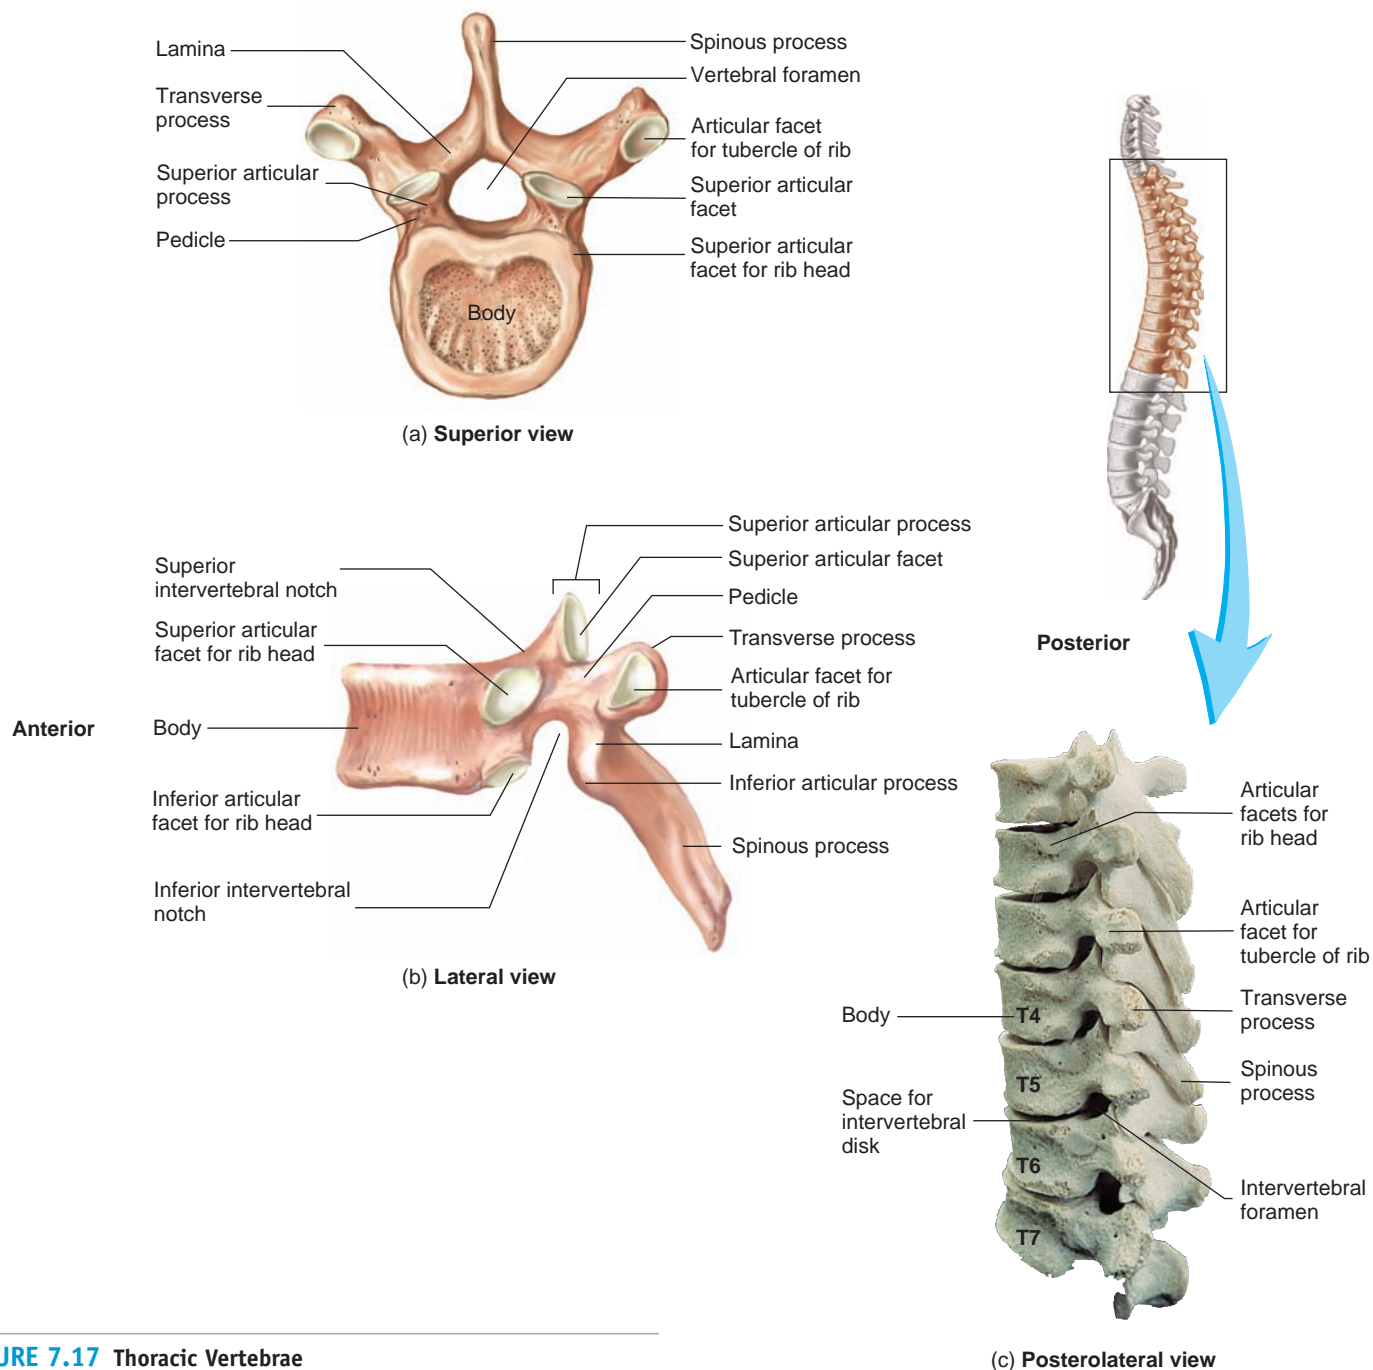

FIGURE 7.17 Thoracic Vertebrae

vertebra or even the first thoracic. The superior articular facets face superiorly and the inferior articular facets face inferiorly.

The **thoracic vertebrae** (see figure 7.13; figure 7.17) possess long, thin spinous processes, which are directed inferiorly, and they have relatively long transverse processes. The first 10 thoracic vertebrae have articular facets on their transverse processes, where they articulate with the tubercles of the ribs. Additional articular facets are on the superior and inferior margins of the body where the heads of the ribs articulate. The head of most ribs articulates with the inferior articular facet of

one vertebra and the superior articular facet for the rib head on the next vertebra down.

The **lumbar vertebrae** (see figure 7.13; figure 7.18) have large, thick bodies and heavy, rectangular transverse and spinous processes. The superior articular facets face medially, and the inferior articular facets face laterally. When the superior articular surface of one lumbar vertebra joins the inferior articulating surface of another lumbar vertebra, the resulting arrangement adds strength to the inferior portion of the vertebral column and limits rotation of the lumbar vertebrae.

FIGURE 7.18 Lumbar Vertebrae

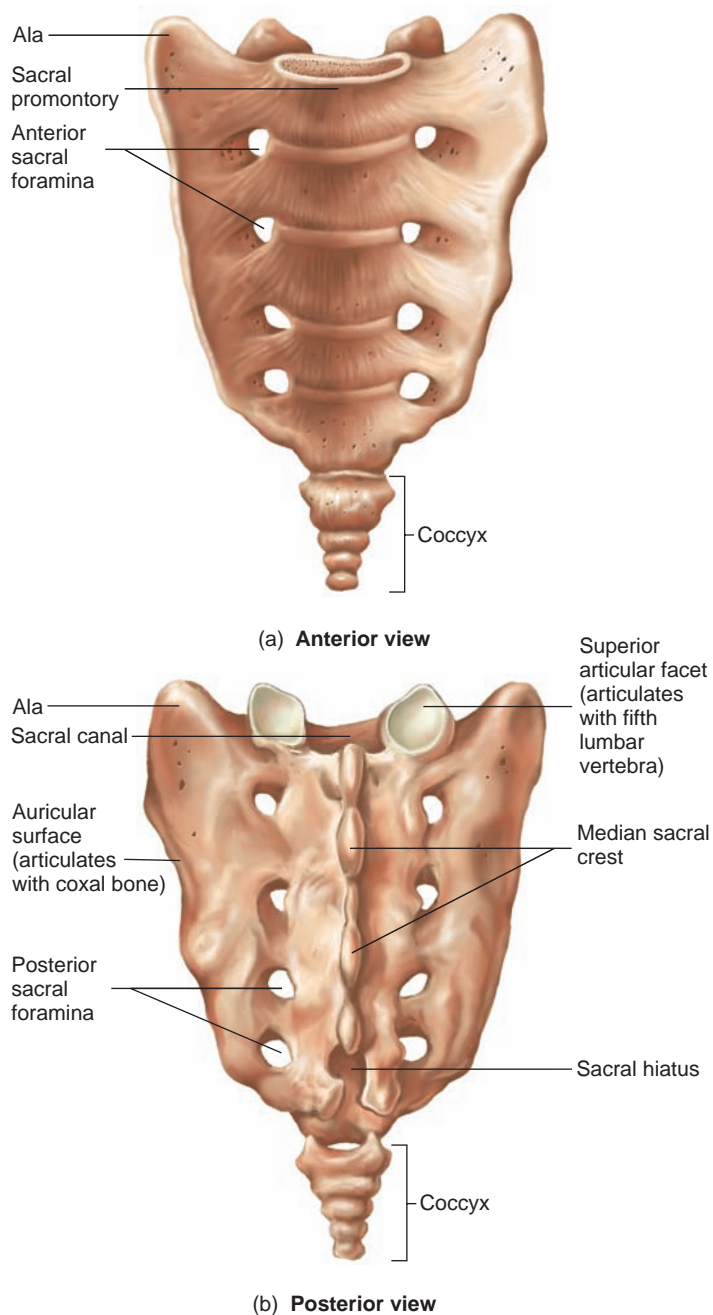

FIGURE 7.19 Sacrum

PREDICT 3

Why are the lumbar vertebrae more massive than the cervical vertebrae?

The **sacral** (sā'kräl) **vertebrae** (see figure 7.13; figure 7.19) are highly modified, compared with the others. These five vertebrae are fused into a single bone called the **sacrum** (sā'krüm).

The transverse processes of the sacral vertebrae fuse to form the lateral parts of the sacrum. The superior surfaces of the lateral parts are wing-shaped areas called the **alae** (ā'lē; wings). Much

of the lateral surfaces of the sacrum are ear-shaped **auricular surfaces**, which join the sacrum to the pelvic bones. The spinous processes of the first four sacral vertebrae partially fuse to form projections, called the **median sacral crest**, along the dorsal surface of the sacrum. The spinous process of the fifth vertebra does not form, thereby leaving a **sacral hiatus** (hī-ā'tūs) at the inferior end of the sacrum, which is often the site of anesthetic injections. The intervertebral foramina are divided into anterior and posterior foramina, called the **sacral foramina**, which are lateral to the midline. Anterior and posterior branches of the spinal nerves pass through these foramina. The anterior edge of the body of the first sacral vertebra bulges to form the **sacral promontory** (see figure 7.13), a landmark that separates the abdominal cavity from the pelvic cavity. The sacral promontory can be felt during a vaginal examination, and it is used as a reference point during measurement of the pelvic inlet.

The **coccyx** (kok'siks; shaped like a cuckoo's bill; see figures 7.13 and 7.19), or tailbone, is the most inferior portion of the vertebral column and usually consists of three to five more or less fused vertebrae that form a triangle, with the apex directed inferiorly. The coccygeal vertebrae are greatly reduced in size relative to the other vertebrae and have neither vertebral foramina nor well-developed processes.

- 13** Describe the four major curvatures of the vertebral column; explain what causes them and when they develop. Define scoliosis, kyphosis, and lordosis.
- 14** Describe the structures forming the vertebral foramen. Where do spinal nerves exit the vertebral column?
- 15** Describe how superior and inferior articular processes help support and allow movement of the vertebral column.
- 16** Name and give the number of each type of vertebra. Describe the characteristics that distinguish the different types of vertebrae.

Whiplash

Whiplash is a traumatic hyperextension of the cervical vertebrae. The head is a heavy object at the end of a flexible column, and it may become hyperextended when the head "snaps back" as a result of a sudden acceleration of the body. This commonly occurs in "rear-end" automobile accidents, or athletic injuries, in which the body is quickly forced forward while the head remains stationary. Common injuries resulting from whiplash are fracture of the spinous processes of the cervical vertebrae and herniated disks, with an anterior tear of the annulus fibrosus. These injuries can cause posterior pressure on the spinal cord or spinal nerves and strained or torn muscles, tendons, and ligaments.

Variation in Lumbar Vertebrae

The fifth lumbar vertebra or first coccygeal vertebra may become fused into the sacrum. Conversely, the first sacral vertebra may fail to fuse with the rest of the sacrum, resulting in six lumbar vertebrae.

Vertebral Column Injuries

Because the cervical vertebrae are rather delicate and have small bodies, dislocations and fractures are more common in this area than in other regions of the column. Because the lumbar vertebrae have massive bodies and carry a large amount of weight, fractures are less common, but ruptured intervertebral disks are more common in this area than in other regions of the column. The coccyx is easily broken in a fall in which a person sits down hard on a solid surface.

Thoracic Cage

The **thoracic cage**, or **rib cage**, protects the vital organs within the thorax and forms a semi-rigid chamber that can increase and decrease in volume during respiration. It consists of the thoracic vertebrae, the ribs with their associated costal (rib) cartilages, and the sternum (figure 7.20a).

Ribs and Costal Cartilages

The 12 pairs of **ribs** are classified as either true or false ribs. The superior 7 pairs are called **true ribs**, or **vertebrosternal** (ver'tē'brō-ster'nāl) **ribs**; they articulate with the thoracic vertebrae and attach directly through their **costal cartilages** to the sternum. The inferior 5 pairs, or **false ribs**, articulate with the thoracic vertebrae but do not attach directly to the sternum. The false ribs consist of two groups. The eighth, ninth, and tenth ribs, the **vertebrochondral** (ver'tē-brō-kon'drāl) **ribs**, are joined by a common cartilage to the costal cartilage of the seventh rib, which, in turn, is attached to the sternum. Two of the false ribs, the eleventh and twelfth ribs, are also called **floating**, or **vertebral**, **ribs** because they do not attach to the sternum. The costal cartilages are flexible and permit the thoracic cage to expand during respiration.

Most ribs have two points of articulation with the thoracic vertebrae (figure 7.20b and c). First, the **head** articulates with the bodies of two adjacent vertebrae and the intervertebral disk between them. The head of each rib articulates with the inferior articular facet of the superior vertebra and the superior articular facet of the inferior vertebra. Second, the **tubercle** articulates with the transverse process of the inferior vertebra. The **neck** is between the head and tubercle, and the **body**, or shaft, is the main part of the rib. The **angle** of the rib is located just lateral to the tubercle and is the point of greatest curvature.

Rib Defects

A **separated rib** is a dislocation between a rib and its costal cartilage. As a result of the dislocation, the rib can move, override adjacent ribs, and cause pain. Separation of the tenth rib is the most common.

The angle is the weakest part of the rib and may be fractured in a crushing accident, such as an automobile accident.

The transverse processes of the seventh cervical vertebra may form separate bones called **cervical ribs**. These ribs may be just tiny pieces of bone or may be long enough to reach the sternum. The first lumbar vertebra may develop lumbar ribs.

Sternum

The **sternum**, or breastbone, has been described as being sword-shaped and has three parts (see figure 7.20a). The **manubrium** (mä-noo'brē-üm; handle) is the sword handle, the **body**, or gladiolus (sword), is the blade, and the **xiphoid** (zi'foyed; sword) **process** is the sword tip. The superior margin of the manubrium has a **jugular** (neck), or **suprasternal notch** in the midline, which can be easily felt at the anterior base of the neck (figure 7.21). The first rib and the clavicle articulate with the manubrium. The point at which the manubrium joins the body of the sternum can be felt as a prominence on the anterior thorax called the **sternal angle** (see figure 7.20a). The cartilage of the second rib attaches to the sternum at the sternal angle, the third through seventh ribs attach to the body of the sternum, and no ribs attach to the xiphoid process.

Sternal Angle and Thoracic Landmarks

The sternal angle is important clinically because the second rib is found lateral to it and can be used as a starting point for counting the other ribs. Counting ribs is important because they are landmarks used to locate structures in the thorax, such as areas of the heart. The sternum often is used as a site for taking red bone marrow samples because it is readily accessible. Because the xiphoid process of the sternum is attached only at its superior end, it may be broken during cardiopulmonary resuscitation (CPR) and then may lacerate the liver.

- 17 *What is the function of the thoracic (rib) cage? Distinguish among true, false, and floating ribs, and give the number of each type.*
- 18 *Describe the articulation of the ribs with thoracic vertebrae.*
- 19 *Describe the parts of the sternum. Name the structures that attach to, or articulate with, the sternum.*

APPENDICULAR SKELETON

The appendicular skeleton (see figure 7.1) consists of the bones of the **upper** and **lower limbs** and the **girdles** by which they are attached to the body. The term *girdle* means a belt or a zone and refers to the two zones, pectoral and pelvic, where the limbs are attached to the body.

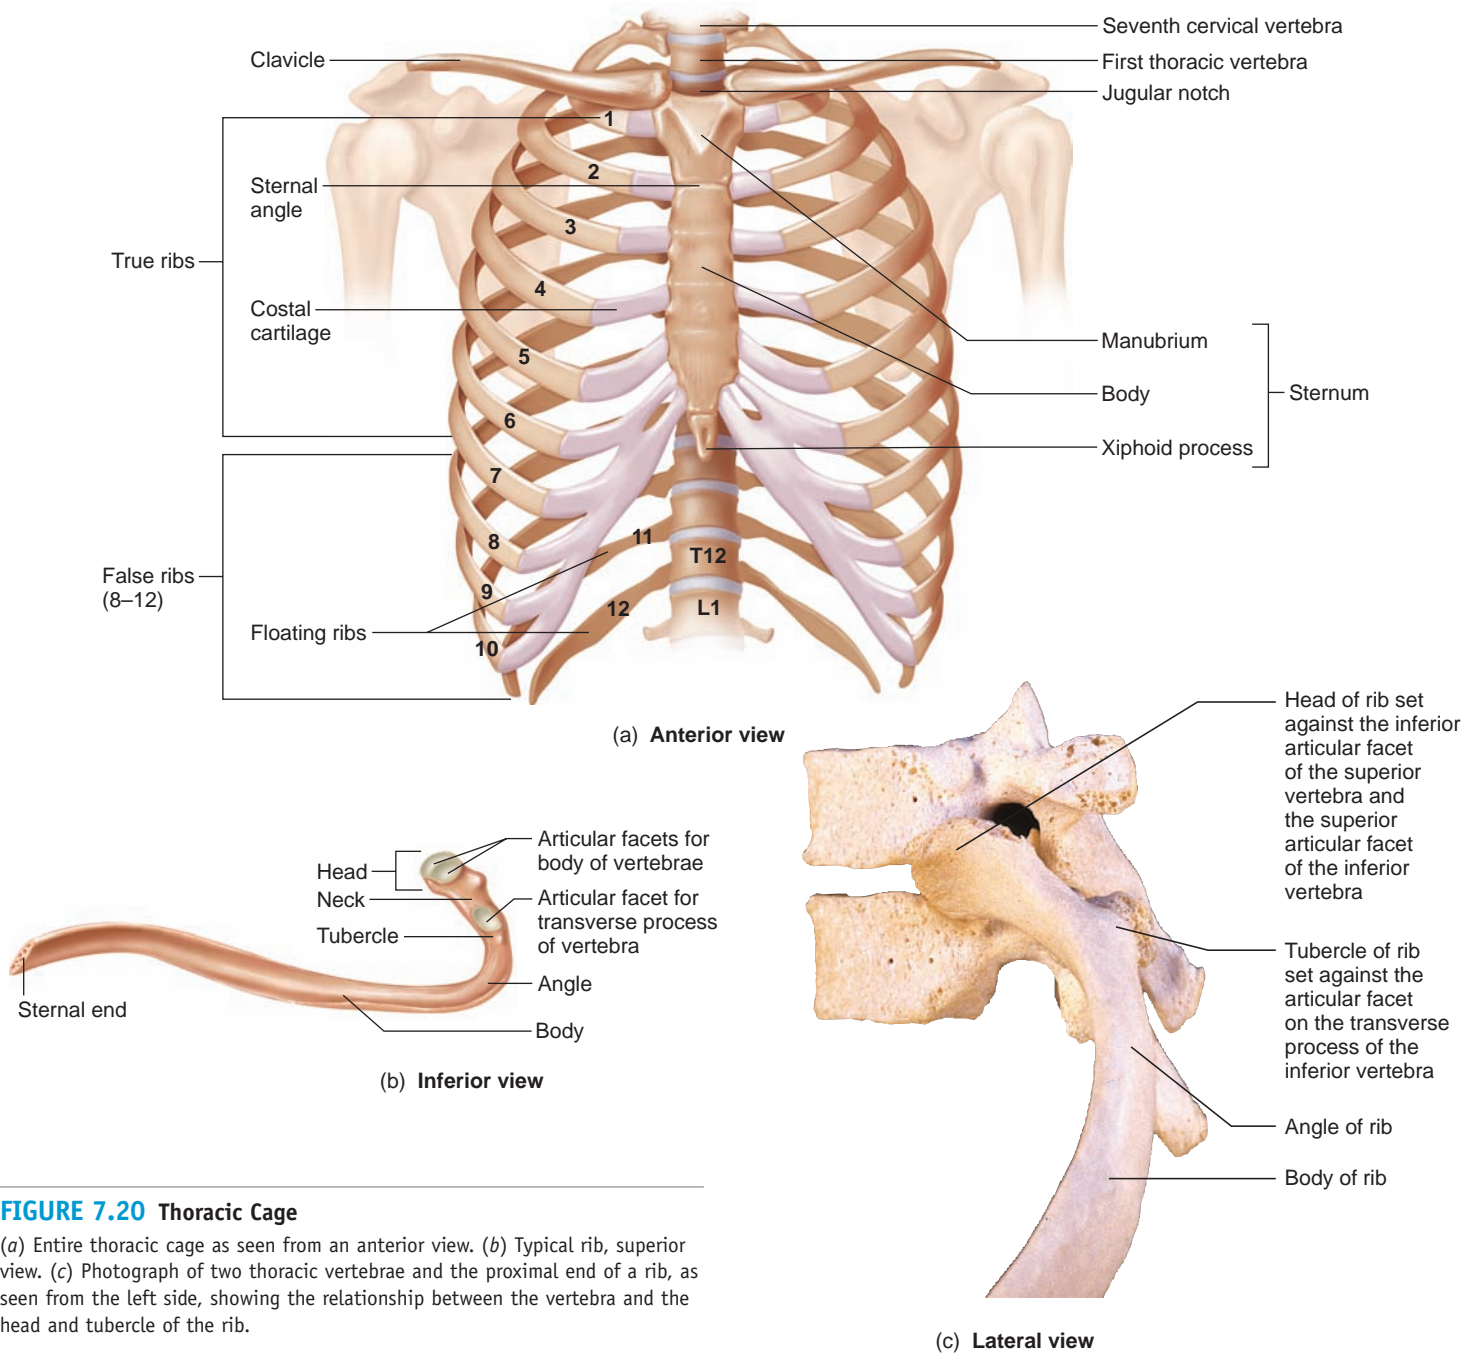

FIGURE 7.20 Thoracic Cage

(a) Entire thoracic cage as seen from an anterior view. (b) Typical rib, superior view. (c) Photograph of two thoracic vertebrae and the proximal end of a rib, as seen from the left side, showing the relationship between the vertebra and the head and tubercle of the rib.

FIGURE 7.21 Surface Anatomy Showing Bones of the Upper Thorax

Pectoral Girdle and Upper Limb

The human upper limb (figure 7.22) is extremely mobile. It is capable of a wide range of movements, including lifting, grasping, pulling, and touching. Many structural characteristics of the upper limb reflect these functions. The upper limb and its girdle are attached rather loosely by muscles to the rest of the body, an arrangement that allows considerable freedom of movement of this extremity. This freedom of movement allows placement of the hand in a wide range of positions to accomplish its functions.

Pectoral Girdle

The **pectoral** (pek'tō-rāl), or **shoulder, girdle** consists of two pairs of bones that attach the upper limb to the body: Each pair is composed of a **scapula** (skap'ū-lā), or shoulder blade (figure 7.23), and a **clavicle** (klav'i-kl), or collarbone (see figures 7.20, 7.22, and 7.23). The scapula is a flat, triangular bone that can easily be seen and felt in a living person (see figure 7.14). The base of the triangle, the superior border, faces superiorly; the apex, the inferior angle, is directed inferiorly.

Anterior view

FIGURE 7.22 Bones of the Pectoral Girdle and Right Upper Limb

The large **acromion** (ă-krō'mē-on; shoulder tip) **process** of the scapula, which can be felt at the tip of the shoulder, has three functions: (1) to form a protective cover for the shoulder joint, (2) to form the attachment site for the clavicle, and (3) to provide attachment points for some of the shoulder muscles. The **scapular spine** extends from the acromion process across the posterior surface of the scapula and divides that surface into a small **supraspinous fossa** superior to the spine and a larger **infraspinous fossa** inferior to the spine. The deep, anterior surface of the scapula constitutes the **subscapular fossa**. The smaller **coracoid** (meaning shaped like a crow's beak) **process** provides attachments for some shoulder and arm muscles. A **glenoid** (glē'noyd, glen'oyd) **cavity**, located in the superior lateral portion of the bone, articulates with the head of the humerus.

The clavicle (see figures 7.20, 7.22, and 7.23c) is a long bone with a slight sigmoid (S-shaped) curve and is easily seen and felt in the living human (see figure 7.21). The lateral end of the clavicle articulates with the acromion process, and its medial end articulates with the manubrium of the sternum. These articulations form the only bony connections between the pectoral girdle and the axial skeleton. Because the clavicle holds the upper limb away from the body, it facilitates the limb's mobility.

20 Name the bones that make up the pectoral girdle. Describe their functions.

21 What are the functions of the acromion process and the coracoid process of the scapula?

PREDICT 4

A broken clavicle changes the position of the upper limb in what way?

Arm

The arm, the part of the upper limb from the shoulder to the elbow, contains only one bone, the **humerus** (figure 7.24). The humeral **head** articulates with the glenoid cavity of the scapula. The **anatomical neck**, immediately distal to the head, is almost nonexistent; thus, a surgical neck has been designated. The **surgical neck** is so-named because it is a common fracture site that often requires surgical repair. If it becomes necessary to remove the humeral head because of disease or injury, it is removed down to the surgical neck. The **greater tubercle** is located on the lateral surface, and the **lesser tubercle** is located on the anterior surface of the proximal end of the humerus, where they are sites of muscle attachment. The groove between the two tubercles contains one tendon of the biceps brachii muscle and is called the **intertubercular, or bicipital** (bī-sip'i-tāl), **groove**. The **deltoid tuberosity** is located on the lateral surface of the humerus a little more than a third of the way along its length and is the attachment site for the deltoid muscle.

The articular surfaces of the distal end of the humerus exhibit unusual features where the humerus articulates with the two forearm bones. The lateral portion of the articular surface is very rounded, articulates with the radius, and is called the **capitulum** (kā-pit'ū-lūm; head-shaped). The medial portion somewhat resembles a spool or pulley, articulates with the ulna, and is called

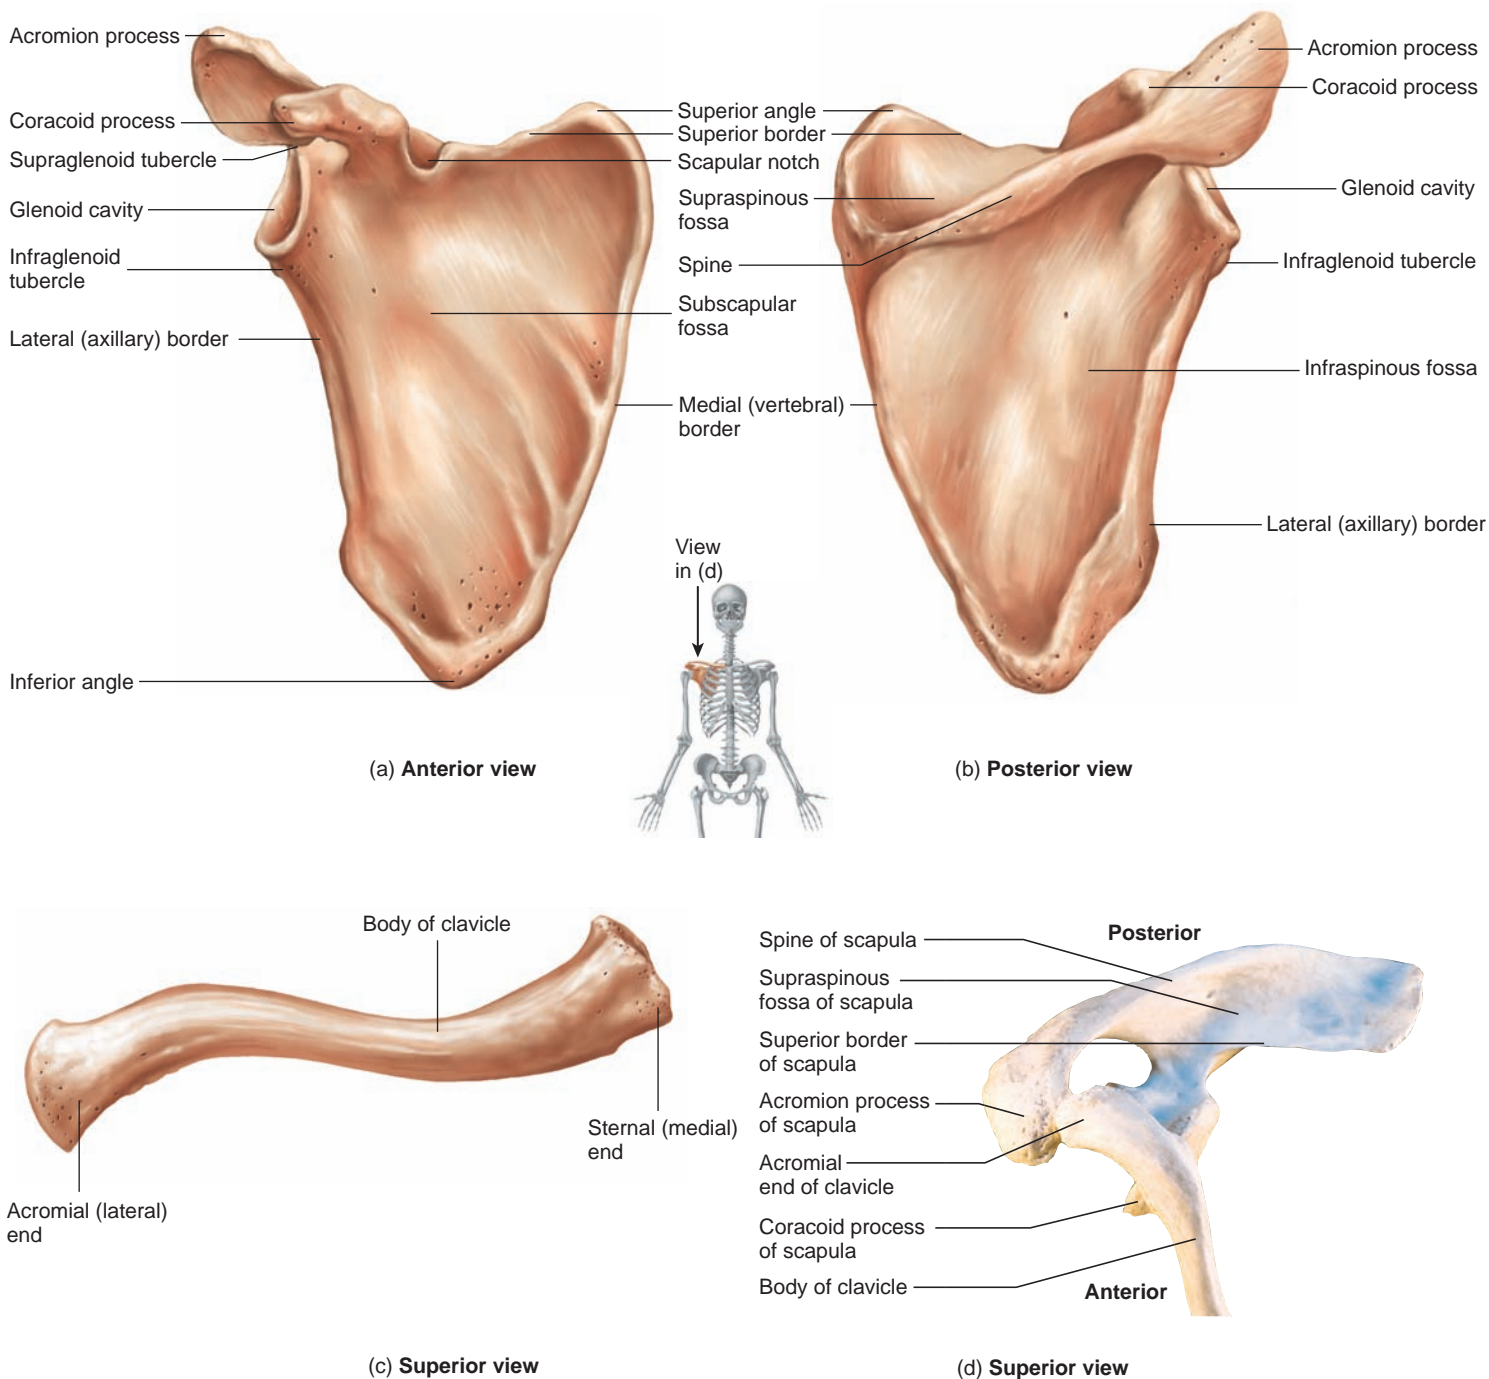

FIGURE 7.23 Right Scapula and Clavicle

(a) Right scapula, anterior view. (b) Right scapula, posterior view. (c) Right clavicle, superior view. (d) Photograph of the right scapula and clavicle from a superior view, showing the relationship between the distal end of the clavicle and the acromion process of the scapula.

the **trochlea** (trok'lē-ă; spool). Proximal to the capitulum and the trochlea are the **medial** and **lateral epicondyles**, which are points of muscle attachment for the muscles of the forearm.

Forearm

The forearm has two bones. The **ulna** is on the medial side of the forearm, the side with the little finger. The **radius** is on the lateral, or thumb side, of the forearm (figure 7.25).

The proximal end of the ulna has a C-shaped articular surface, called the **trochlear**, or **semilunar, notch** that fits over the trochlea of the humerus. The trochlear notch is bounded by two processes. The larger, posterior process is the **olecranon** (ō-lek'ră-non; the point of the elbow) **process**. It can easily be felt and is commonly referred to as “the elbow” (see figure 7.27). Posterior arm muscles attach to the olecranon process. The smaller, anterior process is the **coronoid** (kōr'ō-noyd; crow's beak) **process**.

FIGURE 7.24 Right Humerus

PREDICT 5

Explain the function of the olecranon and coronoid fossae on the distal humerus (see figure 7.25).

The distal end of the ulna has a small **head**, which articulates with both the radius and the wrist bones (see figures 7.25 and 7.27). The head can be seen on the posterior, medial (ulnar) side of the distal forearm. The posteromedial side of the head has a small **styloid** (stī'loyd; shaped like a stylus or writing instrument) **process**, to which ligaments of the wrist are attached.

The proximal end of the radius is the **head**. It is concave and articulates with the capitulum of the humerus. The lateral surfaces of the head constitute a smooth cylinder, where the radius rotates against the **radial notch** of the ulna. As the forearm rotates (supination and pronation; see chapter 8), the proximal end of the ulna stays in place, and the radius rotates. The **radial tuberosity** is the point at which a major anterior arm muscle, the biceps brachii, attaches.

The distal end of the radius, which articulates with the ulna and the carpals, is somewhat broadened, and a **styloid process** to which wrist ligaments are attached is located on the lateral side of the distal radius.

FIGURE 7.25 Right Ulna and Radius

Radius Fractures

The radius is the most commonly fractured bone in people over 50 years old. It is often fractured as the result of a fall on an outstretched hand. The most common site of fracture is 2.5 cm proximal to the wrist, and the fracture is often comminuted, or impacted. Such a fracture, which results in posterior displacement of the hand (extension), is called a Colles fracture.

Wrist

The wrist is a relatively short region between the forearm and hand; it is composed of eight **carpal** (kar'päl) **bones** arranged into two rows of four each (figure 7.26). The proximal row of carpals, lateral to medial, includes the **scaphoid** (skaf'oyd), which is boat-shaped; the **lunate** (loo'nāt), which is moon-shaped; the three-cornered **triquetrum** (trī-kwē'rūm, trī-kwet'rūm); and

FIGURE 7.26 Bones of the Right Wrist and Hand

the pea-shaped **pisiform** (pis'i-fōrm), which is located on the palmar surface of the triquetrum. The distal row of carpals, from medial to lateral, includes the **hamate** (ha'māt), which has a hooked process on its palmar side, called the hook of the hamate; the head-shaped **capitate** (kap'i-tāt); the **trapezoid** (trap'ē-zoyd), which is shaped like a trapezoid (a four-sided geometric form with two parallel sides); and the **trapezium** (tra-pē'zē-ūm), which is shaped like a trapezium (a four-sided geometric form with no two sides parallel). A number of mnemonics have been developed to help students remember the carpal bones. This one allows students to remember them in order from lateral to medial for the proximal row (top) and from medial to lateral (by the thumb) for the distal row: **So Long Top Part, Here Comes The Thumb**, that is Scaphoid, Lunate, Triquetrum, Pisiform, Hamate, Capitate, Trapezoid, and Trapezium.

The eight carpals, taken together, are convex posteriorly and concave anteriorly. The anterior concavity of the carpals is accentuated by the tubercle of the trapezium at the base of the thumb and the hook of the hamate at the base of the little finger. A ligament stretches across the wrist from the tubercle of the trapezium to the hook of the hamate to form a tunnel on the anterior surface of the wrist called the **carpal tunnel**. Tendons, nerves, and blood vessels pass through this tunnel to enter the hand.

Carpal Tunnel Syndrome

The bones and ligaments that form the walls of the carpal tunnel do not stretch. Edema (fluid buildup) or connective tissue deposition may occur within the carpal tunnel as the result of trauma or some other problem. The edema or connective tissue may apply pressure against the nerve and vessels passing through the tunnel, causing carpal tunnel syndrome, which consists of tingling, burning, and numbness in the hand. Carpal tunnel syndrome occurs more frequently in people whose work involves extending the wrist and flexing the fingers, as in typing. The number of cases has increased in recent decades among people who perform repetitive tasks, such as computer keyboarding.

Hand

Five **metacarpals** are attached to the carpal bones and constitute the bony framework of the hand (see figure 7.26). They are numbered one to five, starting with the most lateral metacarpal, at the base of the thumb. The metacarpals form a curve so that, in the resting position, the palm of the hand is concave. The distal ends of the metacarpals help form the knuckles of the hand (figure 7.27). The spaces between the metacarpals are occupied by soft tissue.

The five **digits** of each hand include one thumb and four fingers. Each digit consists of small long bones called **phalanges**

FIGURE 7.27 Surface Anatomy Showing Bones of the Pectoral Girdle and Upper Limb

(fă-lan'jēz; sing. *phalanx*, a line or wedge of soldiers holding their spears, tips outward, in front of them). The thumb has two phalanges, called proximal and distal. Each finger has three phalanges designated proximal, middle, and distal. One or two **sesamoid** (ses'ă-moyd; resembling a sesame seed) **bones** (not shown in figure 7.26) often form near the junction between the proximal phalanx and the metacarpal of the thumb. Sesamoid bones are small bones located within some tendons increasing their mechanical advantage where they cross joints.

PREDICT 6

Explain why the dried, articulated skeleton appears to have much longer “fingers” than are seen in the hand with the soft tissue intact.

- 22** Name the important sites of muscle attachment on the humerus.
- 23** Give the points of articulation between the scapula, humerus, radius, ulna, and wrist bones.
- 24** What is the function of the radial tuberosity? Of the styloid processes? Name the part of the ulna commonly referred to as “the elbow.”
- 25** List the eight carpal bones. What is the carpal tunnel?
- 26** What bones form the hand? The knuckles? How many phalanges are in each finger and in the thumb?

Pelvic Girdle and Lower Limb

The lower limbs support the body and are essential for normal standing, walking, and running. The general pattern of the lower limb (figure 7.28) is very similar to that of the upper limb, except that the pelvic girdle is attached much more firmly to the body than is the pectoral girdle, and the bones in general are thicker, heavier, and longer than those of the upper limb. These structures

FIGURE 7.28 Bones of the Right Half of the Pelvic Girdle and Right Lower Limb

FIGURE 7.29 Pelvis

reflect the function of the lower limb in the support and movement of the body.

Pelvic Girdle

The right and left **coxal** (kok'sul) **bones**, os coxae, or hipbones, join each other anteriorly and the **sacrum** posteriorly to form a ring of bone called the **pelvic girdle**. The **pelvis** (pel'vis; basin; figure 7.29) includes the pelvic girdle and the coccyx. Each coxal bone consists of a large, concave bony plate superiorly, a slightly narrower region in the center, and an expanded bony ring inferiorly, which surrounds a large **obturator** (ob'too-rā-tōr; to occlude or close up, indicating that the foramen is occluded by soft tissue) **foramen**. A fossa called the **acetabulum** (as-ě-tab'ū-lūm; a shallow vinegar cup—a common household item in ancient times) is located on the lateral surface of each coxal bone and is the point of articulation of the lower limb with the girdle. The articular surface of the acetabulum is crescent-shaped and occupies only the superior and lateral aspects of the fossa. The pelvic girdle is the place of attachment for the lower limbs, supports the weight of the body, and protects internal organs. Because the pelvic girdle is a complete bony ring, it provides more stable support but less mobility than the incomplete ring of the pectoral girdle. In addition, the pelvis in a woman protects the developing fetus and forms a passageway through which the fetus passes during delivery.

The Sacroiliac Joint

Each sacroiliac joint is formed by the junction of the auricular surface of a coxal bone and one articular surface of the sacrum. The sacroiliac joints receive most of the weight of the upper body and are strongly supported by ligaments. Excessive strain on the joints, however, can cause slight joint movement and can stretch connective tissue and associated nerve endings in the area and cause pain. Thus is derived the expression “My aching sacroiliac!” This problem sometimes develops in pregnant women because of the forward weight distribution of the fetus.

Each coxal bone is formed by the fusion of three bones during development: the **ilium** (il'ē-ūm; groin), the **ischium** (is'kē-ūm; hip), and the **pubis** (pū'bis; genital hair). All three bones join near the center of the acetabulum (figure 7.30a). The superior portion of the ilium is called the **iliac crest** (figure 7.30b and c). The crest ends anteriorly as the **anterior superior iliac spine** and posteriorly as the **posterior superior iliac spine**. The crest and anterior spine can be felt and even seen in thin individuals (figure 7.31). The anterior superior iliac spine is an important anatomical landmark used, for example, to find the correct location for giving gluteal injections into the hip. A dimple overlies the posterior superior iliac spine just superior to the buttocks. The **greater sciatic** (sī-at'ik) **notch** is on the posterior side of the ilium, just inferior to the posterior inferior iliac spine. The sciatic

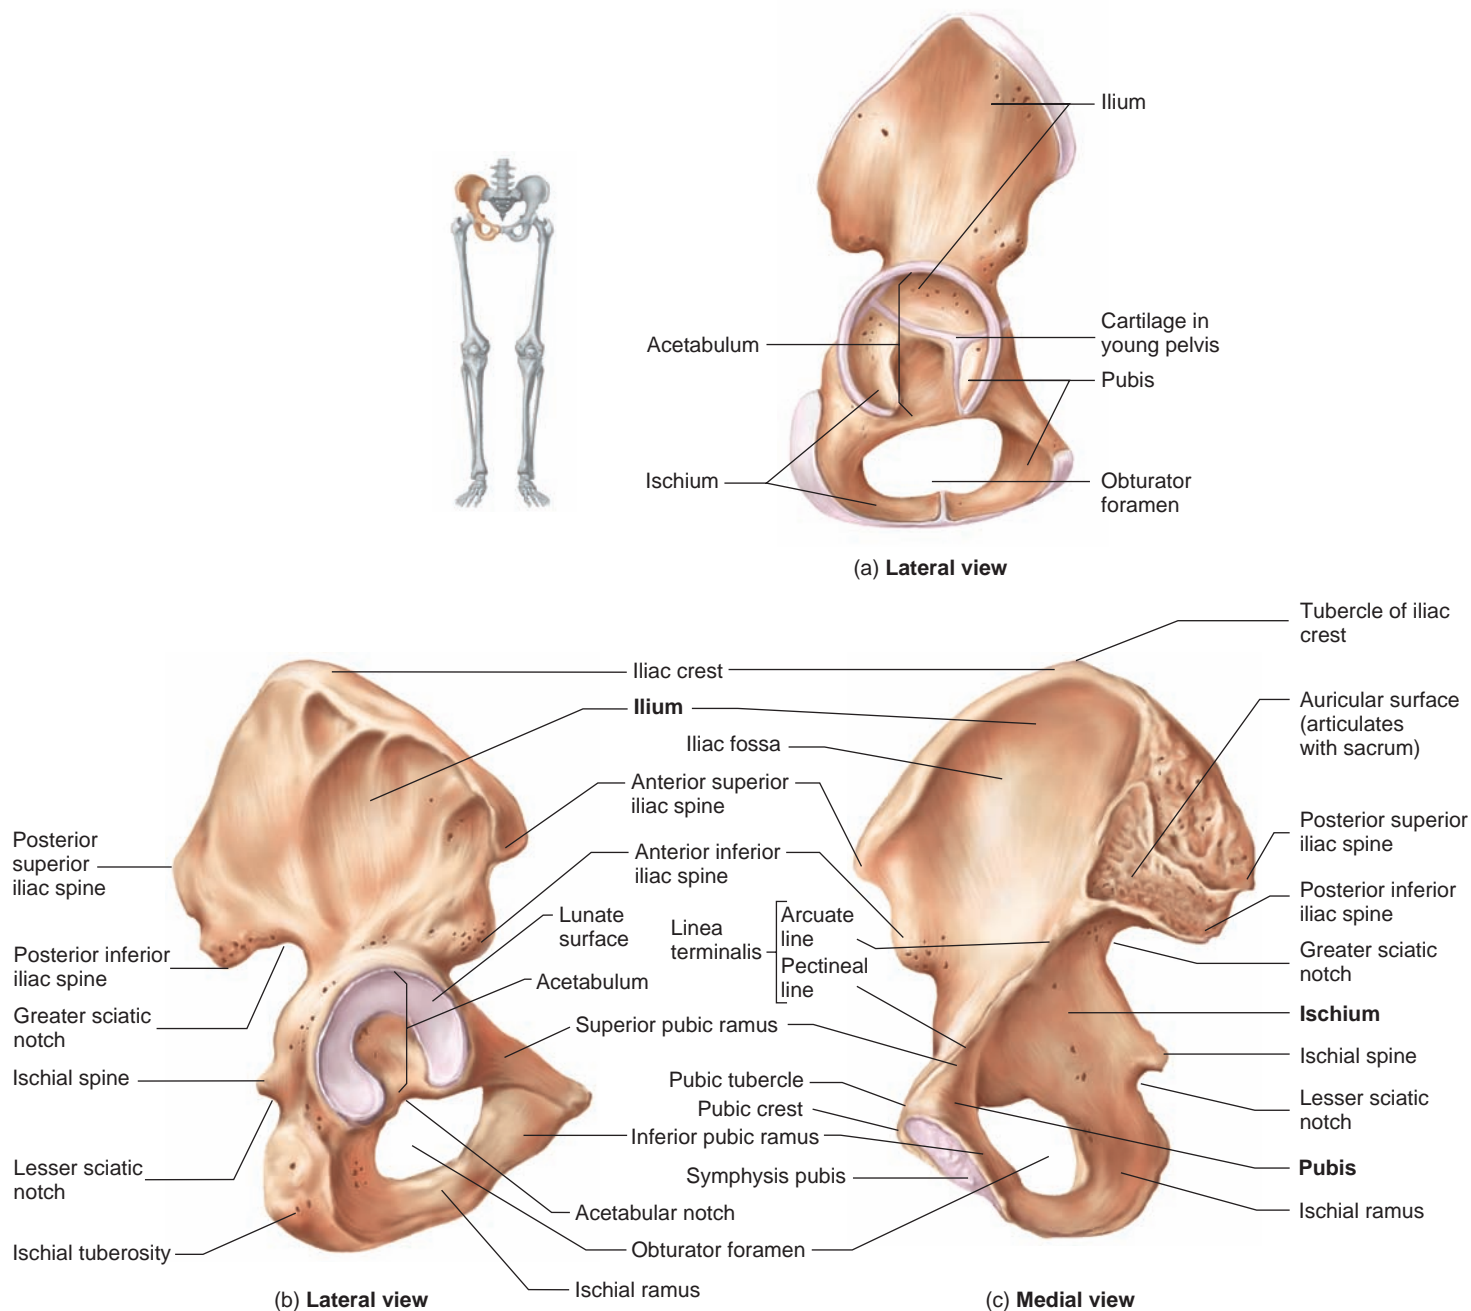

FIGURE 7.30 Coxal Bone

The three bones forming the coxal bone are bolded. (a) Right coxal bone of a growing child. Each coxal bone is formed by fusion of the ilium, ischium, and pubis. The three bones can be seen joining near the center of the acetabulum, separated by lines of cartilage. (b) Right coxal bone, lateral view. (c) Right coxal bone, medial view.

nerve passes through the greater sciatic notch. The **auricular surface** of the ilium joins the sacrum to form the **sacroiliac joint** (see figure 7.29). The medial side of the ilium consists of a large depression called the **iliac fossa**.

The ischium possesses a heavy **ischial** (is'kē-āl) **tuberosity**, where posterior thigh muscles attach and on which a person sits (see figure 7.30b). The pubis possesses a **pubic crest**, medially and a **pubic tubercle** laterally where abdominal muscles attach (see figure 7.30c). The pubic crest can be felt anteriorly. Just inferior to

the pubic crest is the point of junction, the **symphysis** (sim'fi-sis; a coming together) **pubis**, or **pubic symphysis**, between the two coxal bones (see figure 7.29).

The pelvis can be thought of as having two parts divided by an imaginary plane passing from the sacral promontory along the **linea terminalis** of the ilium to the pubic crest (see figure 7.32). The bony boundary of this plane is the **pelvic brim**. The **false**, or **greater, pelvis** is superior to the pelvic brim and is partially surrounded by bone on the posterior and lateral sides. During life,

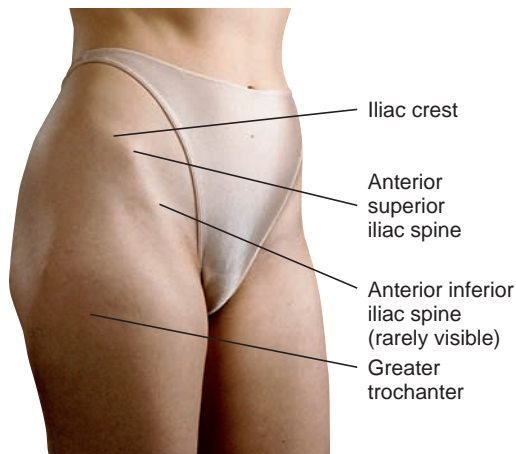

FIGURE 7.31 Surface Anatomy Showing an Anterior View of the Hipbones

the abdominal muscles form the anterior wall of the false pelvis. The **true pelvis** is inferior to the pelvic brim and is completely surrounded by bone. The superior opening of the true pelvis, at the level of the pelvic brim, is the **pelvic inlet**. The inferior opening of the true pelvis, bordered by the inferior margin of the pubis, the

ischial spines and tuberosities, and the coccyx, is the **pelvic outlet** (see figure 7.32c).

Comparison of the Male and Female Pelvis

The male pelvis usually is more massive than the female pelvis as a result of the greater weight and size of the male, and the female pelvis is broader and has a larger, more rounded pelvic inlet and outlet (figure 7.32a and b), consistent with the need to allow the fetus to pass through these openings in the female pelvis during delivery. Table 7.11 lists additional differences between the male and female pelvis.

- 27** Define the pelvic girdle. What bones fuse to form each coxal bone? Where and with what bones does each coxal bone articulate?
- 28** Name the important sites of muscle attachment on the pelvis.
- 29** Distinguish between the true pelvis and the false pelvis.
- 30** Describe the differences between a male and a female pelvis.

Pelvic Outlet and Birth

A wide, circular pelvic inlet and a pelvic outlet with widely spaced ischial spines can facilitate delivery. A smaller pelvic outlet can cause problems during delivery; thus, the size of the pelvic inlet and outlet is routinely measured during prenatal pelvic examinations of pregnant women. If the pelvic outlet is too small for normal delivery, delivery can be accomplished by **cesarean section**, which is the surgical removal of the fetus through the abdominal wall.

Gluteal Injections

The large gluteal muscles (hip muscles; see chapter 10) are a common site for intramuscular injections. Gluteal injections are made in the superolateral region of the hip (figure D) because a large nerve (the sciatic nerve; see chapter 12) lies deep to the other gluteal regions. The landmarks for such an injection are the anterior superior iliac spine and the tubercle of the iliac crest, which lies about one-third of the way along the iliac crest from anterior to posterior.

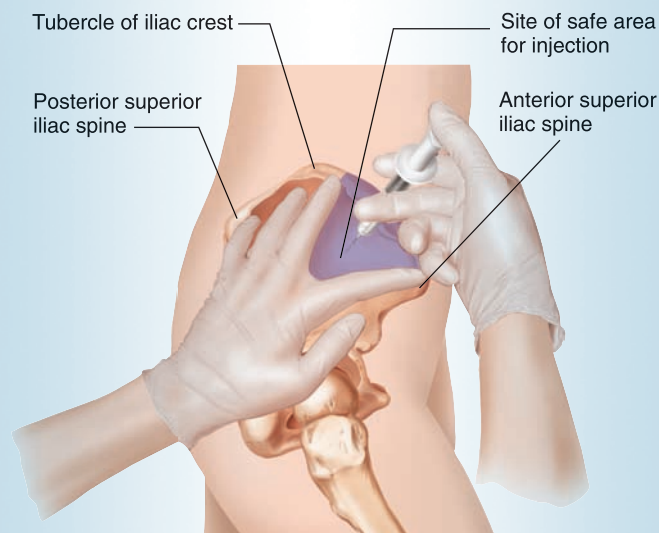

FIGURE D Gluteal Injection Site

Thigh

The thigh, like the arm, contains a single bone, which is called the **femur**. The femur has a prominent, rounded **head**, where it articulates with the acetabulum, and a well-defined **neck**; both are located at an oblique angle to the shaft of the femur (figure 7.33). The proximal shaft exhibits two projections: a **greater trochanter** (trō-kan'ter; runner) lateral to the neck and a smaller, or **lesser trochanter** inferior and posterior to the neck. Both trochanters are attachment sites for muscles that fasten the hip to the thigh. The greater trochanter and its attached muscles form a bulge that can be seen as the widest part of the hips (see figure 7.31). The distal end of the femur has **medial** and **lateral condyles**, smooth, rounded surfaces that articulate with the tibia. Located proximally to the condyles are the **medial** and **lateral epicondyles**, important sites of ligament attachment. An **adductor tubercle**, to which muscles attach, is located just proximal to the medial epicondyle.

The **patella**, or kneecap, is a large sesamoid bone located within the tendon of the quadriceps femoris muscle group, which is the major muscle group of the anterior thigh (figure 7.34). The patella articulates with the patellar groove of the femur to create a smooth articular surface over the anterior distal end of the femur. The patella holds the tendon away from the distal end of the femur and therefore changes the angle of the tendon between the quadriceps femoris muscle and the tibia, where the tendon attaches. This

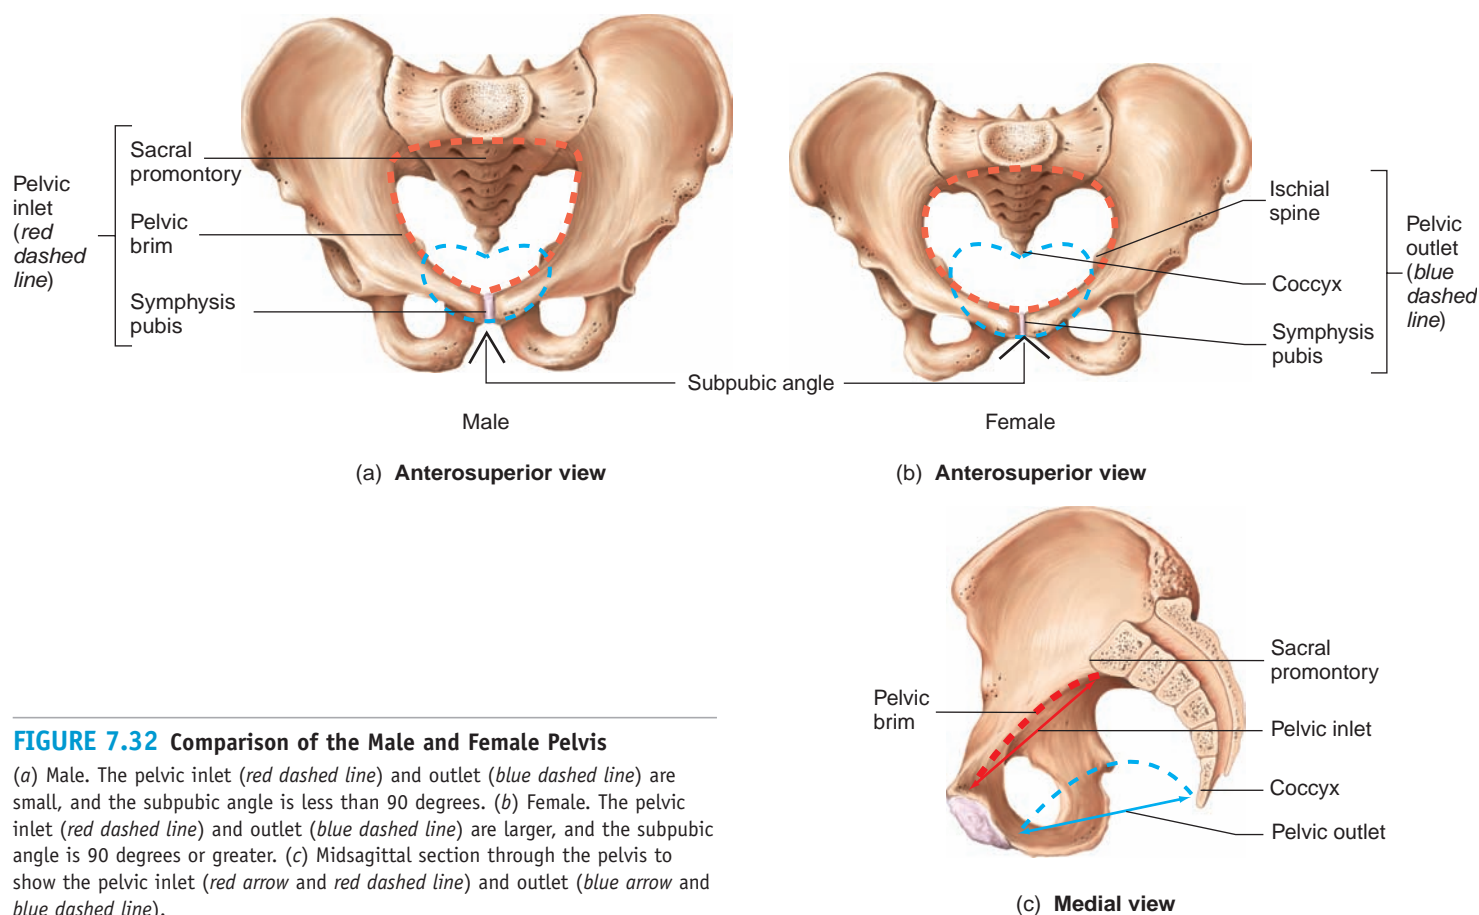

FIGURE 7.32 Comparison of the Male and Female Pelvis

(a) Male. The pelvic inlet (red dashed line) and outlet (blue dashed line) are small, and the subpubic angle is less than 90 degrees. (b) Female. The pelvic inlet (red dashed line) and outlet (blue dashed line) are larger, and the subpubic angle is 90 degrees or greater. (c) Midsagittal section through the pelvis to show the pelvic inlet (red arrow and red dashed line) and outlet (blue arrow and blue dashed line).

Area	Description
TABLE 7.11 Differences Between the Male and Female Pelvis (See Figure 7.32)	
General	In females, somewhat lighter in weight and wider laterally but shorter superiorly to inferiorly and less funnel-shaped; less obvious muscle attachment points in females than in males
Sacrum	Broader in females with the inferior part directed more posteriorly; the sacral promontory does not project as far anteriorly in females
Pelvic inlet	Heart-shaped in males; oval in females
Pelvic outlet	Broader and more shallow in females
Subpubic angle	Less than 90 degrees in males; 90 degrees or more in females
Ilium	More shallow and flared laterally in females
Ischial spines	Farther apart in females
Ischial tuberosities	Turned laterally in females and medially in males

change in angle increases the force that can be applied from the muscle to the tibia. As a result of this increase in applied force, less muscle contraction force is required to move the tibia.

Leg

The leg is the part of the lower limb between the knee and the ankle. Like the forearm, it consists of two bones: the **tibia** (tib'ē-ă), or shinbone, and the **fibula** (fib'ū-lă; resembling a clasp or buckle; figure 7.35). The tibia is by far the larger of the two and supports most of the weight of the leg. A **tibial tuberosity**, which is the attachment point for the quadriceps femoris muscle group, can easily be seen and felt just inferior to the patella (figure 7.36). The **anterior crest** forms the shin. The proximal end of the tibia has flat **medial** and **lateral condyles**, which articulate with the condyles of the femur. Located between the condyles is the **intercondylar eminence**, which is a ridge between the two articular surfaces of the proximal tibia. The distal end of the tibia is enlarged to form the **medial malleolus** (ma-lē'ō-lūs; mallet-shaped), which helps form the medial side of the ankle joint.

The fibula does not articulate with the femur but has a small proximal head where it articulates with the tibia. The distal end of

FIGURE 7.33 Right Femur

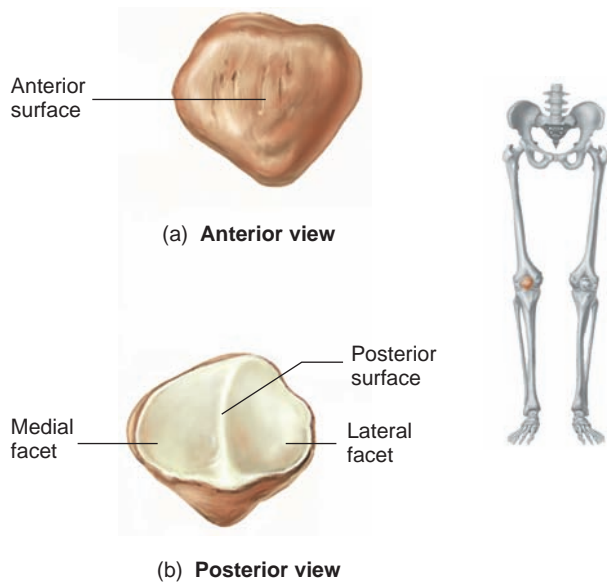

FIGURE 7.34 Right Patella

Patellar Defects

If the patella is severely fractured, the tendon from the quadriceps femoris muscle group may be torn, resulting in a severe decrease in muscle function. In extreme cases, it may be necessary to remove the patella to repair the tendon. Patella removal results in a decrease in the amount of power the quadriceps femoris muscle can generate at the tibia.

The patella normally tracks in the patellar groove on the anterodistal end of the femur. Abnormal tracking of the patella can become a problem in some teenagers, especially females. As a young woman's hips widen during puberty, the angles at the joints between the hips and the tibia may change considerably. As the knee becomes located more medially relative to the hip, the patella may be forced to track more laterally than normal. This lateral tracking may result in pain in the knees of some young athletes.

CASE STUDY

Fracture of the Femoral Neck

An 85-year-old woman who lived alone at home was found lying on her kitchen floor by her daughter, who had come to check on her mother. The woman could not rise, even with help, and when she tried she experienced extreme pain in her right hip. Her daughter immediately dialed 911 and her mother was taken by paramedics to the hospital.

The elderly woman's hip was x-rayed in the emergency room, and it was determined that she had a fracture of the right femoral neck. A femoral neck fracture is commonly, but incorrectly, called a broken hip. Two days later, she received a partial hip replacement in which the head and neck of the femur were replaced, but not the acetabulum.

In the case of falls involving femoral neck fracture, it is not always clear whether the fall caused the femoral neck to fracture or whether a fracture of the femoral neck caused the fall. Femoral neck fractures are among the most common injuries resulting in morbidity (disease) and mortality (death) in older adults. Despite treatment with anti-coagulants and antibiotics, about 5% of patients with femoral neck fractures develop deep vein thrombosis (blood clot) and about 5% develop wound infections, either of which can be life-threatening. Hospital mortality is 1%–7% among patients with femoral neck fractures, and nearly 20% of femoral neck fracture victims die within 3 months of the fracture.

Four percent of women over age 85 experience femoral neck fractures each year. Only about 25% of victims ever fully recover from the injury. Forty percent of all deaths caused by injury in men over age 65 are from falls and 58% of injury deaths result from falls among women of the same age group. Many of those falls result in, or from, femoral neck fractures.

PREDICT 7

Fracture of the femoral neck increases dramatically with age, and 81% of victims are women. The average age of such injury is 82. Why is the femoral neck so commonly injured (*hint*: see figure 7.1), and why are elderly women the group most commonly affected?

the fibula is also slightly enlarged as the **lateral malleolus** to create the lateral wall of the ankle joint. The lateral and medial malleoli can be felt and seen as prominent lumps on both sides of the ankle (see figure 7.36). The thinnest, weakest portion of the fibula is just proximal to the lateral malleolus.

PREDICT 8

Explain why modern ski boots are designed with high tops that extend partway up the leg.

Foot

The proximal portion of the foot consists of seven **tarsal** (tar'sāl; the sole of the foot) **bones** (figure 7.37). The **talus** (tā'lūs), or ankle bone, articulates with the tibia and the fibula to form the ankle joint. It also articulates with the calcaneus and navicular. The **calcaneus** (kal-kā'nē-us; heel), the heel bone, is the largest and strongest bone in the foot. It is located inferior to the talus and supports that bone. The calcaneus protrudes posteriorly, is the important attachment point for the large calf muscles, and can be easily felt as the heel of the foot. The **navicular** (nā-vik'ū-lar), which is boat-shaped, lies between the talus posteriorly and the cuneiforms anteriorly. The talus, calcaneus, and navicular are proximal in the foot but do not form a row. The proximal foot is relatively much larger than the wrist. The distal four bones do form a row. The medial, wedge-shaped three bones of the distal row are called **cuneiforms** (kū'-nē-i-fōrmz). They are the **medial cuneiform**, **intermediate cuneiform**, and **lateral cuneiform**. The **cubeiform** (kū'boyd), which is cube-shaped, is the most lateral of

FIGURE 7.35 Right Tibia and Fibula

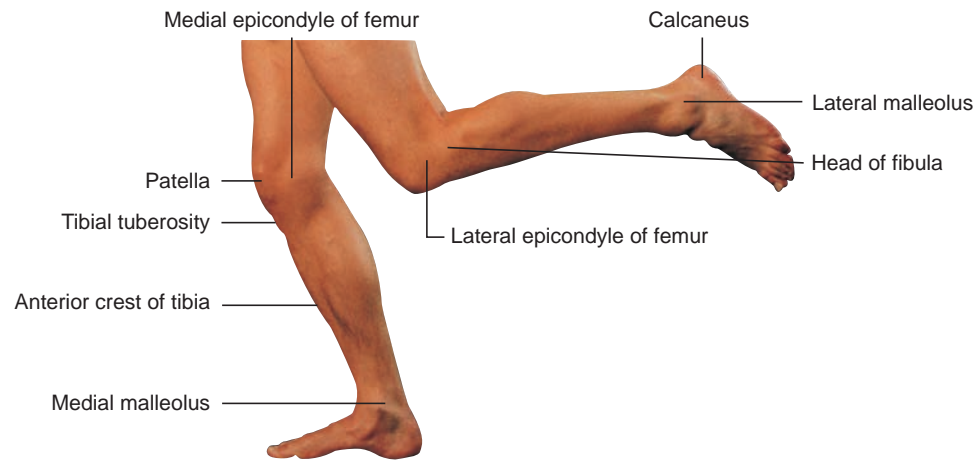

FIGURE 7.36 Surface Anatomy Showing Bones of the Lower Limb

Fractures of the Malleoli

Turning the plantar surface of the foot outward so that it faces laterally is called eversion. Forceful eversion of the foot, such as when a person slips and twists the ankle or jumps and lands incorrectly on the foot, may cause the distal ends of the tibia and/or fibula to fracture (figure *Ea*). Such fractures are not uncommon in soccer, football, and basketball players. When the foot is forcefully everted, the medial malleolus moves inferiorly toward the ground or floor and the talus slides laterally, forcing the medial and lateral malleoli to separate. The ligament holding the medial malleolus to the tarsal bones is stronger than the bones it connects, and often it does not tear as the bones separate because of the eversion. Instead, the medial malleolus breaks. Also, as the talus slides laterally, the force can shear off the lateral malleolus or, more commonly, can cause the fibula to break superior to the lateral malleolus. This type of injury to the tibia and fibula is often called a Pott's fracture.

Turning the plantar surface of the foot inward so that it faces medially is called inversion. Forceful inversion of the foot can fracture the fibula just proximal to the lateral malleolus (figure *Eb*). More often, because the ligament holding the medial malleolus to the tarsal bones is weaker than the bones it connects, the inversion of the foot causes a sprain in which ligaments are damaged.

FIGURE E Fracture of the Medial or Lateral Malleolus

the distal row. A mnemonic for the distal row is **MILC**—that is, **Medial, Intermediate, and Lateral** cuneiforms and the **Cuboid**; A mnemonic for the proximal three bones is **No Thanks Cow**, that is **Navicular, Talus, and Calcaneus**.

The **metatarsals** and **phalanges** of the foot are arranged in a manner very similar to that of the metacarpals and phalanges of the hand, with the great toe analogous to the thumb (see figure 7.37). Small sesamoid bones often form in the tendons of muscles attached to the great toe. The ball of the foot is the junction between the metatarsals and phalanges. The foot as a unit is convex dorsally and concave ventrally to form the arches of the foot (described more fully in chapter 8).

PREDICT 9

A decubitus ulcer is a chronic ulcer that appears in pressure areas of skin overlying a bony prominence in bedridden or otherwise immobilized patients. Where are likely sites for decubitus ulcers to occur?

The foot has three major **arches**, which distribute the weight of the body between the heel and the ball of the foot during standing and walking (see figure 7.37*b*). As the foot is placed on the ground, weight is transferred from the tibia and the fibula to the talus. From there, the weight is distributed first to the heel (calcaneus) and then through the arch system along the lateral side of the foot to the ball of the foot (head of the metatarsals). This effect can be observed when a person with wet, bare feet walks across a dry surface; the print of the heel, the lateral border of the foot, and the ball of the foot can be seen, but the middle of the plantar surface and the medial border leave no impression. The medial side leaves no mark because the arches on this side of the foot are higher than those on the lateral side. The shape of the arches is maintained by the configuration of the bones, the ligaments connecting them, and the muscles acting on the foot.

FIGURE 7.37 Bones of the Right Foot

The medial longitudinal arch is formed by the calcaneus, talus, navicular, cuneiforms, and three medial metatarsals. The lateral longitudinal arch is formed by the calcaneus, cuboid, and two lateral metatarsals. The transverse arch is formed by the cuboid and cuneiforms.

- 31** What is the function of the greater trochanter and the lesser trochanter?
- 32** Describe the function of the patella.
- 33** Name the bones of the leg.
- 34** Give the points of articulation among the pelvis, femur, leg, and ankle.
- 35** What is the function of the tibial tuberosity?

- 36** Name the seven tarsal bones. Which bones form the ankle joint? What bone forms the heel?
- 37** Describe the bones of the foot. How many phalanges are in each toe?
- 38** List the three arches of the foot and describe their function.

SUMMARY

The gross anatomy of the skeletal system considers the features of bone, cartilage, tendons, and ligaments that can be seen without the use of a microscope. Dried, prepared bones display the major features of bone but obscure the relationship between bone and soft tissue.

General Considerations (p. 204)

Bones have processes, smooth surfaces, and holes that are associated with ligaments, muscles, joints, nerves, and blood vessels.

Axial Skeleton (p. 206)

The axial skeleton consists of the skull, hyoid bone, vertebral column, and thoracic cage.

Skull

- The skull, or cranium, can be thought of as a single unit.
- The parietal bones are joined at the midline by the sagittal suture; they are joined to the frontal bone by the coronal suture, to the occipital bone by the lambdoid suture, and to the temporal bone by the squamous suture.
- Nuchal lines are the points of attachment for neck muscles.
- Several skull features are seen from a lateral view.
 - The external auditory meatus transmits sound waves toward the eardrum.
 - Important neck muscles attach to the mastoid process.
 - The temporal lines are attachment points of the temporalis muscle.
 - The zygomatic arch, from the temporal and zygomatic bones, forms a bridge across the side of the skull.
- Several skull features are seen from a frontal view.
 - The orbits contain the eyes.
 - The nasal cavity is divided by the nasal septum, and the hard palate separates the nasal cavity from the oral cavity.
 - Sinuses within bone are air-filled cavities. The paranasal sinuses, which connect to the nasal cavity, are the frontal, sphenoidal, and maxillary sinuses and the ethmoidal labyrinth.
 - The mandible articulates with the temporal bone.
- Several skull features are inside the cranial cavity.
 - The crista galli is a point of attachment for one of the meninges.
 - The olfactory nerves extend into the roof of the nasal cavity through the cribriform plate.
 - The sella turcica is occupied by the pituitary gland.
 - The spinal cord and brain are connected through the foramen magnum.
- Several features are on the inferior surface of the skull.
 - Occipital condyles are points of articulation between the skull and the vertebral column.
 - Blood reaches the brain through the internal carotid arteries, which pass through the carotid canals, and the vertebral arteries, which pass through the foramen magnum.
 - Most blood leaves the brain through the internal jugular veins, which exit through the jugular foramina.
 - Styloid processes provide attachment points for three muscles involved in movement of the tongue, hyoid bone, and pharynx.
 - The hard palate forms the floor of the nasal cavity.
- The skull is composed of 22 bones.
 - The auditory ossicles, which function in hearing, are located inside the temporal bones.
 - The braincase protects the brain.
 - The facial bones protect the sensory organs of the head and are muscle attachment sites (mastication, facial expression, and eye muscles).
 - The mandible and maxillae possess alveolar processes with sockets for the attachment of the teeth.

Hyoid Bone

The hyoid bone, which “floats” in the neck, is the attachment site for throat and tongue muscles.

Vertebral Column

- The vertebral column provides flexible support and protects the spinal cord.
- The vertebral column has four major curvatures: cervical, thoracic, lumbar, and sacral/coccygeal. Abnormal curvatures are lordosis (lumbar), kyphosis (thoracic), and scoliosis (lateral).
- A typical vertebra consists of a body, a vertebral arch, and various processes.
 - Part of the body and the vertebral arch (pedicle and lamina) form the vertebral foramen, which contains and protects the spinal cord.
 - Spinal nerves exit through the intervertebral foramina.
 - The transverse and spinous processes are points of muscle and ligament attachment.
 - Vertebrae articulate with one another through the superior and inferior articular processes.
- Adjacent bodies are separated by intervertebral disks. The disk has a fibrous outer covering (annulus fibrosus) surrounding a gelatinous interior (nucleus pulposus).
- Several types of vertebrae can be distinguished.
 - All seven cervical vertebrae have transverse foramina, and most have bifid spinous processes.
 - The 12 thoracic vertebrae are characterized by long, downward-pointing spinous processes and demifacets.
 - The five lumbar vertebrae have thick, heavy bodies and processes.
 - The sacrum consists of five fused vertebrae and attaches to the coxal bones to form the pelvis.
 - The coccyx consists of four fused vertebrae attached to the sacrum.

Thoracic Cage

- The thoracic cage (consisting of the ribs, their associated costal cartilages, and the sternum) protects the thoracic organs and changes volume during respiration.
- Twelve pairs of ribs attach to the thoracic vertebrae. They are divided into seven pairs of true ribs and five pairs of false ribs. Two pairs of false ribs are floating ribs.
- The sternum is composed of the manubrium, the body, and the xiphoid process.

Appendicular Skeleton (p. 233)

The appendicular skeleton consists of the upper and lower limbs and the girdles that attach the limbs to the body.

Pectoral Girdle and Upper Limb

- The upper limb is attached loosely and functions in grasping and manipulation.
- The pectoral girdle consists of the scapulae and clavicles.
 - The scapula articulates with the humerus and the clavicle. It is an attachment site for shoulder, back, and arm muscles.
 - The clavicle holds the shoulder away from the body, permitting free movement of the arm.
- The arm bone is the humerus.
 - The humerus articulates with the scapula (head), the radius (capitulum), and the ulna (trochlea).
 - Sites of muscle attachment are the greater and lesser tubercles, the deltoid tuberosity, and the epicondyles.
- The forearm contains the ulna and radius.
 - The ulna and radius articulate with each other and with the humerus and wrist bones.
 - The wrist ligaments attach to the styloid processes of the radius and ulna.
- Eight carpal, or wrist, bones are arranged in two rows.
- The hand consists of five metacarpal bones.
- The phalanges are digital bones. Each finger has three phalanges, and the thumb has two phalanges.

Pelvic Girdle and Lower Limb

- The lower limb is attached solidly to the coxal bone and functions in support and movement.

- The pelvic girdle consists of the right and left coxal bones and sacrum. Each coxal bone is formed by the fusion of the ilium, the ischium, and the pubis.
 - The coxal bones articulate with each other (symphysis pubis) and with the sacrum (sacroiliac joint) and the femur (acetabulum).
 - Important sites of muscle attachment are the iliac crest, the iliac spines, and the ischial tuberosity.
 - The female pelvis has a larger pelvic inlet and outlet than the male pelvis.
- The thighbone is the femur.
 - The femur articulates with the coxal bone (head), the tibia (medial and lateral condyles), and the patella (patellar groove).
 - Sites of muscle attachment are the greater and lesser trochanters, as well as the adductor tubercle.
 - Sites of ligament attachment are the lateral and medial epicondyles.
- The leg consists of the tibia and the fibula.
 - The tibia articulates with the femur, the fibula, and the talus. The fibula articulates with the tibia and the talus.
 - Tendons from the thigh muscles attach to the tibial tuberosity.
- Seven tarsal bones form the proximal portion of the foot.
- The foot consists of five metatarsal bones.
- The toes have three phalanges each, except for the big toe, which has two.
- The bony arches transfer weight from the heels to the toes and allow the foot to conform to many different positions.

REVIEW AND COMPREHENSION

- Which of these is part of the appendicular skeleton?
 - cranium
 - ribs
 - clavicle
 - sternum
 - vertebra
- A knoblike lump on a bone is called a
 - spine.
 - facet.
 - tuberosity.
 - sulcus.
 - ramus.
- The superior and middle nasal conchae are formed by projections of the
 - sphenoid bone.
 - vomer bone.
 - palatine process of maxillae.
 - palatine bone.
 - ethmoid bone.
- The perpendicular plate of the ethmoid and the _____ form the nasal septum.
 - palatine process of the maxilla
 - horizontal plate of the palatine
 - vomer
 - nasal bone
 - lacrimal bone
- Which of these bones does *not* contain a paranasal sinus?
 - ethmoid
 - sphenoid
 - frontal
 - temporal
 - maxilla
- The mandible articulates with the skull at the
 - styloid process.
 - occipital condyle.
 - mandibular fossa.
 - zygomatic arch.
 - medial pterygoid.
- The nerves for the sense of smell pass through the
 - cribriform plate.
 - nasolacrimal canal.
 - internal acoustic meatus.
 - optic canal.
 - orbital fissure.
- The major blood supply to the brain enters through the
 - foramen magnum.
 - carotid canals.
 - jugular foramina.
 - both a and b.
 - all of the above.
- The site of the sella turcica is the
 - sphenoid bone.
 - maxillae.
 - frontal bone.
 - ethmoid bone.
 - temporal bone.
- Which of these bones is *not* in contact with the sphenoid bone?
 - maxilla
 - inferior nasal concha
 - ethmoid
 - parietal
 - vomer
- A herniated disk occurs when
 - the annulus fibrosus ruptures.
 - the intervertebral disk slips out of place.
 - the spinal cord ruptures.
 - too much fluid builds up in the nucleus pulposus.
 - all of the above.
- The weight-bearing portion of a vertebra is the
 - vertebral arch.
 - articular process.
 - body.
 - transverse process.
 - spinous process.
- Transverse foramina are found only in
 - cervical vertebrae.
 - thoracic vertebrae.
 - lumbar vertebrae.
 - the sacrum.
 - the coccyx.
- Articular facets on the bodies and transverse processes are found only on
 - cervical vertebrae.
 - thoracic vertebrae.
 - lumbar vertebrae.
 - the sacrum.
 - the coccyx.
- Which of these statements concerning ribs is true?
 - The true ribs attach directly to the sternum with costal cartilage.
 - There are five pairs of floating ribs.
 - The head of the rib attaches to the transverse process of the vertebra.
 - Vertebrochondral ribs are classified as true ribs.
 - Floating ribs do not attach to vertebrae.

16. The point where the scapula and clavicle connect is the
 - a. coracoid process.
 - b. styloid process.
 - c. glenoid cavity.
 - d. acromion process.
 - e. capitulum.
17. The distal medial process of the humerus to which the ulna joins is the
 - a. epicondyle.
 - b. deltoid tuberosity.
 - c. malleolus.
 - d. capitulum.
 - e. trochlea.
18. Which of these is *not* a point of muscle attachment on the pectoral girdle or upper limb?
 - a. epicondyles
 - b. mastoid process
 - c. radial tuberosity
 - d. spine of scapula
 - e. greater tubercle
19. The bone/bones of the foot on which the tibia rests is the
 - a. talus.
 - b. calcaneus.
 - c. metatarsals.
 - d. navicular.
 - e. phalanges.
20. A place where nerves or blood vessels pass from the trunk to the lower limb is the
 - a. pubic crest.
 - b. greater sciatic notch.
 - c. ischial tuberosity.
 - d. iliac crest.
 - e. pubis symphysis.
21. The projection on the coxal bone of the pelvic girdle that is used as a landmark for finding an injection site is the
 - a. ischial tuberosity.
 - b. iliac crest.
 - c. anterior superior iliac spine.
 - d. posterior inferior iliac spine.
 - e. ischial spine.
22. When comparing the pectoral girdle with the pelvic girdle, which of these statements is true?
 - a. The pectoral girdle has greater mass than the pelvic girdle.
 - b. The pelvic girdle is more firmly attached to the body than the pectoral girdle.
 - c. The pectoral girdle has the limbs more securely attached than the pelvic girdle.
 - d. The pelvic girdle allows greater mobility than the pectoral girdle.
23. When comparing a male pelvis with a female pelvis, which of these statements is true?
 - a. The pelvic inlet in males is larger and more circular.
 - b. The subpubic angle in females is less than 90 degrees.
 - c. The ischial spines in males are closer together.
 - d. The sacrum in males is broader and less curved.
24. A site of muscle attachment on the proximal end of the femur is the
 - a. greater trochanter.
 - b. epicondyle.
 - c. greater tubercle.
 - d. intercondylar eminence.
 - e. condyle.
25. The process that forms the large lateral bump in the ankle is the lateral
 - a. malleolus.
 - b. condyle.
 - c. epicondyle.
 - d. tuberosity.
 - e. tubercle.

Answers in Appendix E

CRITICAL THINKING

1. A patient has an infection in the nasal cavity. Name seven adjacent structures to which the infection could spread.
2. A patient is unconscious. Radiographic films reveal that the superior articular process of the atlas has been fractured. Which of the following could have produced this condition: falling on the top of the head or being hit in the jaw with an uppercut? Explain.
3. If the vertebral column is forcefully rotated, what part of the vertebra is most likely to be damaged? In what area of the vertebral column is such damage most likely?
4. An asymmetric weakness of the back muscles can produce which of the following: scoliosis, kyphosis, or lordosis? Which can result from pregnancy? Explain.
5. What might be the consequences of a broken forearm involving both the ulna and the radius when the ulna and radius fuse to each other during repair of the fracture?
6. Suppose you need to compare the length of one lower limb with the length of the other in an individual. Using bony landmarks, suggest an easy way to accomplish the measurements.
7. A paraplegic individual develops decubitus ulcers (pressure sores) on the buttocks from sitting in a wheelchair for extended periods. Name the bony protuberance responsible.
8. Why are more women than men knock-kneed?
9. On the basis of bone structure of the lower limb, explain why it is easier to turn the foot medially (sole of the foot facing toward the midline of the body) than laterally. Why is it easier to cock the wrist medially than laterally?
10. Justin Time leaped from his hotel room to avoid burning to death in a fire. If he landed on his heels, what bone was likely fractured? Unfortunately for Justin, a 240 lb firefighter ran by and stepped heavily on the proximal part of Justin's foot (not the toes). What bones could have been broken?

Visit this book's website at www.mhhe.com/seeley8 for chapter quizzes, interactive learning exercises, and other study tools.

8 Articulations and Movement

Muscles pull on bones to make them move, but movement would not be possible without joints between the bones. Humans would resemble statues, were it not for the joints between bones that allow bones to move once the muscles have provided the pull. Machine parts most likely to wear out are those that rub together and they require the most maintenance. Movable joints are places in the body where the bones rub together, yet we tend to pay little attention to them. Fortunately, our joints are self-maintaining, but damage to or disease of a joint can make movement very difficult. We realize then how important the movable joints are for normal function.

An **articulation**, or **joint**, is a place where two or more bones come together. We usually think of joints as being movable, but that is not always the case. Many joints allow only limited movement, and others allow no apparent movement. The structure of a given joint is directly correlated with its degree of movement. Fibrous joints have

much less movement than joints containing fluid and having smooth articulating surfaces.

Joints develop between adjacent bones or areas of ossification, and movement is important in determining the type of joint that develops. If movement is restricted—even in a highly movable joint—at any time during an individual's life, the joint may be transformed into a nonmovable joint.

This chapter presents a scheme for *naming joints* (p. 253) and an explanation of *classes of joints* (p. 253) *types of movement* (p. 259), and *range of motion* (p. 263). It then presents a *description of selected joints* (p. 263) and summarizes the *effects of aging on the joints* (p. 272).

Colorized scanning electron micrograph of a chondrocyte within a lacuna surrounded by cartilage matrix. Cartilage provides the durable, resilient cushion within joints.

NAMING JOINTS

Joints are commonly named according to the bones or portions of bones that are united at the joint, such as the temporomandibular joint between the temporal bone and the mandible.

PREDICT 1

What is the name of the joint between the metacarpals and the phalanges?

Some joints are simply given the Greek or Latin equivalent of the common name, such as **cubital** (kū'bi-tāl; cubit, elbow or forearm) **joint** for the elbow joint.

1 What criteria are used to name joints?

CLASSES OF JOINTS

The three major kinds of joints are classified structurally as fibrous, cartilaginous, and synovial. In this classification scheme, joints are categorized according to the major connective tissue type that binds the bones together, and whether or not a fluid-filled joint capsule is present. Joints may also be classified according to their function. This classification is based on the degree of motion at each joint and includes the terms *synarthrosis* (nonmovable joint), *amphiarthrosis* (slightly movable joint), and *diarthrosis* (freely movable joint). This functional classification is somewhat limited and is not used in this book. The structural classification scheme with its various subclasses allows for a more precise classification and is the scheme used in this book.

Fibrous Joints

Fibrous joints consist of two bones that are united by fibrous connective tissue, have no joint cavity, and exhibit little or no movement. Joints in this group are classified further as sutures, syndesmoses, or gomphoses (table 8.1), based on their structure.

Sutures

Sutures (soo'choorz) are seams between the bones of the skull (figure 8.1). Some sutures may become completely immovable in older adults. Few sutures are smooth, and the opposing bones often interdigitate (have interlocking, fingerlike processes). This interdigitation adds considerable stability to sutures. The tissue between the bones is dense regular collagenous connective tissue, and the periosteum on the inner and outer surfaces of the adjacent bones continues over the joint. The two layers of periosteum plus the dense fibrous connective tissue in between form a **sutural ligament**.

In a newborn, a membranous area called a **fontanel** (fon'tā-nel'; little fountain, so-named because the membrane can be seen to move with the pulse; soft spot) is present within some of the sutures. A fontanel makes the skull flexible during the birth process and allows for growth of the head after birth (figure 8.2).

The margins of bones within sutures are sites of continuous intramembranous bone growth, and many sutures eventually

TABLE 8.1 Fibrous and Cartilaginous Joints

Class and Example of Joint	Bones or Structures Joined	Movement
Fibrous Joints		
<i>Sutures</i>		
Coronal	Frontal and parietal	None
Lambdoid	Occipital and parietal	None
Sagittal	The two parietal bones	None
Squamous	Parietal and temporal	Slight
<i>Syndesmoses</i>		
Radioulnar	Ulna and radius	Slight
Stylohyoid	Styloid process and hyoid bone	Slight
Stylomandibular	Styloid process and mandible	Slight
Tibiofibular	Tibia and fibula	Slight
<i>Gomphoses</i>		
Dentoalveolar	Tooth and alveolar process	Slight
Cartilaginous Joints		
<i>Synchondroses</i>		
Epiphyseal plate	Diaphysis and epiphysis of a long bone	None
Sternocostal	Anterior cartilaginous part of first rib; between rib and sternum	Slight
Sphenooccipital	Sphenoid and occipital	None
<i>Symphyses</i>		
Intervertebral	Bodies of adjacent vertebrae	Slight
Manubriosternal	Manubrium and body of sternum	None
Symphysis pubis	The two coxal bones	None except during childbirth
Xiphisternal	Xiphoid process and body of sternum	None

become ossified. For example, ossification of the suture between the two frontal bones occurs shortly after birth so that they usually form a single frontal bone in the adult skull. In most normal adults, the coronal, sagittal, and lambdoid sutures are not fused. In some very old adults, however, even these sutures become ossified. A **synostosis** (sin-os-tō'sis) results when two bones grow together across a joint to form a single bone.

PREDICT 2

Predict the result of a sutural synostosis that occurs prematurely in a child's skull before the brain has reached its full size.

Syndesmoses

A **syndesmosis** (sin'dez-mō'sis; to fasten or bind) is a fibrous joint in which the bones are farther apart than in a suture and are joined by ligaments. Some movement may occur at

FIGURE 8.1 Sutures, Superior View

syndesmoses because of flexibility of the ligaments, such as in the radioulnar syndesmosis, which binds the radius and ulna together (figure 8.3).

Gomphoses

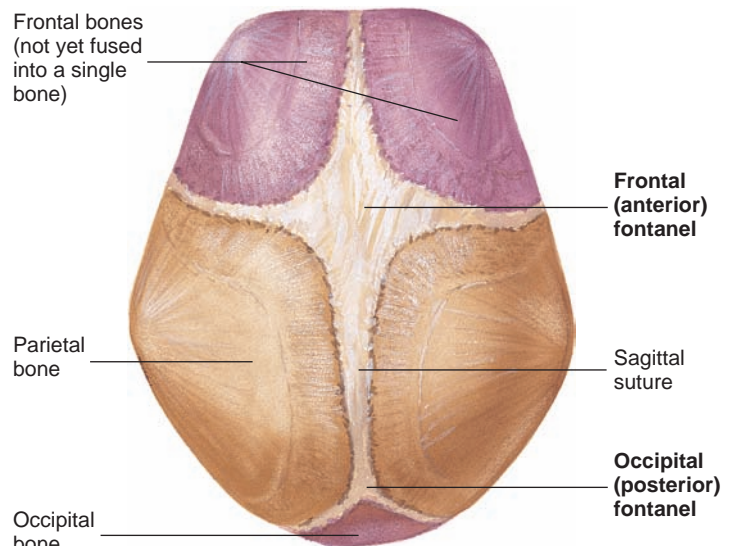

Gomphoses (gom-fō'sēz) are specialized joints consisting of pegs that fit into sockets and that are held in place by fine bundles of regular collagenous connective tissue. The joints between the teeth and the sockets (alveoli) of the mandible and maxillae are gomphoses (figure 8.4). The connective tissue bundles between the teeth and their sockets are called **periodontal ligaments**; they allow a slight amount of “give” to the teeth during mastication.

Gingivitis
 The gingiva, or gums, are the soft tissues covering the alveolar process. Neglect of the teeth can result in **gingivitis**, an inflammation of the gingiva, often resulting from bacterial infection. Left untreated, gingivitis can spread to the tooth socket, resulting in periodontal disease, the leading cause of tooth loss in the United States. Periodontal disease involves an accumulation of plaque and bacteria and the resulting inflammation, which gradually destroys the periodontal ligaments and the bone. As a result, teeth may become so loose that they come out of their sockets. Proper brushing, flossing, and professional cleaning to remove plaque can usually prevent gingivitis and periodontal disease.

2 Define fibrous joint, describe three types, and give an example of each. What is a synostosis? Where are periodontal ligaments found?

(a) Lateral view

(b) Superior view

FIGURE 8.2 Fetal Skull Showing Fontanelles and Sutures

Cartilaginous Joints

Cartilaginous joints unite two bones by means of either hyaline cartilage or fibrocartilage (see table 8.1). Joints containing hyaline cartilage are called **synchondroses**; joints containing fibrocartilage are called **symphyses**.

Synchondroses

A **synchondrosis** (sin'kon-drō'sis; union through cartilage) consists of two bones joined by hyaline cartilage where little or no movement occurs (figure 8.5a). The epiphyseal plates of growing bones are synchondroses (figure 8.5b). Most synchondroses are temporary, with bone eventually replacing them to form synostoses. On the other hand,

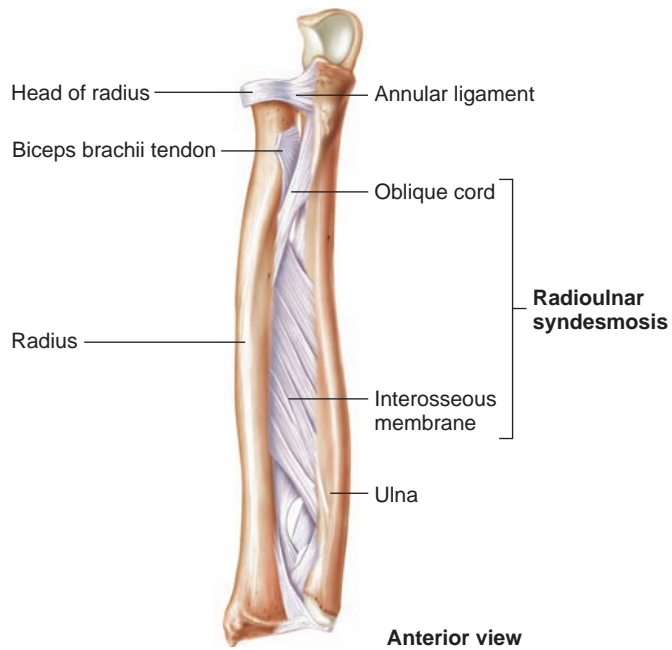

FIGURE 8.3 Right Radioulnar Syndesmosis

FIGURE 8.4 Gomphosis Between a Tooth and Alveolar Bone of the Mandible

some synchondroses persist throughout life. An example is the sternocostal synchondrosis between the first rib and the sternum by way of the first costal cartilage (figure 8.5c). All the costal cartilages begin as synchondroses, but, because of the movement that occurs between them and the sternum, all but the first usually develop synovial joints at those junctions. As a result, even though the **costochondral joints** (between the ribs and the costal cartilages) are retained, most costal cartilages no longer qualify as synchondroses because one end of the cartilage attaches to bone (the sternum) by a synovial joint.

Symphyses

A **symphysis** (sim'fi-sis; a growing together) consists of fibrocartilage uniting two bones. Symphyses include the junction between the manubrium and the body of the sternum (see figure 8.5c), the symphysis pubis (figure 8.6), and the intervertebral disks (see figures 7.13 and 7.14). Some of these joints are slightly movable because of the somewhat flexible nature of fibrocartilage.

Joint Changes During Pregnancy

During pregnancy certain hormones, such as estrogen, progesterone, and relaxin, act on the connective tissue of joints, such as the symphysis pubis, causing them to become more stretchable and allowing the joints to loosen. This change allows the pelvic opening to enlarge at the time of delivery. After delivery, the connective tissue of the symphysis pubis returns to its original condition. The enlarged pelvic opening, however, may not return completely to its original size, and the woman may have slightly wider hips after the birth of the child.

The same hormones may act on the connective tissue of other joints in the body, such as the arches of the feet, causing them to relax, which may result in fallen arches (see "Arch Problems," p. 272). They may also act on some of a baby's joints, such as the hip, causing the joints to become more mobile than normal. Increased mobility of the hip can result in congenital (appearing at birth) subluxation, or congenital dislocation, of the hip. Congenital hip dislocation occurs approximately once in every 670 births.

- 3** Define cartilaginous joints, describe two types, and give an example of each. Why are costochondral joints unique?

Synovial Joints

Synovial (si-nō'vē-āl; joint fluid; *syn*, coming together, *ovia*, resembling egg albumin) **joints** contain synovial fluid and allow considerable movement between articulating bones (figure 8.7). These joints are anatomically more complex than fibrous and cartilaginous joints. Most joints that unite the bones of the appendicular skeleton are synovial joints, reflecting the far greater mobility of the appendicular skeleton, compared with that of the axial skeleton.

The articular surfaces of bones within synovial joints are covered with a thin layer of hyaline cartilage called **articular cartilage**, which provides a smooth surface where the bones meet. In some synovial joints, a flat plate or pad of fibrocartilage, called an **articular disk**, is located between the articular cartilages of bones. The circumference of the disk is attached to the fibrous capsule. Examples of joints with articular disks are the temporomandibular, sternoclavicular, and acromioclavicular joints. A **meniscus** is an incomplete, crescent-shaped fibrocartilage pad found in joints such as the knee and wrist. A meniscus is much like an articular disk with a hole in the center. The circumference of the meniscus is attached to the fibrous joint capsule.

The articular surfaces of the bones that meet at a synovial joint are enclosed within a synovial **joint cavity**, which is surrounded by a **joint capsule**. This capsule helps hold the bones together while allowing for movement. The joint capsule consists of two layers: an outer **fibrous capsule** and an inner **synovial membrane** (see

FIGURE 8.5 Synchondroses

(a) Synchondroses (epiphyseal plates) between the developing bones of the coxal bone. (b) Epiphyseal plates (frontal section of proximal femur). (c) Sternocostal synchondroses.

FIGURE 8.6 Symphysis Pubis

figure 8.7). The fibrous capsule consists of dense irregular connective tissue and is continuous with the fibrous layer of the periosteum that covers the bones united at the joint. Portions of the fibrous capsule may thicken and the collagen fibers become regularly arranged to form ligaments. In addition, ligaments and tendons may be present outside the fibrous capsule, thereby contributing to the strength and stability of the joint while limiting movement in some directions.

The synovial membrane lines the joint cavity, except over the articular cartilage and articular disks. It is a thin, delicate membrane consisting of a collection of modified connective tissue cells either intermixed with part of the fibrous capsule or separated from it by a layer of areolar tissue or adipose tissue. The membrane produces synovial fluid, which consists of a serum (blood fluid) filtrate and secretions from the synovial cells. Synovial fluid is a complex mixture of polysaccharides, proteins, fat, and cells. The major polysaccharide is hyaluronic acid, which provides much of the slippery consistency

FIGURE 8.7 Structure of a Synovial Joint

and lubricating qualities of synovial fluid. Synovial fluid forms an important thin lubricating film that covers the surfaces of a joint.

PREDICT 3

What would happen if a synovial membrane covered the articular cartilage?

In certain synovial joints, such as the shoulder and knee, the synovial membrane extends as a pocket, or sac, called a **bursa** (ber'sā; pocket) for a distance away from the rest of the joint cavity (see figure 8.7). Bursae contain synovial fluid, providing a cushion between structures that otherwise would rub against each other, such as tendons rubbing on bones or other tendons. Some bursae, such as the subcutaneous olecranon bursae, are not associated with joints but provide a cushion between the skin and underlying bony prominences, where friction could damage the tissues. Other bursae extend along tendons for some distance, forming **tendon sheaths**. **Bursitis** (ber-sī'tis) is an inflammation of a bursa and may cause considerable pain around the joint and restrict movement.

At the peripheral margin of the articular cartilage, blood vessels form a vascular circle that supplies the cartilage with nourishment, but no blood vessels penetrate the cartilage or enter the joint cavity. Additional nourishment to the articular cartilage comes from the underlying cancellous bone and from the synovial fluid covering the articular cartilage. Sensory nerves enter the fibrous

capsule and, to a lesser extent, the synovial membrane. They not only supply information to the brain about pain in the joint but also furnish constant information to the brain about the position of the joint and its degree of movement (see chapter 14). Nerves do not enter the cartilage or joint cavity.

- 4 Describe the structure of a synovial joint. How do the different parts of the joint permit joint movement? What are articular disks and where are they found?
- 5 Define bursa and tendon sheath. What is their function?

Types of Synovial Joints

Synovial joints are classified according to the shape of the adjoining articular surfaces. The six types of synovial joints are plane, saddle, hinge, pivot, ball-and-socket, and ellipsoid. These joints are listed in table 8.2. Movements at synovial joints are described as **uniaxial** (occurring around one axis), **biaxial** (occurring around two axes situated at right angles to each other), or **multiaxial** (occurring around several axes).

Plane, or gliding, joints consist of two opposed flat surfaces of about equal size in which a slight amount of gliding motion can occur between the bones (figure 8.8). These joints are considered uniaxial because some rotation is also possible but is limited by ligaments and adjacent bone. Examples are the articular processes between vertebrae.

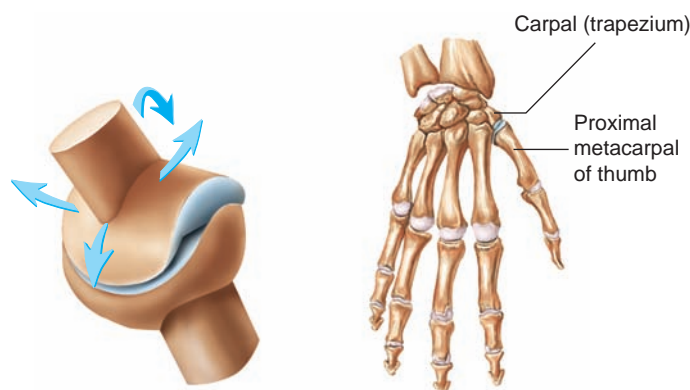

TABLE 8.2 Types of Joints

Class	Example	Structures Joined	Movement
Plane (uniaxial)	Acromioclavicular	Acromion process of scapula and clavicle	Slight
	Carpometacarpal	Carpals and metacarpals 2–5	Slight
	Costovertebral	Ribs and vertebrae	Slight
	Intercarpal	Between carpals	Slight
	Intertarsal	Between tarsals	Slight
	Intervertebral	Between articular processes of adjacent vertebrae	Slight
	Sacroiliac	Between sacrum and coxal bone (complex joint with several planes and synchondroses)	Slight
	Tarsometatarsal	Tarsals and metatarsals	Slight
Saddle (biaxial)	Carpometacarpal pollicis	Carpal and metacarpal of thumb	Two axes
	Intercarpal	Between carpals	Slight
	Sternoclavicular	Manubrium of sternum and clavicle	Slight
Hinge (uniaxial)	Cubital (elbow)	Humerus, ulna, and radius	One axis
	Genu (knee)	Femur and tibia	One axis
	Interphalangeal	Between phalanges	One axis
	Talocrural (ankle)	Talus, tibia, and fibula	Multiple axes, one predominates
Pivot (uniaxial)	Atlantoaxial	Atlas and axis	Rotation
	Proximal radioulnar	Radius and ulna	Rotation
	Distal radioulnar	Radius and ulna	Rotation
Ball-and-socket (multiaxial)	Coxal (hip)	Coxal bone and femur	Multiple axes
	Glenohumeral (shoulder)	Scapula and humerus	Multiple axes
Ellipsoid (biaxial or multiaxial)	Atlantooccipital	Atlas and occipital bone	Two axes
	Metacarpophalangeal (knuckles)	Metacarpals and phalanges	Two axes
	Metatarsophalangeal	Metatarsals and phalanges	Two axes
	Radiocarpal (wrist)	Radius and carpals	Multiple axes
	Temporomandibular	Mandible and temporal bone	Multiple axes, one predominates

Saddle joints consist of two saddle-shaped articulating surfaces oriented at right angles to each other so that complementary surfaces articulate with each other (figure 8.9). Saddle joints are biaxial joints. The carpometacarpal joint of the thumb is an example.

Hinge joints are uniaxial joints (figure 8.10). They consist of a convex cylinder in one bone applied to a corresponding concavity in the other bone. Examples include the elbow and knee joints.

Pivot joints are uniaxial joints that restrict movement to rotation around a single axis (figure 8.11). A pivot joint consists of a relatively cylindrical bony process that rotates within a ring composed partly of bone and partly of ligament. The articulation between the head of the radius and the proximal end of the ulna

**FIGURE 8.8** Plane Joint**FIGURE 8.9** Saddle Joint

FIGURE 8.10 Hinge Joint

FIGURE 8.13 Ellipsoid Joint

FIGURE 8.11 Pivot Joint

FIGURE 8.12 Ball-and-Socket Joint

is an example. The articulation between the dens, a process on the axis (see chapter 7), and the atlas is another example.

Ball-and-socket joints consist of a ball (head) at the end of one bone and a socket in an adjacent bone into which a portion of the ball fits (figure 8.12). This type of joint is multiaxial, allowing a wide range of movement in almost any direction. Examples are the shoulder and hip joints.

Ellipsoid joints (or condyloid joints) are modified ball-and-socket joints (figure 8.13). The articular surfaces are ellipsoid in shape rather than spherical as in regular ball-and-socket joints. Ellipsoid joints are biaxial, because the shape of the joint limits its range of movement almost to a hinge motion in two axes and restricts rotation. The atlantooccipital joint is an example.

6 *On what basis are synovial joints classified? Describe the types of synovial joints, and give examples of each. What movements does each type of joint allow?*

TYPES OF MOVEMENT

A joint's structure relates to the movements that occur at that joint. Some joints are limited to only one type of movement; others can move in several directions. With few exceptions, movement is best described in relation to the anatomical position: (1) movement away from the anatomical position and (2) movement returning a structure toward the anatomical position. Most movements are accompanied by movements in the opposite direction and therefore are listed in pairs.

Gliding Movements

Gliding movements are the simplest of all the types of movement. These movements occur in plane joints between two flat or nearly flat surfaces where the surfaces slide or glide over each other. These joints often give only slight movement, such as between carpal bones.

Angular Movements

Angular movements are those in which one part of a linear structure, such as the body as a whole or a limb, is bent relative to another part of the structure, thereby changing the angle between the two parts. Angular movements also involve the movement of a solid rod, such as a limb, that is attached at one end to the body so that the angle at which it meets the body changed. The most common angular movements are flexion and extension and abduction and adduction.

Flexion and Extension

Flexion and extension can be defined in a number of ways, but in each case exceptions to the definition exist. The literal definition is to bend and straighten, respectively. This bending and straightening can easily be seen in the elbow (figure 8.14) or knee (see figure 8.16). The following definition, however, has more utility and fewer exceptions, with reference to the coronal plane. **Flexion** is movement of a body part anterior to the coronal plane, or in the anterior direction. **Extension** is movement of a body part posterior to the coronal plane, or in the posterior direction (figure 8.15).

The exceptions to defining flexion and extension according to the coronal plane are the knee and foot. At the knee, flexion moves the leg in a posterior direction and extension moves it in an anterior direction (figure 8.16). Movement of the foot toward the plantar surface, such as when standing on the toes, is commonly

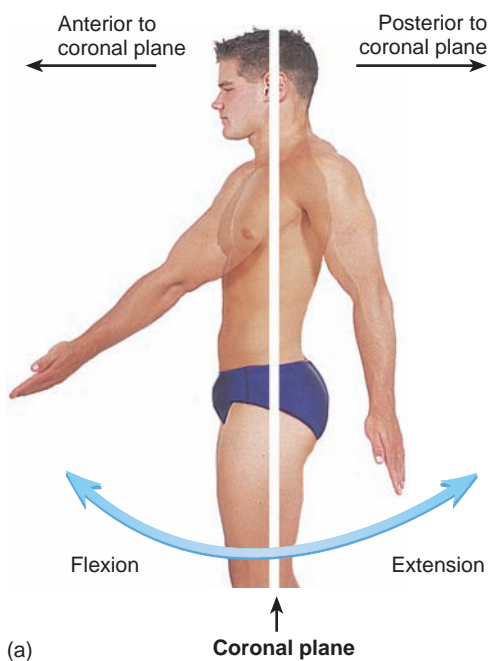

FIGURE 8.14 Flexion and Extension of the Elbow

called **plantar flexion**; movement of the foot toward the shin, such as when walking on the heels, is called **dorsiflexion** (figure 8.17).

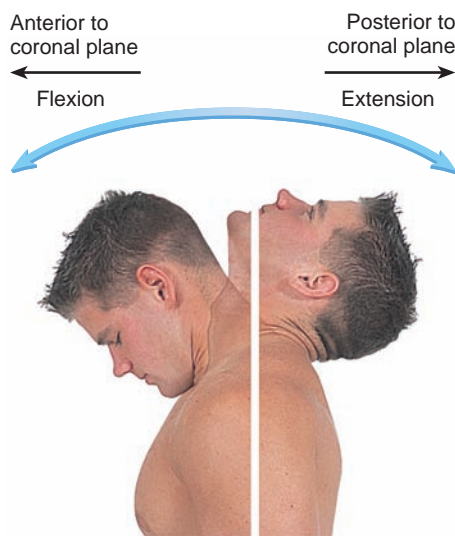

Hyperextension

Hyperextension is usually defined as an abnormal, forced extension of a joint beyond its normal range of motion. For example, if a person falls and attempts to break the fall by putting out a hand, the force of the fall directed into the hand and wrist may cause hyperextension of the wrist, which may result in sprained joints or broken bones. Some health professionals, however, define hyperextension as the normal movement of structures, except the leg, into the space posterior to the anatomical position.

Coronal plane

FIGURE 8.15 Flexion and Extension Defined According to the Coronal Plane

Flexion and extension of (a) the shoulder, (b) the neck, and (c) the trunk.

FIGURE 8.16 Flexion and Extension of the Knee

Abduction and Adduction

Abduction (to take away) is movement away from the median plane; **adduction** (to bring together) is movement toward the midline. Moving the upper limbs away from the body, such as in the outward portion of doing jumping jacks, is abduction, and bringing the upper limbs back toward the body is adduction (figure 8.18a). Abduction of the fingers involves spreading the fingers apart, away from the midline of the hand, and adduction is bringing them back together (figure 8.18b). Abduction of the thumb moves it anteriorly, away from the palm. Abduction of the wrist, which is sometimes called radial deviation, is movement of the hand away from the midline of the body, and adduction of the wrist, which is sometimes called ulnar deviation, results in movement of the hand toward the midline of the body. Abduction of the head is tilting the

FIGURE 8.17 Dorsiflexion and Plantar Flexion of the Foot

FIGURE 8.18 Abduction and Adduction

Abduction and adduction of (a) the upper limb and (b) the fingers.

head to one side or the other and is commonly called lateral flexion of the neck. Bending at the waist to one side is usually called **lateral flexion** of the vertebral column, rather than abduction.

- 7** Define flexion and extension. How are they different for the upper and lower limbs? What is hyperextension?
- 8** Contrast abduction and adduction. Describe these movements for the head, upper limbs, wrist, fingers, lower limbs, and toes. For what part of the body is the term lateral flexion used?

Circular Movements

Circular movements involve the rotation of a structure around an axis or movement of the structure in an arc.

Rotation

Rotation is the turning of a structure around its long axis, such as rotation of the head, the humerus, or the entire body (figure 8.19). Medial rotation of the humerus with the forearm flexed brings the hand toward the body. Rotation of the humerus so that the hand moves away from the body is lateral rotation.

Pronation and Supination

Pronation (prō-nā'shūn) and **supination** (soo'pi-nā'shūn) refer to the unique rotation of the forearm (figure 8.20). The word *prone* means lying facedown; the word *supine* means lying faceup. Pronation is rotation of the forearm so that the palm faces posteriorly in relation to the anatomical position. The palm of the hand faces inferiorly if the elbow is flexed to 90 degrees. Supination is rotation of the forearm so that the palm faces anteriorly in relation to the anatomical position. The palm of the hand faces superiorly if the elbow is flexed to 90 degrees. In pronation, the radius and ulna cross; in supination, they are in a parallel position. The head of the radius rotates against the radial notch of the ulna during supination and pronation.

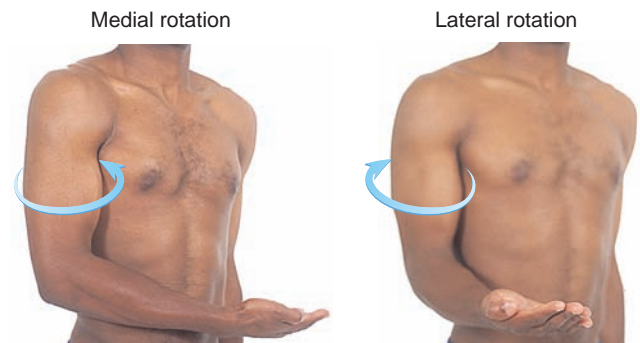

FIGURE 8.19 Medial and Lateral Rotation of the Arm

FIGURE 8.20 Pronation and Supination of the Hand

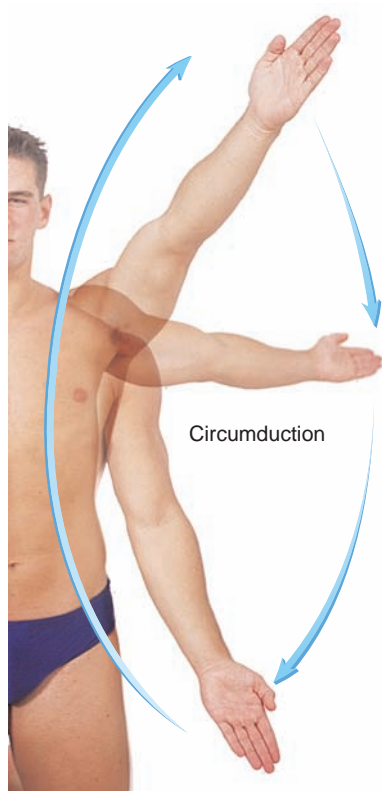

FIGURE 8.21 Circumduction

Circumduction

Circumduction is a combination of flexion, extension, abduction, and adduction (figure 8.21). It occurs at freely movable joints, such as the shoulder. In circumduction, the arm moves so that it describes a cone with the shoulder joint at the apex.

- 9** Distinguish among rotation, circumduction, pronation, and supination. Give an example of each.

Special Movements

Special movements are those movements unique to only one or two joints; they do not fit neatly into one of the other categories.

Elevation and Depression

Elevation moves a structure superiorly; **depression** moves it inferiorly (figure 8.22). The scapulae and mandible are primary examples. Shrugging the shoulders is an example of scapular elevation. Depression of the mandible opens the mouth, and elevation closes it.

Protraction and Retraction

Protraction consists of moving a structure in a gliding motion in an anterior direction (figure 8.23). **Retraction** moves the structure back to the anatomical position or even more posteriorly. As with elevation and depression, the mandible and scapulae are primary examples. Pulling the scapulae back toward the vertebral column is retraction.

FIGURE 8.22 Elevation and Depression of the Scapula

FIGURE 8.23 Protraction and Retraction of the Mandible

FIGURE 8.24 Excursion of the Mandible

Excursion

Lateral excursion is moving the mandible to either the right or left of the midline (figure 8.24), such as in grinding the teeth or chewing. **Medial excursion** returns the mandible to the neutral position.

FIGURE 8.25 Opposition and Reposition of the Thumb and Little Finger

Opposition and Reposition

Opposition is a unique movement of the thumb and little finger (figure 8.25). It occurs when these two digits are brought toward each other across the palm of the hand. The thumb can also oppose the other digits, but those digits flex to touch the tip of the opposing thumb. **Reposition** is the movement returning the thumb and little finger to the neutral, anatomical position.

Inversion and Eversion

Inversion consists of turning the ankle so that the plantar surface of the foot faces medially, toward the opposite foot. **Eversion** is turning the ankle so that the plantar surface faces laterally (figure 8.26). Inversion of the foot is sometimes called supination, and eversion is called pronation.

- 10** Define the following jaw movements: *protraction, retraction, lateral excursion, medial excursion, elevation, and depression.*
- 11** Define *opposition and reposition.*
- 12** What terms are used for *flexion and extension of the foot? For turning the side of the foot medially or laterally?*

Combination Movements

Most movements that occur in the course of normal activities are combinations of the movements named previously and are described by naming the individual movements involved in the combined movement. For example, when a person steps forward

FIGURE 8.26 Inversion and Eversion of the Foot

at a 45-degree angle to the side, the movement at the hip is a combination of flexion and abduction.

PREDICT 4

What combination of movements is required at the shoulder and elbow joints for a person to move the right upper limb from the anatomical position to touch the right side of the head with the fingertips?

RANGE OF MOTION

Range of motion is an expression of the amount of mobility that can be demonstrated in a given joint. The **active range of motion** is the amount of movement that can be accomplished by contraction of the muscles that normally act across a joint. The **passive range of motion** is the amount of movement that can be accomplished at a joint when the structures that meet at the joint are moved by an outside force, such as when a therapist holds onto the forearm of a patient and moves it toward the patient's arm, flexing the elbow joint. The active and passive ranges of motion for normal joints are usually about equal.

The range of motion for a given joint is influenced by a number of factors, including the shape of the articular surfaces of the bones forming the joint, the amount and shape of cartilage covering those articular surfaces, the strength and location of ligaments and tendons surrounding the joint, the strength and location of the muscles associated with the joint, the amount of fluid in and around the joint, the amount of pain in and around the joint, and the amount of use or disuse the joint has received over time. Abnormalities in the range of motion can occur when any of those components changes. For example, damage to a ligament associated with a given joint may increase the range of motion of that joint. A torn piece of cartilage within a joint can limit its range of motion. If the nerve supply to a muscle is damaged so that the muscle is weakened, the active range of motion for the joint acted on by that muscle may decrease, but the passive range of motion for the joint should remain unchanged. Fluid buildup and/or pain in or around a joint (such as when the soft tissues around the joint develop edema following an injury) can severely limit both the active and passive ranges of motion for that joint. With disuse, both the active and passive ranges of motion for a given joint decrease.

- 13** Define *range of motion. Contrast active range of motion with passive range of motion. What factors influence range of motion?*

DESCRIPTION OF SELECTED JOINTS

It is impossible in a limited space to describe all the joints of the body; therefore, only selected joints are described in this chapter, and they have been chosen because of their representative structure, important function, or clinical significance.

Temporomandibular Joint

The mandible articulates with the temporal bone to form the **temporomandibular joint (TMJ)**. The mandibular condyle fits into the mandibular fossa of the temporal bone. A fibrocartilage

FIGURE 8.27 Right Temporomandibular Joint, Lateral View

articular disk is located between the mandible and the temporal bone, dividing the joint into superior and inferior joint cavities (figure 8.27). The joint is surrounded by a fibrous capsule, to which the articular disk is attached at its margin, and is strengthened by lateral and accessory ligaments.

The temporomandibular joint is a combination plane and ellipsoid joint, with the ellipsoid portion predominating. Depression of the mandible to open the mouth involves an anterior gliding motion of the mandibular condyle and articular disk relative to the temporal bone, which is about the same motion that occurs in protraction of the mandible; it is followed by a hinge motion between the articular disk and the mandibular head. The mandibular condyle is also capable of slight mediolateral movement, allowing excursion of the mandible.

Shoulder Joint

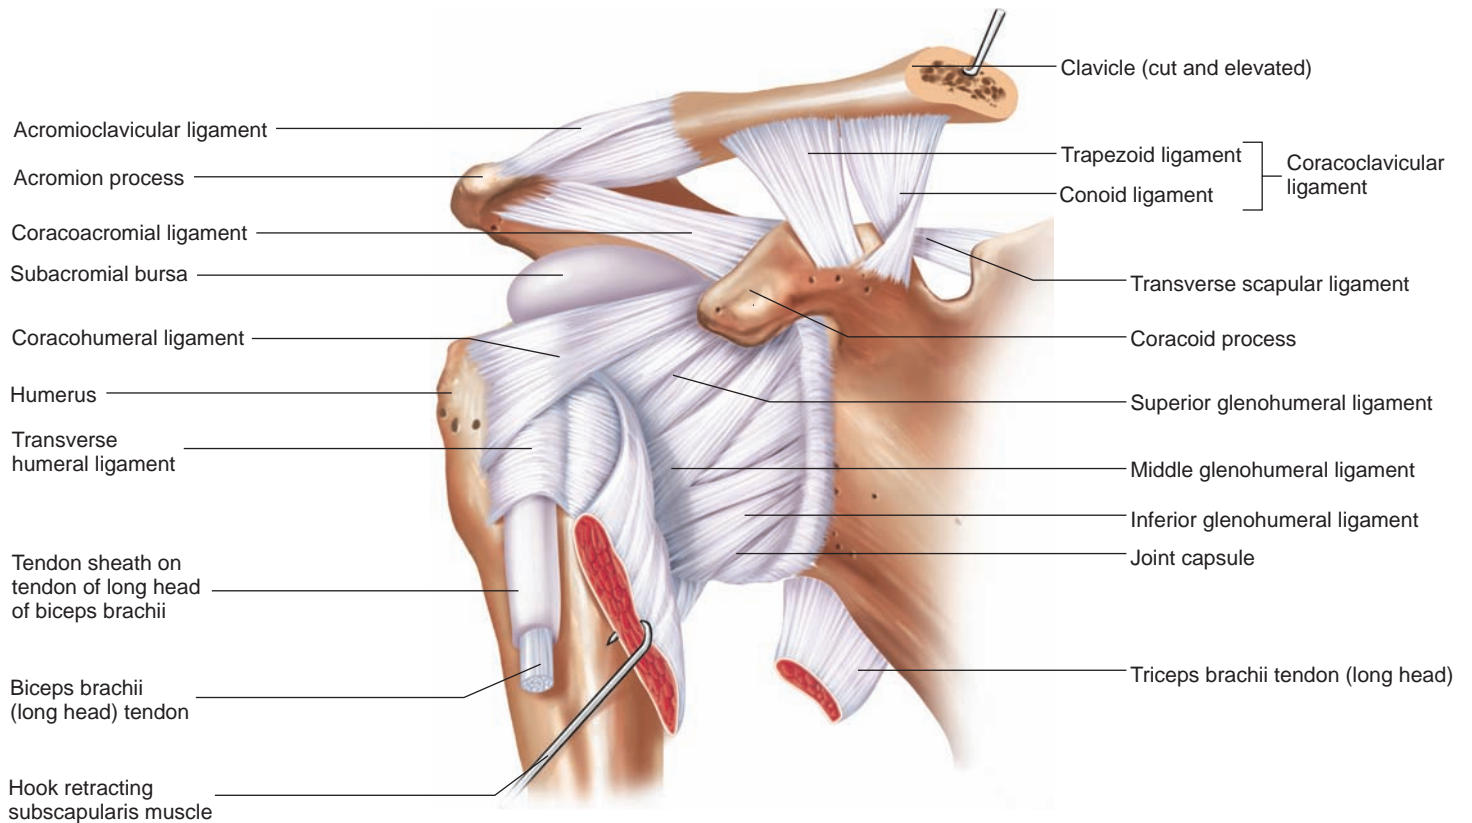

The **shoulder**, or **glenohumeral joint** is a ball-and-socket joint (figure 8.28) in which stability is reduced and mobility is increased compared with the other ball-and-socket joint, the hip. Flexion, extension, abduction, adduction, rotation, and circumduction can all occur at the shoulder joint. The rounded head of the humerus articulates with the shallow glenoid cavity of the scapula. The rim of the glenoid cavity is built up slightly by a fibrocartilage ring, the **glenoid labrum**, to which the joint capsule is attached. A **subscapular bursa** (not shown in figure 8.28) opens into the joint cavity. A **subacromial bursa** is located near the joint cavity but is separated from the cavity by the joint capsule (see figure 8.28).

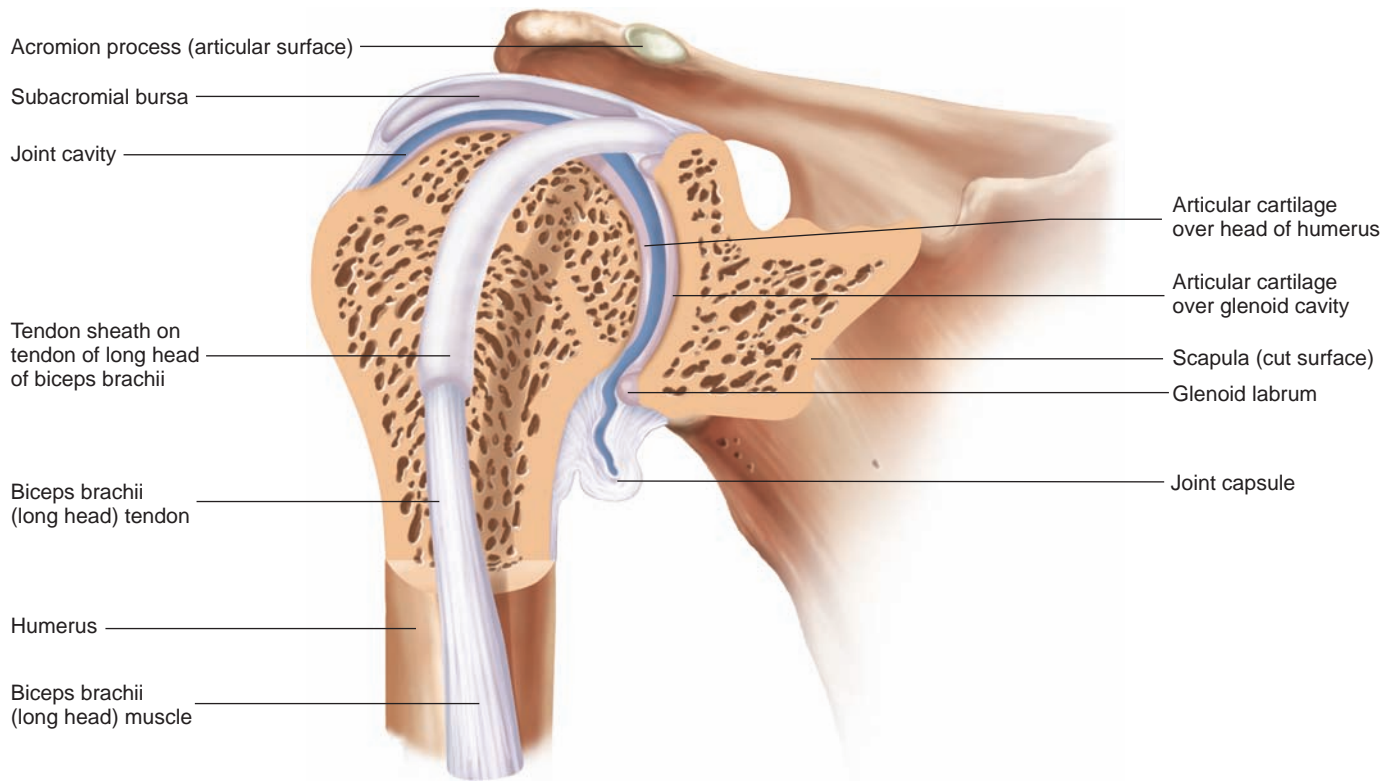

TMJ Disorders

TMJ disorders are conditions that cause most chronic orofacial pain. The conditions include joint noise; pain in the muscles, joint, or face; headache; and reduction in the range of joint movement. TMJ pain is often felt as referred pain in the ear. Patients may go to a physician complaining of an earache and are then referred to a dentist. As many as 65%–75% of people between ages 20 and 40 experience some of these symptoms. Symptoms appear to affect men and women about equally, but only about 10% of the symptoms are severe enough to cause people to seek medical attention. Women experience severe pain eight times more often than do men.

TMJ disorders are classified as those involving the joint, with or without pain; those involving only muscle pain; and those involving both the joint disorder and muscle pain. TMJ disorders are also classified as acute or chronic. Acute cases are usually self-limiting and have an identifiable cause. Chronic cases are not self-limiting, may be permanent, and often have no apparent cause. Chronic TMJ disorders are not easily treated, and chronic TMJ pain has much in common with other types of chronic pain. Whereas some people learn to live with the pain, others experience psychological problems, such as a sense of helplessness and hopelessness, high tension, and loss of sleep and appetite. Drug dependency may occur if strong drugs are used to control the pain, and relationships, lifestyle, vocation, and social interactions may be disrupted. Many of these problems may make the pain worse through positive feedback. Treatment includes teaching the patient to reduce jaw movements that aggravate the problem and to reduce stress and anxiety. Physical therapy may help relax the muscles and restore function. Analgesic and anti-inflammatory drugs may be used, and oral splints may be helpful, especially at night.

(b) Frontal section

FIGURE 8.28 Right Shoulder Joint

TABLE 8.3 Ligaments of the Shoulder Joint (See Figure 8.28)

Ligament	Description
Glenohumeral (superior, middle, and inferior)	Three slightly thickened longitudinal sets of fibers on the anterior side of the capsule; extend from the humerus to the margin of the glenoid cavity
Transverse humeral	Lateral, transverse fibrous thickening of the joint capsule; crosses between the greater and lesser tubercles and holds down the tendon from the long head of the biceps brachii muscle
Coracohumeral	Crosses from the root of the coracoid process to the humeral neck
Coracoacromial	Crosses above the joint between the coracoid process and the acromion process; an accessory, protective ligament

The stability of the joint is maintained primarily by three sets of ligaments and four muscles. The ligaments of the shoulder are listed in table 8.3. The four muscles, referred to collectively as the **rotator cuff**, hold the humeral head tightly within the glenoid cavity. These muscles are discussed in more detail in chapter 10. The head of the humerus is also supported against the glenoid cavity by the tendon from the biceps brachii muscle in the anterior part of the arm. This tendon is unusual in that it passes through the articular capsule of the shoulder joint before crossing the head of the humerus and attaching to the scapula at the supraglenoid tubercle (see figure 7.24a).

Shoulder Disorders

The most common traumatic shoulder disorders are **dislocation** and muscle or tendon **tears**. The shoulder is the most commonly dislocated joint in the body. The major ligaments cross the superior part of the shoulder joint, and no major ligaments or muscles are associated with the inferior side. As a result, dislocation of the humerus is most likely to occur inferiorly into the axilla. Because the axilla contains very important nerves and arteries, severe and permanent damage may occur when the humeral head dislocates inferiorly. The axillary nerve is the most commonly damaged (see chapter 12).

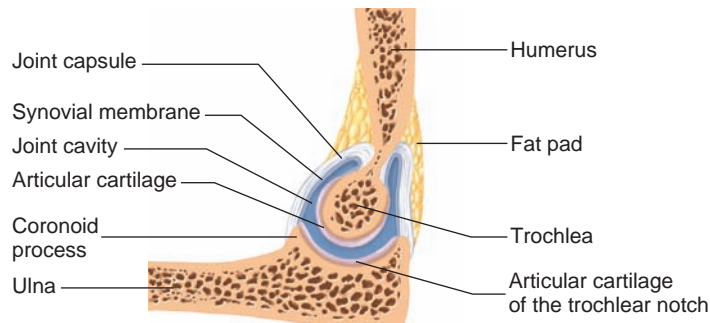

Chronic shoulder disorders include tendonitis (inflammation of tendons), bursitis (inflammation of bursae), and arthritis (inflammation of joints). Bursitis of the subacromial bursa can become very painful when the large shoulder muscle, called the deltoid muscle, compresses the bursa during shoulder movement.

PREDICT 5

Separation of the shoulder consists of stretching or tearing the ligaments of the acromioclavicular joint (acromioclavicular, or AC, separation). Using figure 8.28a and your knowledge of the articulated skeleton for assistance, explain the nature of a shoulder separation and predict the problems that may follow a separation.

Elbow Joint

The **elbow joint** (figure 8.29) is a compound hinge joint consisting of the **humeroulnar joint**, between the humerus and ulna, and the **humeroradial joint**, between the humerus and radius. The **proximal radioulnar joint**, between the proximal radius and

FIGURE 8.30 Right Coxal, or Hip, Joint

ulna, is also closely related. The shape of the trochlear notch and its association with the trochlea of the humerus (see figure 8.29a) limit movement at the elbow joint to flexion and extension. The rounded radial head, however, rotates in the radial notch of the ulna and against the capitulum of the humerus (see figure 8.29b), allowing pronation and supination of the hand.

Elbow Problems

Olecranon bursitis is an inflammation of the olecranon bursa. This inflammation can be caused by excessive rubbing of the elbow against a hard surface and is sometimes referred to as **student's elbow**. The radial head can become subluxated (partial joint separation) from the annular ligament of the radius. This condition is called **nursemaid's elbow**. If a child is lifted by one hand, the action may subluxate (partially dislocate) the radial head.

The elbow joint is surrounded by a joint capsule. The humeroulnar joint is reinforced by the **ulnar collateral ligament** (see figure 8.29c). The humeroradial and proximal radioulnar joints are reinforced by the **radial collateral ligament** and **radial annular ligament** (see figure 8.29d). A subcutaneous **olecranon bursa** covers the proximal and posterior surfaces of the olecranon process.

Hip Joint

The femoral head articulates with the relatively deep, concave acetabulum of the coxal bone to form the **coxal, or hip, joint** (figure 8.30). The head of the femur is more nearly a complete ball than the articulating surface of any other bone of the body. The acetabulum is deepened and strengthened by a lip of fibrocartilage called the **acetabular labrum**, which is incomplete inferiorly, and by a **transverse acetabular ligament**, which crosses the acetabular notch on the inferior edge of the acetabulum. The hip is capable

of a wide range of movement, including flexion, extension, abduction, adduction, rotation, and circumduction.

Hip Dislocation
Dislocation of the hip may occur when the hip is flexed and the femur is driven posteriorly, such as when a person sitting in an automobile is involved in an accident. The head of the femur usually dislocates posterior to the acetabulum, tearing the acetabular labrum, the fibrous capsule, and the ligaments. Fracture of the femur and the coxal bone often accompanies hip dislocation.

An extremely strong joint capsule, reinforced by several ligaments, extends from the rim of the acetabulum to the neck of the femur (table 8.4). The **iliofemoral ligament** is especially strong. When standing, most people tend to thrust the hips anteriorly. This position is relaxing because the iliofemoral ligament supports much of the body's weight. The **ligament of the head of the femur** (round ligament of the femur) is located inside the hip joint between the femoral head and the acetabulum. This ligament does not contribute much toward strengthening the hip joint; however, it does carry a small nutrient artery to the head of the femur in about 80% of the population. The acetabular labrum, ligaments of the hip, and the surrounding muscles make the hip joint much more stable but less mobile than the shoulder joint.

TABLE 8.4 Ligaments of the Hip Joint (See Figure 8.30)	
Ligament	Description
Transverse acetabular	Bridges gap in the inferior margin of the fibrocartilage acetabular labrum
Iliofofemoral	Strong, thick band between the anterior inferior iliac spine and the intertrochanteric line of the femur
Pubofemoral	Extends from the pubic portion of the acetabular rim to the inferior portion of the femoral neck
Ischiofemoral	Bridges the ischial acetabular rim and the superior portion of the femoral neck; less well defined
Ligament of the head of the femur	Weak, flat band from the margin of the acetabular notch and the transverse ligament to a fovea in the center of the femoral head

Knee Joint

The **knee joint** traditionally is classified as a modified hinge joint located between the femur and the tibia (figure 8.31). Actually, it is a complex ellipsoid joint that allows flexion, extension, and a small amount of rotation of the leg. The distal end of the femur

TABLE 8.5 Ligaments of the Knee Joint (See Figure 8.31)

Ligament	Description	Ligament	Description
Patellar	Thick, heavy, fibrous band between the patella and the tibial tuberosity; actually part of the quadriceps femoris tendon	Anterior cruciate	Extends obliquely, superiorly, and posteriorly from the anterior intercondylar eminence of the tibia to the medial side of the lateral femoral condyle
Patellar retinaculum	Thin band from the margins of the patella to the sides of the tibial condyles	Posterior cruciate	Extends superiorly and anteriorly from the posterior intercondylar eminence to the lateral side of the medial condyle
Oblique popliteal	Thickening of the posterior capsule; extension of the semimembranous tendon	Coronary (medial and lateral)	Attaches the menisci to the tibial condyles (not illustrated)
Arcuate popliteal	Extends from the posterior fibular head to the posterior fibrous capsule	Transverse	Connects the anterior portions of the medial and lateral menisci
Tibial collateral	Thickening of the lateral capsule from the medial epicondyle of the femur to the medial surface of the tibia; also called the medial collateral ligament	Meniscofemoral (anterior and posterior)	Joins the posterior part of the lateral menisci to the medial condyle of the femur, passing anterior and posterior to the posterior cruciate ligament
Fibular collateral	Round ligament extending from the lateral femoral epicondyle to the head of the fibula; also called the lateral collateral ligament		

has two large ellipsoid surfaces and a deep fossa between them. The femur articulates with the proximal end of the tibia, which is flattened and smooth laterally, with a crest called the intercondylar eminence in the center (see figure 7.36). The margins of the tibia are built up by thick fibrocartilage articular disks, called **menisci** (mĕ-nis'is; crescent-shaped; see figure 8.31*b* and *d*), that deepen the articular surface. The fibula does not articulate with the femur but articulates only with the lateral side of the tibia.

Two **cruciate** (kroo'shĕ-āt; crossed) **ligaments** extend between the intercondylar eminence of the tibia and the fossa of the femur (see figure 8.31*b*, *d*, and *e*). The anterior cruciate ligament prevents anterior displacement of the tibia relative to the femur, and the posterior cruciate ligament prevents posterior displacement of the tibia. The joint is also strengthened by **collateral** and **popliteal ligaments** and by the tendons of the thigh muscles, which extend around the knee (table 8.5).

A number of bursae surround the knee (see figure 8.31*f*). The largest is the **suprapatellar bursa**, which is a superior extension of the joint capsule that allows for movement of the anterior thigh muscles over the distal end of the femur. Other knee bursae include the subcutaneous prepatellar bursa and the deep infrapatellar bursa, as well as the popliteal bursa, the gastrocnemius bursa, and the subcutaneous infrapatellar bursa (not shown in figure 8.31).

Ankle Joint and Arches of the Foot

The distal tibia and fibula form a highly modified hinge joint with the talus called the **ankle**, or **talocrural** (tā'lō-kroo'rāl), **joint** (figure 8.32). The medial and lateral malleoli of the tibia and fibula, which form the medial and lateral margins of the ankle, are rather extensive, whereas the anterior and posterior margins are almost nonexistent. As a result, a hinge joint is created. A fibrous

**FIGURE 8.32 Ligaments of the Right Ankle Joint**

CLINICAL FOCUS

Knee Injuries and Disorders

Injuries to the medial side of the knee are much more common than injuries to the lateral side. The **fibular (lateral) collateral ligament** strengthens the joint laterally and is stronger than the tibial (medial) collateral ligament. Damage to the collateral ligaments occurs as a result of blows to the opposite side of the knee. Severe blows to the medial side of the knee, which would damage the fibular collateral ligament, are far less common than blows to the lateral side of the knee, which damage the **tibial collateral ligament**.

In addition, the **medial meniscus** is fairly tightly attached to the tibial collateral ligament and is damaged 20 times more often in a knee injury than the lateral meniscus, which is thinner and not attached to the fibular collateral ligament. A **torn meniscus** may result in a “clicking” sound during extension of the leg; if the damage is more severe, the torn piece of cartilage may move between the articulating surfaces of the tibia and femur, causing the knee to “lock” in a partially flexed position.

If the knee is driven anteriorly or if the knee is hyperextended, the **anterior cruciate ligament** may be torn, which causes the knee joint to be very unstable. If the knee is flexed and the tibia is driven posteriorly, the **posterior cruciate ligament** may be torn. Surgical replacement of a cruciate ligament with a transplanted or an artificial ligament repairs the damage.

A common type of football injury results from a block or tackle to the lateral side of the knee, which can cause the knee to bend inward, tearing the tibial (medial) collateral ligament and opening the medial side of the joint. The **medial meniscus**, which is strongly attached to this ligament, often is torn as well. In severe medial knee injuries, the anterior cruciate ligament is also damaged (figure A). Tearing of the tibial collateral ligament, medial meniscus, and

anterior cruciate ligament is often referred to as “the unhappy triad of injuries.”

Bursitis in the **subcutaneous prepatellar bursa** (see figure 8.31f), commonly called “housemaid’s knee,” may result from prolonged work performed while on the hands and knees. Another bursitis, “clergyman’s knee,” results from excessive kneeling and affects the **subcutaneous infrapatellar bursa**. This type of bursitis is common among carpet layers and roofers.

Other common knee problems are **chondromalacia** (kon’drō-mā-lā’shē-ā), or softening

of the cartilage, which results from abnormal movement of the patella within the patellar groove, and **fat pad syndrome**, which consists of an accumulation of fluid in the fat pad posterior to the patella. An acutely swollen knee appearing immediately after an injury is usually a sign of blood accumulation within the joint cavity and is called a **hemarthrosis** (hē’marthrō’sis, hem’ar-thrō’sis). A slower accumulation of fluid, “water on the knee,” may be caused by bursitis.

FIGURE A Injury to the Right Knee

capsule surrounds the joint, with the medial and lateral parts thickened to form ligaments. Other ligaments also help stabilize the joint (table 8.6). Dorsiflexion, plantar flexion, and limited inversion and eversion can occur at this joint.

The ligaments of the arches (see figure 7.39) serve two major functions: to hold the bones in their proper relationship as seg-

ments of the arch and to provide ties across the arch somewhat like a bowstring. As weight is transferred through the arch system, some of the ligaments are stretched, giving the foot more flexibility and allowing it to adjust to uneven surfaces. When weight is removed from the foot, the ligaments recoil and restore the arches to their unstressed shape.

TABLE 8.6 Ligaments of the Ankle and Arch (See Figure 8.32)

Ligament	Description
Medial	Thickening of the medial fibrous capsule that attaches the medial malleolus to the calcaneus, navicular, and talus; also called the deltoid ligament
Calcaneofibular	Extends from the lateral malleolus to the lateral surface of the calcaneus; separate from the capsule
Anterior talofibular	Extends from the lateral malleolus to the neck of the talus; fused with the joint capsule
Long plantar	Extends from the calcaneus to the cuboid and bases of metatarsals 2–5
Plantar calcaneocuboid	Extends from the calcaneus to the cuboid
Plantar calcaneonavicular (short plantar)	Extends from the calcaneus to the navicular

Ankle Injury

The ankle is the most frequently injured major joint in the body. The most common ankle injuries result from forceful inversion of the foot. A **sprained ankle** results when the ligaments of the ankle are torn partially or completely. The calcaneofibular ligament tears most often (figure B), followed in frequency by the anterior talofibular ligament. A fibular fracture can occur with severe inversion because the talus can slide against the lateral malleolus and break it (see chapter 7).

**FIGURE B Injury of the Right Ankle**

Arch Problems

The arches of the foot normally form early in fetal life. Failure to form results in congenital **flat feet**, or fallen arches, a condition in which the arches, primarily the medial longitudinal arch, are depressed or collapsed (see figure 7.39). This condition is not always painful. Flat feet may also occur when the muscles and ligaments supporting the arch fatigue and allow the arch, usually the medial longitudinal arch, to collapse. During prolonged standing, the plantar calcaneonavicular ligament may stretch, flattening the medial longitudinal arch. The transverse arch may also become flattened. The strained ligaments can become painful.

The plantar fascia is the deep connective tissue superficial to the ligaments in the central plantar surface of the foot and the thinner fascia on the medial and lateral sides of the plantar surface (see figure 8.32). **Plantar fasciitis**, which is an inflammation of the plantar fascia, can be a problem for distance runners as a result of continuous stretching.

- 14** For each of the following joints, name the bones of the joint, the specific part of the bones that form the joint, the type of joint, and the possible movement(s) at the joint: temporomandibular, shoulder, elbow, hip, knee, and ankle.
- 15** Describe dislocations of the shoulder and hip. What conditions are most likely to cause each type?
- 16** List the most common knee injuries, and tell which part of the knee is most often damaged in each type.
- 17** Define a sprain, and describe which portions of the ankle joint are most commonly damaged when it is sprained.

EFFECTS OF AGING ON THE JOINTS

A number of changes occur within many joints as a person ages. Those that occur in synovial joints have the greatest impact and often present major problems for elderly people. In general, as a person ages, the tissues of the body become less flexible and less elastic as protein cross-linking, especially in fibrous connective tissue, increases. The most important proteins related to tissue flexibility are elastin and collagen. Tissue repair slows as cell proliferation rates decline and the rate of new blood vessel development decreases. These general changes can significantly affect synovial joints. With use, the cartilage covering articular surfaces can wear down. When a person is young, production of new, resilient matrix compensates for the wear. As a person ages, the rate of replacement declines and the matrix becomes more rigid, thus adding to its rate of wear. The production rate of lubricating synovial fluid also declines with age, further contributing to the wear of the articular cartilage. In addition, the ligaments and tendons surrounding a joint shorten and become less flexible with age, resulting in a decrease in the range of motion of the joint. With age, muscles, which strengthen the joints, tend to weaken. Older people often experience a general decrease in activity, which causes the joints to become less flexible and their range of motion to decrease.

- 18** List the age-related factors that contribute to cartilage wear in synovial joints. List the age-related factors that cause a loss of flexibility and loss of range of motion in synovial joints.

CLINICAL FOCUS

Joint Disorders

ARTHRITIS

Arthritis, an inflammation of any joint, is the most common and best known of the joint disorders, affecting 10% of the world's population and 14% of the U.S. population. There are over 37 million cases of arthritis in the United States alone. More than 100 types of arthritis exist. Classification is often based on the cause and progress of the arthritis. Its causes include infectious agents, metabolic disorders, trauma, and immune disorders. Mild exercise retards joint degeneration and enhances mobility. Swimming and walking are recommended for people with arthritis, but running, tennis, and aerobics are not recommended. Therapy depends on the type of arthritis but usually includes the use of anti-inflammatory drugs. Current research is focusing on the possible development of antibodies against the cells that initiate the inflammatory response in the joints or against cell surface markers on those cells.

Osteoarthritis (OA), or **degenerative arthritis**, is the most common type of arthritis, affecting 10% of people in the United States (85% of those over age 70). OA may begin as a molecular abnormality in articular cartilage, with heredity and normal wear-and-tear of the joint important contributing factors. Slowed metabolic rates with increased age also seem to contribute to OA. Inflammation is usually secondary in this disorder. It tends to occur in the weight-bearing joints, such as the knees, and is more common in overweight individuals. OA is becoming more common in younger people as a result of increasing rates of childhood obesity.

The first line of treatment for osteoarthritis is to change the lifestyle to reduce stress on affected joints. Synovial joints require movement to remain healthy. Long periods of inactivity may cause joints to stiffen. **Moderate exercise** helps reduce pain and increase flexibility. Exercising also helps people reduce excess weight, which can place stress on joints of the lower limbs. Older people should avoid high-impact sports, such as jogging, tennis, and racquetball, which place stress on the joints. Cycling and walking are recommended, but swimming is the best for people with osteoarthritis, as it exercises the muscles and joints without stressing the joints. Wearing

shock-absorbing shoes can help. Splints or braces worn over an affected joint may be necessary to align the joint properly and distribute weight around it.

Applying heat, such as with hot soaks, warm paraffin, heating pads, low-power infrared light, or diathermy (mild electric currents that produce heat), directly over the joint may be helpful. Moving to a warmer climate, however, does not seem to make much difference.

The American Geriatrics Society has released guidelines for managing chronic pain in elderly patients with osteoarthritis. They recommend acetaminophen (Tylenol) or other **nonsteroidal anti-inflammatory drugs (NSAIDs)**, such as aspirin and ibuprofen (Advil), for mild to moderate pain. Capsaicin, a component of hot red peppers, may help relieve pain when applied as a skin cream (Zostrix). Capsaicin seems to reduce levels of a chemical, substance P, that contributes both to joint inflammation and to the conduction of pain sensations to the brain. If pain becomes a major problem and over-the-counter pain relievers appear ineffective, physicians may inject corticosteroids directly into the affected joint.

Synvisc and Hyalgan are two drugs derived from **hyaluronic acid**, a natural substance that lubricates joints. They may be administered by injection into the joint when standard medication and exercise programs fail to relieve pain. **Glucosamine** and **chondroitin sulfate** are also natural substances associated with joints. If taken orally or by injection, they may help affected joints. However, glucosamine may also raise blood sugar levels, so people with diabetes should not use it without consulting their physician. Injections of genetically treated cells from synovial fluid, which are able to block the immune factors thought to cause the breakdown of joint cartilage, are currently under investigation. An immune system protein called **transforming growth factor beta (TGF- β)**, introduced by gene therapy, is showing some promise in repairing cartilage damaged by osteoarthritis.

If other treatments fail, **surgical procedures** may be used to relieve pain and increase function in osteoarthritis patients. Using arthroscopy, a surgeon can examine the joint and clean out bone and cartilage fragments that stimulate

pain and inflammation. In **osteotomy**, the bones of the joint are reshaped to better align the joint. In a procedure called **chondroplasty**, a small amount of healthy cartilage is removed and grown in the laboratory. The newly grown cartilage is then implanted into the joint, where it may stimulate the regeneration of damaged tissue. Research is currently underway to grow new cartilage from stem cells.

Joint replacement is discussed at the end of this "Clinical Focus." If the affected joint cannot be replaced, surgeons may perform a procedure called **arthrodesis**, in which the bones meeting at the joint are fused together. This procedure is intended to eliminate the pain, but the joint is eliminated and movement at that point becomes impossible.

Rheumatoid arthritis (RA) is the second most common type of arthritis. It affects about 3% of all women and about 1% of all men in the United States. It is a general connective tissue disorder that affects the skin, vessels, lungs, and other organs, but it is most pronounced in the joints. It is severely disabling and most commonly destroys small joints, such as those in the hands and feet (figure C). The initial cause is unknown but may involve a transient **infection** or an **autoimmune disease** (an immune reaction to one's own tissues; see chapter 22) that develops against collagen. A genetic predisposition may also exist. Whatever the cause, the ultimate course appears to be immunologic. People with classic RA have a protein, **rheumatoid factor**, in their blood. In RA, the synovial fluid and associated connective tissue cells proliferate, forming a **pannus** (clothlike layer), which causes the joint capsule to become thickened and which destroys the articular cartilage. In advanced stages, opposing joint surfaces can become fused. **Juvenile rheumatoid arthritis** is similar to the adult type in many ways, but no rheumatoid factor is found in the serum.

Hemophilic arthritis may result from bleeding into the joint cavity caused by hemophilia, a hereditary disease characterized by a deficient clotting mechanism in the blood. Some evidence exists that the iron in the blood is toxic to the chondrocytes, resulting in degeneration of the articular cartilage.

JOINT INFECTIONS

Lyme disease is the result of a bacterial infection (*Borrelia burgdorferi*) transmitted to humans by a **tick** vector (usually *Ixodes sp.*) that affects the brain, nerves, eyes, heart, and joints. The chronic arthritis and central nervous system dysfunction that are symptoms of the disease are severely disabling but rarely fatal.

The disease is named for an epidemic of childhood arthritis occurring in Lyme, Connecticut, in 1975. Lyme disease has probably existed in Europe for many years and in North America since before the first European colonization, but it was not recognized as a distinct disease before 1975. Humans and domestic animals are only incidental hosts to the ticks, which normally infect wild mammals and birds. Deer are of particular concern as carriers of the ticks. The northeastern United States was greatly deforested during the eighteenth and nineteenth centuries, and deer and other wildlife populations declined dramatically. The more recent abandonment and reforestation of farms in New England has led to an increase in the deer and tick populations, with a resurgence of the associated joint and nervous system disease.

Nearly 300,000 cases of Lyme disease have been reported in the United States since 1982 and over 20,000 new cases are reported each year. Although the disease is most common in the northeastern United States, it is relatively rare in Canada. In the United States, scattered cases have been reported in the north central

states, along the West Coast, and scattered throughout the eastern, southeastern, and central states.

Early manifestations of the disease include flulike symptoms, with a localized skin rash. If untreated, the bacterium can spread to the nervous system, heart, and joints within a few weeks to months. A human vaccine against Lyme disease is currently being used for high-risk individuals.

Suppurative (pus-forming) **arthritis** may result from a number of infectious agents. These joint infections may be transferred from another infected site in the body or may be systemic (i.e., throughout the body). Usually, only one joint, normally, one of the larger joints, is affected, and the course of suppurative arthritis, if treated early, is transitory. With prolonged infection, however, the articular surfaces may degenerate. **Tuberculous arthritis** can occur as a secondary infection from pulmonary tuberculosis and is more damaging than typical suppurative arthritis. It usually affects the spine or large joints and causes ulceration of the articular cartilages and even erosion of the underlying bone. Transient arthritis of multiple joints is a common symptom of rheumatic fever, but permanent damage seldom occurs in joints with this disorder.

GOUT

Gout is a group of metabolic disorders involving joints. These disorders are largely idiopathic

(of unknown cause), although some cases of gout seem to be familial (occur in families and therefore are probably genetic). Gout is more common in males than in females. The ultimate problem in gout patients is an increase in **uric acid** in the blood because of too much synthesis or decreased removal through the kidneys. The limited solubility of uric acid salts in the body results in the precipitation of **monosodium urate crystals** in various tissues, including the kidneys and joint capsules.

The earliest symptom of gout is transient arthritis resulting from urate crystal accumulation in a joint, causing irritation of the synovial membrane. This irritation can ultimately lead to an inflammatory response in the joints, and both the crystal deposition and the inflammation can become chronic. This condition is called **gouty arthritis**. Normally, only one or two joints are affected. The most commonly affected joints (85% of the cases) are the base of the **great toe** and other foot and leg joints to a lesser extent. Any joint may ultimately be involved, and damage to the kidneys from crystal formation occurs in almost all advanced cases. **Kidney failure** may occur in untreated cases. With modern medications, these complications seldom occur. Weight control and reduced alcohol consumption can help prevent gout.

Pseudogout is a disorder that causes pain and swelling similar to that seen in gout, but it is characterized by calcium hypophosphate crystal deposits in joints.

HALLUX VALGUS AND BUNION

In people who wear pointed shoes, the great toe can be deformed and displaced laterally, a condition called **hallux valgus** (hal'üks val'güs). Bunions are often associated with hallux valgus. A **bunion** is a bursitis that develops over the first metatarsophalangeal joint because of pressure and rubbing by shoes.

JOINT REPLACEMENT

As a result of recent advancements in biomedical technology, many joints of the body can now be replaced by artificial joints. Joint replacement, called **arthroplasty**, was first developed in the late 1950s. One of the major reasons for its use is to eliminate unbearable pain in patients near ages 55 to 60 with joint disorders. Osteoarthritis is the leading disease requiring joint replacement and accounts for two-thirds of the patients. Rheumatoid arthri-

tis accounts for more than half of the remaining cases.

The major objectives in the design of joint prostheses (artificial replacements) include the development of stable articulations, low friction, solid fixation to the bone, and normal range of motion. Synthetic replacement materials are being designed by biomedical engineers to accomplish these objectives. Prosthetic joints usually are composed of metal, such as stainless steel, titanium alloys, or cobalt–chrome alloys, in combination with modern plastics, such as high-density polyethylene, silastic, or elastomer.

The bone of the articular area is removed on one side (a procedure called **hemireplacement**) or both sides (**total replacement**) of the joint, and the artificial articular areas are glued to the bone with a synthetic adhesive, such as methylmethacrylate. The smooth metal surface rubbing against the

smooth plastic surface provides a low-friction contact, with a range of movement that depends on the design.

The success of joint replacement depends on the joint being replaced, the age and condition of the patient, the state of the technology, and the definition of success. Success is usually defined as minimizing pain while maintaining movement. Most reports are based on examinations of patients 2–10 years after joint replacement. The technology is improving constantly, so current reports do not adequately reflect the effect of the most recent improvements. Still, reports indicate a success rate of 80%–90% in hip replacements and 60% or more in ankle and elbow replacements. The major reason for the failure of prosthetic joints is loosening of the artificial joint from the bone to which it is attached. New prostheses with porous surfaces help overcome this problem.

SUMMARY

An articulation, or joint, is a place where two bones come together.

Naming Joints (p. 253)

Joints are named according to the bones or parts of bones involved.

Classes of Joints (p. 253)

Joints are classified according to function or type of connective tissue that binds them together and whether fluid is present between the bones.

Fibrous Joints

1. Fibrous joints are those in which bones are connected by fibrous tissue with no joint cavity. They are capable of little or no movement.
2. Sutures involve interdigitating bones held together by dense fibrous connective tissue. They occur between most skull bones.
3. Syndesmoses are joints consisting of fibrous ligaments.
4. Gomphoses are joints in which pegs fit into sockets and are held in place by periodontal ligaments (teeth in the jaws).
5. Some sutures and other joints can become ossified (synostosis).

Cartilaginous Joints

1. Synchondroses are immovable joints in which bones are joined by hyaline cartilage. Epiphyseal plates are examples.
2. Symphyses are slightly movable joints made of fibrocartilage.

Synovial Joints

1. Synovial joints are capable of considerable movement. They consist of the following.
 - Articular cartilage on the ends of bones provides a smooth surface for articulation. Articular disks can provide additional support.

- A joint cavity is surrounded by a joint capsule of fibrous connective tissue, which holds the bones together while permitting flexibility, and a synovial membrane produces synovial fluid that lubricates the joint.
2. Bursae are extensions of synovial joints that protect skin, tendons, or bone from structures that could rub against them.
 3. Synovial joints are classified according to the shape of the adjoining articular surfaces: plane (two flat surfaces), saddle (two saddle-shaped surfaces), hinge (concave and convex surfaces), pivot (cylindrical projection inside a ring), ball-and-socket (rounded surface into a socket), and ellipsoid (ellipsoid concave and convex surfaces).

Types of Movement (p. 259)

1. Gliding movements occur when two flat surfaces glide over one another.
2. Angular movements include flexion and extension, plantar and dorsiflexion, and abduction and adduction.
3. Circular movements include rotation, pronation and supination, and circumduction.
4. Special movements include elevation and depression, protraction and retraction, excursion, opposition and reposition, and inversion and eversion.
5. Combination movements involve two or more of the previously mentioned movements.

Range of Motion (p. 263)

Range of motion is the amount of movement, active or passive, that can occur at a joint.

Description of Selected Joints (p. 263)

1. The temporomandibular joint is a complex hinge and gliding joint between the temporal and mandibular bones. It is capable of elevation and depression, protraction and retraction, and lateral and medial excursion movements.
2. The shoulder joint is a ball-and-socket joint between the head of the humerus and the glenoid cavity of the scapula that permits a wide range of movement. It is strengthened by ligaments and the muscles of the rotator cuff. The tendon of the biceps brachii passes through the joint capsule. The shoulder joint is capable of flexion and extension, abduction and adduction, rotation, and circumduction.
3. The elbow joint is a compound hinge joint between the humerus, ulna, and radius. Movement at this joint is limited to flexion and extension.
4. The hip joint is a ball-and-socket joint between the head of the femur and the acetabulum of the coxal bone. It is greatly strengthened

by ligaments and is capable of a wide range of movement, including flexion, extension, abduction, adduction, rotation, and circumduction.

5. The knee joint is a complex ellipsoid joint between the femur and the tibia that is supported by many ligaments. The joint allows flexion and extension and slight rotation of the leg.
6. The ankle joint is a special hinge joint of the tibia, fibula, and talus that allows dorsiflexion and plantar flexion and inversion and eversion.
7. Ligaments of the foot arches hold the bones in an arch and transfer weight in the foot.

Effects of Aging on the Joints (p. 272)

With age, the connective tissue of the joints becomes less flexible and less elastic. The resulting joint rigidity increases the rate of wear in the articulating surfaces. The change in connective tissue also reduces the range of motion.

REVIEW AND COMPREHENSION

1. Given these types of joints:

1. gomphosis
2. suture
3. symphysis
4. synchondrosis
5. syndesmosis

Choose the types that are held together by fibrous connective tissue.

- a. 1,2,3 c. 2,3,5 e. 1,2,3,4,5
 - b. 1,2,5 d. 3,4,5
2. Which of these joints is *not* matched with the correct joint type?
 - a. parietal bone to occipital bone—suture
 - b. between the coxal bones—symphysis
 - c. humerus and scapula—synovial
 - d. shafts of the radius and ulna—synchondrosis
 - e. teeth in alveolar process—gomphosis
 3. Which joint is the most movable?
 - a. sutures c. symphyses e. gomphoses
 - b. syndesmoses d. synovial
 4. In which of these joints are periodontal ligaments found?
 - a. sutures c. symphyses e. gomphoses
 - b. syndesmoses d. synovial
 5. The intervertebral disks are an example of
 - a. sutures. c. symphyses. e. gomphoses.
 - b. syndesmoses. d. synovial joints.
 6. Joints containing hyaline cartilage are called _____, and joints containing fibrocartilage are called _____.
 - a. sutures, synchondroses d. synchondroses, symphyses
 - b. syndesmoses, symphyses e. gomphoses, synchondroses
 - c. symphyses, syndesmoses
 7. The inability to produce the fluid that keeps most joints moist would likely be caused by a disorder of the
 - a. cruciate ligaments. d. bursae.
 - b. synovial membrane. e. tendon sheath.
 - c. articular cartilage.
 8. Which of these is *not* associated with synovial joints?
 - a. perichondrium on the surface of articular cartilage
 - b. fibrous capsule d. synovial fluid
 - c. synovial membrane e. bursae

9. Assume that a sharp object penetrated a synovial joint. From this list of structures:

1. tendon or muscle
2. ligament
3. articular cartilage
4. fibrous capsule (of joint capsule)
5. skin
6. synovial membrane (of joint capsule)

Choose the order in which they would most likely be penetrated.

- a. 5,1,2,6,4,3 c. 5,1,2,6,3,4 e. 5,1,2,4,6,3
 - b. 5,2,1,4,3,6 d. 5,1,2,4,3,6
10. Which of these do hinge joints and saddle joints have in common?
 - a. Both are synovial joints.
 - b. Both have concave surfaces that articulate with a convex surface.
 - c. Both are uniaxial joints.
 - d. both a and b
 - e. all of the above
 11. Which of these joints is correctly matched with the type of joint?
 - a. atlas to occipital condyle—pivot
 - b. tarsals to metatarsals—saddle
 - c. femur to coxal bone—ellipsoid
 - d. tibia to talus—hinge
 - e. scapula to humerus—plane
 12. Once a doorknob is grasped, what movement of the forearm is necessary to unlatch the door—that is, turn the knob in a clockwise direction? (Assume using the right hand.)
 - a. pronation c. supination e. extension
 - b. rotation d. flexion
 13. After the door is unlatched, what movement of the elbow is necessary to open it? (Assume the door opens in, and you are on the inside.)
 - a. pronation c. supination e. extension
 - b. rotation d. flexion
 14. After the door is unlatched, what movement of the shoulder is necessary to open it? (Assume the door opens in, and you are on the inside.)
 - a. pronation c. supination e. extension
 - b. rotation d. flexion

15. When grasping a doorknob, the thumb and little finger undergo
 - a. opposition.
 - b. reposition.
 - c. lateral excursion.
 - d. medial excursion.
 - e. dorsiflexion.
16. Spreading the fingers apart is
 - a. rotation.
 - b. depression.
 - c. abduction.
 - d. lateral excursion.
 - e. flexion.
17. A runner notices that the lateral side of her right shoe is wearing much more than the lateral side of her left shoe. This could mean that her right foot undergoes more _____ than her left foot.
 - a. eversion
 - b. inversion
 - c. plantar flexion
 - d. dorsiflexion
 - e. lateral excursion
18. For a ballet dancer to stand on her toes, her feet must
 - a. evert.
 - b. invert.
 - c. plantar flex.
 - d. dorsiflex.
 - e. abduct.
19. A meniscus is found in the
 - a. shoulder joint.
 - b. elbow joint.
 - c. hip joint.
 - d. knee joint.
 - e. ankle joint.
20. A lip (labrum) of fibrocartilage deepens the joint cavity of the
 - a. temporomandibular joint.
 - b. shoulder joint.
 - c. elbow joint.
 - d. knee joint.
 - e. ankle joint.
21. Which of these joints has a tendon inside the joint cavity?
 - a. temporomandibular joint
 - b. shoulder joint
 - c. elbow joint
 - d. knee joint
 - e. ankle joint
22. Which of these structures helps stabilize the shoulder joint?
 - a. rotator cuff muscles
 - b. cruciate ligaments
 - c. medial and lateral collateral ligaments
 - d. articular disk
 - e. all of the above
23. Bursitis of the subacromial bursa could result from
 - a. flexing the wrist.
 - b. kneeling.
 - c. overusing the shoulder joint.
 - d. running a long distance.
 - e. extending the elbow.
24. Which of these does *not* occur with the aging of joints?
 - a. decrease in production of new cartilage matrix
 - b. decline in synovial fluid production
 - c. stretching of ligaments and tendons and increase in range of motion
 - d. weakening of muscles
 - e. increase in protein cross-linking in tissues

Answers in Appendix E

CRITICAL THINKING

1. What would be the result if the sternal synchondroses and the sternocostal synchondrosis of the first rib were to become synostoses?
2. Using an articulated skeleton, examine the following list of joints. Describe the type of joint and the movement(s) possible.
 - a. the joint between the zygomatic bone and the maxilla
 - b. the ligamentous connection between the coccyx and the sacrum
 - c. the elbow joint
3. For each of the following muscles, describe the motion(s) produced when the muscle contracts. It may be helpful to use an articulated skeleton.
 - a. The biceps brachii muscle attaches to the coracoid process of the scapula (one head) and the radial tuberosity of the radius. Name two movements that the muscle accomplishes in the forearm.
 - b. The rectus femoris muscle attaches to the anterior inferior iliac spine and the tibial tuberosity. How does contraction move the thigh? The leg?
 - c. The supraspinatus muscle is located in and attached to the supraspinatus fossa of the scapula. Its tendon runs over the head of the humerus to the greater tubercle. When it contracts, what movement occurs at the glenohumeral (shoulder) joint?
 - d. The gastrocnemius muscle attaches to the medial and lateral condyles of the femur and to the calcaneus. What movement of the leg results when this muscle contracts? Of the foot?
4. Crash McBang hurt his knee in an auto accident by ramming it into the dashboard. The doctor tested the knee for ligament damage by having Crash sit on the edge of a table with his knee flexed at a 90-degree angle. The doctor attempted to pull the tibia in an anterior direction (the anterior drawer test) and then tried to push the tibia in a posterior direction (the posterior drawer test). No unusual movement of the tibia occurred in the anterior drawer test but did occur during the posterior drawer test. Explain the purpose of each test, and tell Crash which ligament he has damaged.

Muscular System

Histology and Physiology

Movements of the limbs, the heart, and other parts of the body are made possible by muscle cells that function like tiny motors. Muscle cells use energy extracted from nutrient molecules much as motors use energy provided by electric current. The nervous system regulates and coordinates muscle cells, so that smooth, coordinated movements are produced much as a computer regulates and coordinates several motors in robotic machines that perform assembly line functions.

This chapter presents the *functions of the muscular system* (p. 279), *general functional characteristics of muscle* (p. 279), and *skeletal muscle structure* (p. 279). The *sliding filament model* (p. 285) of muscle contraction is explained. The *physiology of skeletal muscle fibers* (p. 285), the *physiology of skeletal muscle* (p. 295), the *types of muscle contractions* (p. 299), *fatigue* (p. 301), *energy sources* (p. 303), *slow and fast fibers* (p. 305), and *heat production* (p. 307) are presented. The structure and function of *smooth muscle* (p. 307) and *cardiac muscle* (p. 311) are introduced, but

cardiac muscle is discussed in greater detail in chapter 20. Finally, the *effects of aging on skeletal muscle* (p. 312) are presented. Because skeletal muscle is more abundant and more is known about it, skeletal muscle is examined in the greatest detail.

Color-enhanced scanning electron micrograph of skeletal muscle fibers.

FUNCTIONS OF THE MUSCULAR SYSTEM

Movements within the body are accomplished by cilia or flagella on the surface of some cells, by the force of gravity, or by the contraction of muscles. Most of the body's movements, from the beating of the heart to the running of a marathon, result from muscle contractions. As described in chapter 4, there are three types of muscle tissue: skeletal, smooth, and cardiac. The following are the major functions of muscles:

1. **Body movement.** Most skeletal muscles are attached to bones, are typically under conscious control, and are responsible for most body movements, including walking, running, chewing and manipulating objects with the hands.
2. **Maintenance of posture.** Skeletal muscles constantly maintain tone, which keeps us sitting or standing erect.
3. **Respiration.** Skeletal muscles of the thorax are responsible for the movements necessary for respiration.
4. **Production of body heat.** When skeletal muscles contract, heat is given off as a by-product. This released heat is critical to the maintenance of body temperature.
5. **Communication.** Skeletal muscles are involved in all aspects of communication, such as speaking, writing, typing, gesturing, and facial expression.
6. **Constriction of organs and vessels.** The contraction of smooth muscle within the walls of internal organs and vessels causes constriction of those structures. This constriction can help propel and mix food and water in the digestive tract, propel secretions from organs, and regulate blood flow through vessels.
7. **Heart beat.** The contraction of cardiac muscle causes the heart to beat, propelling blood to all parts of the body.

1 List the functions of skeletal, smooth, and cardiac muscles and explain how each is accomplished.

GENERAL FUNCTIONAL CHARACTERISTICS OF MUSCLE

Muscle tissue is highly specialized to contract, or shorten, forcefully. The process of metabolism extracts energy from nutrient molecules. Part of that energy is used for muscle contraction, and the remainder is used for other cell processes or is released as heat.

Properties of Muscle

Muscle has four major functional properties: contractility, excitability, extensibility, and elasticity.

1. **Contractility** is the ability of muscle to shorten forcefully. When muscle contracts, it causes movement of the structures to which it is attached, or it may increase pressure inside hollow organs or vessels. Although muscle shortens forcefully during contraction, it lengthens passively; that is, gravity,

contraction of an opposing muscle, or the pressure of fluid in a hollow organ or vessel produces a force that acts on the shortened muscle, causing it to lengthen.

2. **Excitability** is the capacity of muscle to respond to a stimulus. Normally, skeletal muscle contracts as a result of stimulation by nerves. Smooth muscle and cardiac muscle can contract without outside stimuli, but they also respond to stimulation by nerves and hormones.
3. **Extensibility** means that muscle can be stretched beyond its normal resting length and is still able to contract.
4. **Elasticity** is the ability of muscle to recoil to its original resting length after it has been stretched.

Types of Muscle Tissue

Table 9.1 provides a comparison of the major characteristics of skeletal, smooth, and cardiac muscle. Skeletal muscle with its associated connective tissue constitutes about 40% of the body's weight and is responsible for locomotion, facial expressions, posture, respiratory movements, and many other body movements. The nervous system voluntarily, or consciously, controls the functions of the skeletal muscles.

Smooth muscle is the most widely distributed type of muscle in the body, and it has the greatest variety of functions. It is in the walls of hollow organs and tubes, the interior of the eye, the walls of blood vessels, and other areas. Smooth muscle performs a variety of functions, including propelling urine through the urinary tract, mixing food in the stomach and intestine, dilating and constricting the pupils, and regulating the flow of blood through blood vessels.

Cardiac muscle is found only in the heart, and its contractions provide the major force for moving blood through the circulatory system. Unlike skeletal muscle, cardiac muscle and many smooth muscles are autorhythmic; that is, they contract spontaneously at somewhat regular intervals, and nervous or hormonal stimulation is not always required for them to contract. Furthermore, unlike skeletal muscle, smooth muscle and cardiac muscle are not consciously controlled by the nervous system. Rather, they are controlled involuntarily, or unconsciously, by the endocrine and autonomic nervous systems (see chapters 16 and 18).

2 Define contractility, excitability, extensibility, and elasticity of muscle tissue.

3 Describe the structure, function, location, and control of the three major muscle tissue types.

SKELETAL MUSCLE STRUCTURE

Skeletal muscles are composed of skeletal **muscle fibers** associated with smaller amounts of connective tissue, blood vessels, and nerves. Skeletal muscle cells are often called skeletal muscle fibers. Each skeletal muscle fiber is a single, long, cylindrical cell containing several nuclei located around the periphery of the fiber near the plasma membrane (figure 9.1). Muscle fibers develop from less mature multinucleated cells called **myoblasts**

TABLE 9.1 Comparison of Muscle Types

Features	Skeletal Muscle	Smooth Muscle	Cardiac Muscle
Location	Attached to bones	Walls of hollow organs, blood vessels, eyes, glands, and skin	Heart
Cell shape	Very long and cylindrical (1 mm–4 cm); extends the length of muscle fasciculi, which in some cases is the length of the muscle	Spindle-shaped (15–200 μm in length, 5–8 μm in diameter)	Cylindrical and branched (100–500 μm in length, 12–20 μm in diameter)
Nucleus	Multiple, peripherally located	Single, centrally located	Single, centrally located
Special cell–cell attachments	None	Gap junctions join some visceral smooth muscle cells together	Intercalated disks join cells to one another
Striations	Yes	No	Yes
Control	Voluntary and involuntary (reflexes)	Involuntary	Involuntary
Capable of spontaneous contraction	No	Yes (some smooth muscle)	Yes
Function	Body movement	Food movement through the digestive tract, emptying of the urinary bladder, regulation of blood vessel diameter, change in pupil size, contraction of many gland ducts, movement of hair, and many other functions	Pumps blood; contractions provide the major force for propelling blood through blood vessels

FIGURE 9.1 Skeletal Muscle Fibers
Skeletal muscle fibers in longitudinal section.

(mī'ō-blasts). Their multiple nuclei result from the fusion of myoblast precursor cells, not from the division of nuclei within myoblasts. Myoblasts are converted to muscle fibers as contractile proteins accumulate within their cytoplasm. Shortly after the myoblasts form, nerves grow into the area and innervate the developing muscle fibers.

The number of skeletal muscle fibers remains relatively constant after birth. Enlargement, or hypertrophy, of muscles after birth therefore results not from a substantial increase in the number of muscle fibers but from an increase in their size. Similarly, hypertrophy of muscles in response to exercise is due mainly to an increase in muscle fiber size, rather than an increase in number.

As seen in longitudinal section, alternating light and dark bands give the muscle fiber a **striated** (stri'āt-ed; banded), or striped, appearance (see figure 9.1). A single fiber can extend from one end of a muscle to the other. In most muscles, the fibers range from approximately 1 mm to about 4 cm in length and from 10 μm to 100 μm in diameter. Large muscles contain a large percentage of large-diameter fibers, whereas small, delicate muscles contain a large percentage of small-diameter fibers. However, any given muscle contains a mixture of small- and large-diameter fibers.

4 Define skeletal muscle fiber. Do the number of muscle fibers increase significantly after birth?

Connective Tissue Coverings of Muscle

Connective tissue associated with skeletal muscle (figure 9.2) is critical to its proper function. Connective tissue provides muscle

FIGURE 9.2 Skeletal Muscle Structure: Connective Tissue, Innervation, and Blood Supply

This figure shows the relationship between muscle fibers, fasciculi, and associated connective tissue layers: the epimysium, perimysium, and endomysium. Arteries, veins, and nerves course together through the connective tissue of muscles. They branch frequently as they approach individual muscle fibers. At the level of the perimysium, axons of neurons branch, and each branch extends to a muscle fiber.

fibers with a solid structure, to which they attach. The connective tissue fibers that surround a muscle and muscle fascicles extend beyond the belly of the muscle to become tendons, which connect muscles to bones or to the dermis of the skin.

The plasma membrane of a muscle fiber (cell) is called a **sarcolemma** (sar'kō-lem'ă). Two delicate connective tissue layers are located just outside the sarcolemma. The deeper and thinner of the two is the **external lamina**. It consists mostly of reticular (collagen) fibers and is so thin that it cannot be distinguished from the sarcolemma when viewed under a light microscope. The

second layer also consists mostly of reticular fibers but is a much thicker layer, called the **endomysium** (en'dō-miz'ē-ŭm, en'dō-mis'ē-ŭm; G. *mys*, muscle). A bundle of muscle fibers with their endomysium is surrounded by another, heavier connective tissue layer called the **perimysium** (per'i-mis'ē-ŭm, per'i-miz'ē-ŭm). Each bundle ensheathed by perimysium is called a muscle **fasciculus** (fă-sik'u-lus). A muscle consists of many fasciculi grouped together and surrounded by a third layer of connective tissue, called the **epimysium** (ep-ī-mis'ē-ŭm). The epimysium is composed of dense collagenous connective tissue and covers the entire surface of the muscle. **Fascia** (fash'ē-ă) is a general term for connective tissue sheets within the body. **Muscular fascia** (formerly *deep fascia*), located superficial to the epimysium, separates and compartmentalizes individual muscles or groups of muscles. It consists of dense irregular collagenous connective tissue.

- 5** Name the connective tissue layers that surround muscle fibers, muscle fasciculi, and whole muscles. Define sarcolemma and muscular fascia.

Nerves and Blood Vessels

The nerves and blood vessels that extend to skeletal muscles are abundant. **Motor neurons** are specialized nerve cells that stimulate muscles to contract. Their cell bodies are located in the brain or spinal cord, and their axons extend to skeletal muscle fibers through nerves. An artery and either one or two veins extend together with a nerve through the connective tissue layers of skeletal muscles (see figure 9.2). Numerous branches of the arteries supply the extensive capillary beds surrounding the muscle fibers, and blood is carried away from the capillary beds by branches of the veins. At the level of the perimysium, the axons of motor neurons branch repeatedly, each branch projecting toward the center of one muscle fiber. The contact between the axons and the muscle fibers, called synapses, or neuromuscular junctions, are described later in the chapter (see “Neuromuscular Junction,” p. 288). Each motor neuron innervates more than one muscle fiber, and every muscle fiber receives a branch of an axon.

- 6** What are motor neurons? How do the axons of motor neurons and blood vessels extend to muscle fibers?

Muscle Fibers

The many nuclei of each muscle fiber lie just inside the sarcolemma, whereas most of the interior of the fiber is filled with myofibrils (figure 9.3). Other organelles, such as the numerous mitochondria and glycogen granules, are packed between the myofibrils. The cytoplasm without the myofibrils is called **sarcoplasm** (sar'kō-plazm). Each **myofibril** (mī-ō-fī'bril) is a threadlike structure approximately 1–3 μm in diameter that extends from one end of the muscle fiber to the other. Two kinds of protein filaments, called **myofilaments** (mī-ō-fil'ă-ments), are major components of myofibrils. **Actin** (ak'tin) **myofilaments**, or thin myofilaments, are approximately 8 nanometers (nm) in diameter and 1000 nm in length, whereas **myosin** (mī'ō-sin) **myofilaments**, or thick myofilaments, are approximately 12 nm in diameter and

FIGURE 9.3 Parts of a Muscle

(a) Part of a muscle attached by a tendon to a bone. A muscle is composed of muscle fasciculi, each surrounded by perimysium. The fasciculi are composed of bundles of individual muscle fibers (muscle cells), each surrounded by endomysium. (b) Enlargement of one muscle fiber. The muscle fiber contains several myofibrils. (c) A myofibril extended out the end of the muscle fiber. The banding patterns of the sarcomeres are shown in the myofibril. (d) A single sarcomere of a myofibril is composed of actin myofilaments and myosin myofilaments. The Z disk anchors the actin myofilaments, and the myosin myofilaments are held in place by titin molecules and the M line.

1800 nm in length. The actin and myosin myofilaments form highly ordered units called **sarcomeres** (sar'kō-mērzh), which are joined end to end to form the myofibrils (figure 9.4a).

Actin and Myosin Myofilaments

Each actin myofilament is composed of two strands of **fibrous actin** (F actin), a series of **tropomyosin** (trō-pō-mī'ō-sin)

molecules, and a series of **troponin** (trō'pō-nin) **molecules** (figure 9.4b and c). The two strands of F actin are coiled to form a double helix, which extends the length of the actin myofilament. Each F actin strand is a polymer of approximately 200 small, globular units called **globular actin** (G actin) monomers. Each G actin monomer has an active site, to which myosin molecules can bind during muscle contraction. Tropomyosin is an elongated

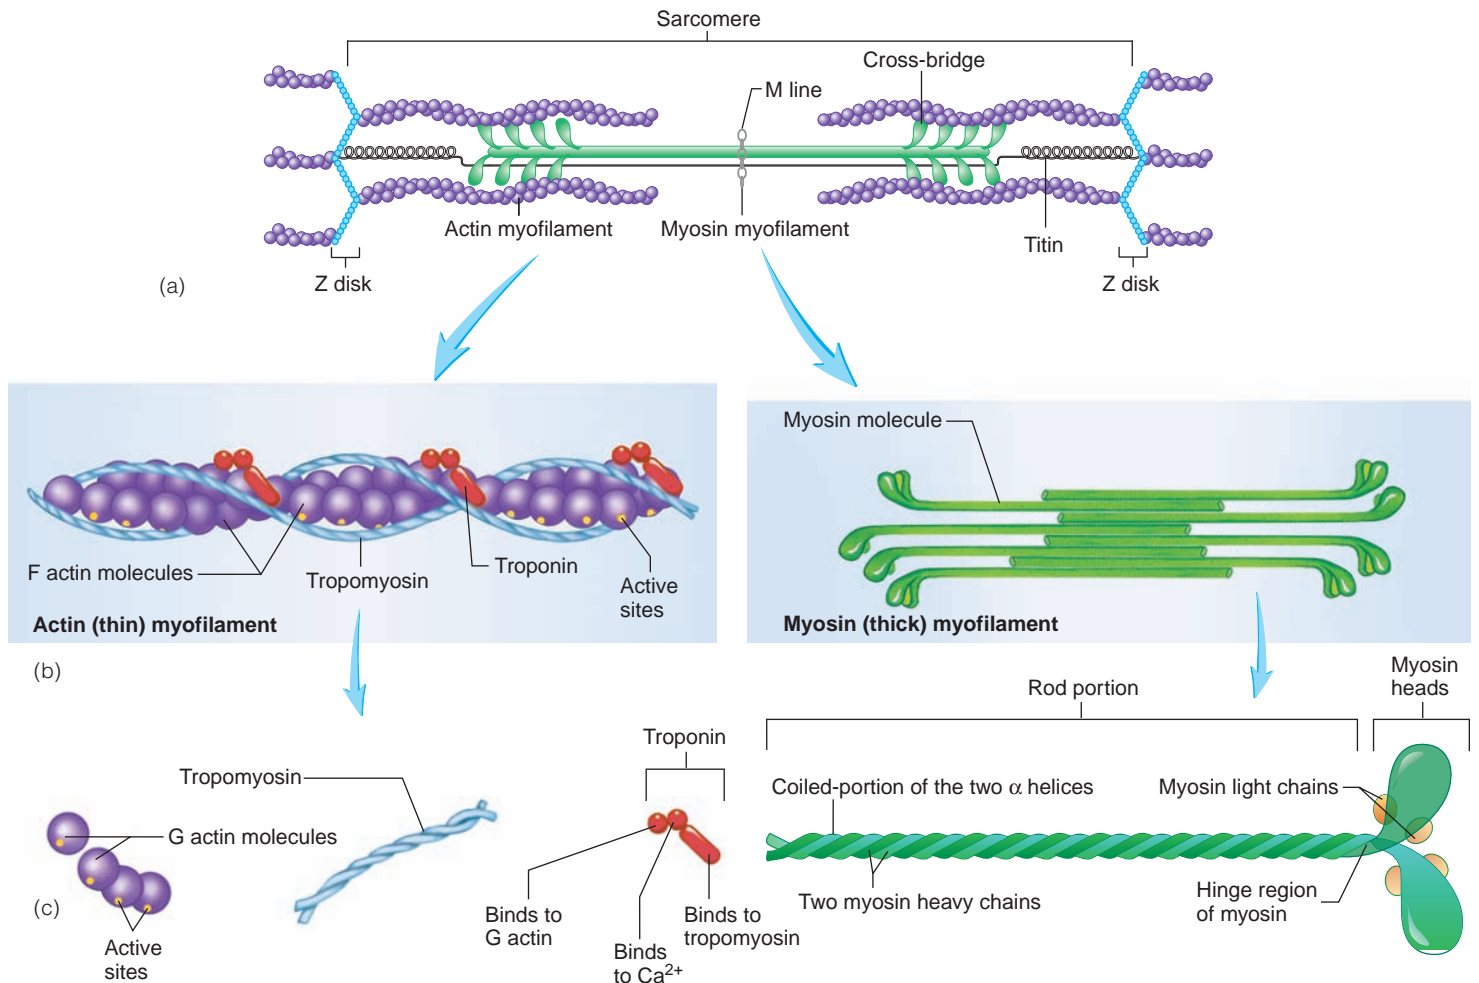

FIGURE 9.4 Structure of Actin and Myosin

(a) The sarcomere consists of actin (thin) myofilaments, attached to the Z disks, and myosin (thick) myofilaments, suspended between the actin myofilaments. (b) Actin myofilaments are made up of F actin (*chains of purple spheres*), tropomyosin, (*blue strands*), and troponin (*red spheres and rod*). Myosin myofilaments are made up of many golf-club-shaped myosin molecules, with all the heads pointing in one direction at one end and the opposite direction at the other end. (c) G actin molecules (*purple spheres*), with their active sites (*yellow*), tropomyosin, and troponin, make up actin myofilaments. Myosin molecules (*green*) are golf-club-shaped structures composed of two molecules of heavy myosin wound together to form the rod portion and double globular heads. Four small light myosin molecules are located on the heads of each of the myosin molecules.

protein that winds along the groove of the F actin double helix. Each tropomyosin molecule is sufficiently long to cover seven G actin active sites. Troponin is composed of three subunits: one that binds to actin, a second that binds to tropomyosin, and a third that has a binding site for Ca^{2+} . The troponin molecules are spaced between the ends of the tropomyosin molecules in the groove between the F actin strands. The complex of tropomyosin and troponin regulates the interaction between active sites on G actin and myosin.

Myosin myofilaments are composed of many elongated **myosin molecules** shaped like golf clubs (see figure 9.4b and c). Each myosin molecule consists of two **heavy myosin molecules** wound together to form a **rod portion** lying parallel to the myosin myofilament and two **heads** that extend laterally (see figure 9.4b and figure 9.3d). Four light myosin chains are attached to the heads of each myosin molecule. Each myosin myofilament consists

of about 300 myosin molecules arranged so that about 150 of them have their heads projecting toward each end. The centers of the myosin myofilaments consist of only the rod portions of the myosin molecules. The myosin heads have three important properties: (1) The heads can bind to active sites on the actin molecules to form **cross-bridges**; (2) the heads are attached to the rod portion by a hinge region that can bend and straighten during contraction; and (3) the heads have ATPase activity, the enzymatic activity that breaks down adenosine triphosphate (ATP), releasing energy. Part of the energy is used to bend the hinge region of the myosin molecule during contraction.

Sarcomeres

Each sarcomere extends from one Z disk to an adjacent Z disk (see figure 9.4; figure 9.5). A **Z disk** is a filamentous network of protein forming a disklike structure for the attachment of actin

(b) The arrangement of I and A bands, H zones, Z disks, and M lines in sarcomeres

(c) Cross sections through regions of the sarcomeres

FIGURE 9.5 Components of Sarcomeres

(a) A sarcomere is the part of a myofibril between two adjacent Z disks. Actin myofilaments are attached to the Z disks. (b) The I band is between the ends of myosin myofilaments on each side of a Z disk. The A band is formed by the myosin myofilaments within a sarcomere. The H zone is between the ends of the actin myofilaments within a sarcomere. Myosin myofilaments are attached to the M line. (c) Cross sections through regions of the sarcomeres show the arrangement of proteins in three dimensions.

myofilaments (see figure 9.5). The arrangement of the actin myofilaments and myosin myofilaments gives the myofibril a banded, or striated, appearance when viewed longitudinally. Each **isotropic** (*ī-sō-trop'ik*), or **I, band** includes a Z disk and extends from each side of the Z disk to the ends of the myosin myofilaments. When seen in longitudinal and cross sections, the I band on each side of the Z disk consists only of actin myofilaments. Each **anisotropic** (*an-ī-sō-trop'ik*), or **A, band** extends the length of the myosin myofilaments within a sarcomere. The actin and myosin myofilaments overlap for some distance at both ends of the A band. In a cross section of the A band where actin and myosin myofilaments overlap, each myosin myofilament

is visibly surrounded by six actin myofilaments. In the center of each A band is a smaller band called the **H zone**, where the actin and myosin myofilaments do not overlap and only myosin myofilaments are present. A dark line, called the **M line**, is in the middle of the H zone and consists of delicate filaments that attach to the center of the myosin myofilaments. The M line helps hold the myosin myofilaments in place, similar to the way the Z disk holds actin myofilaments in place (see figure 9.5b and c). The numerous myofibrils are oriented within each muscle fiber so that A bands and I bands of parallel myofibrils are aligned and thus produce the striated pattern seen through a microscope.

What Makes Muscles Extensible and Elastic?

In addition to actin and myosin, there are other, less visible proteins within sarcomeres. These proteins help hold actin and myosin in place, and one of them accounts for muscle's ability to stretch (extensibility) and recoil (elasticity). **Titin** (tī'tin; see figure 9.3) is one of the largest known proteins, consisting of a single chain of nearly 27,000 amino acids. It attaches to Z disks and extends along myosin myofilaments to the M line. The myosin myofilaments are attached to the titin molecules, which help hold them in position. Part of the titin molecule in the I band functions like a spring, allowing the sarcomere to stretch and recoil. Another large protein, called **nebulin** (neb'ū-lin), appears to hold the actin myofilaments in place. These proteins extend from each side of the Z disk and along the actin myofilaments. Each nebulin molecule is as long as an actin myofilament.

- 7 Define sarcoplasm, myofibril, and myofilament.
- 8 How do G actin, tropomyosin, and troponin combine to form an actin myofilament? Name the molecule or ion to which each of the three subunits of troponin binds.
- 9 Describe the structure of myosin molecules and how they combine to form a myosin myofilament.
- 10 List three important properties of the myosin head. What is a cross-bridge?
- 11 How are Z disks, actin myofilaments, myosin myofilaments, and M lines arranged to form a sarcomere? Describe how this arrangement produces the I band, A band, and H zone.

SLIDING FILAMENT MODEL

The **sliding filament model** of muscle contraction includes all the events that result in actin myofilaments sliding over myosin myofilaments to shorten the sarcomeres of muscle fibers. Actin and myosin myofilaments do not change length during contraction of skeletal muscle. Instead, the actin and myosin myofilaments slide past one another, causing the sarcomeres to shorten (figure 9.6). The shortening of sarcomeres is responsible for the contraction of skeletal muscles. When sarcomeres shorten, the myofibrils also shorten because the myofibrils consist of sarcomeres joined end to end. The myofibrils extend the length of the muscle fibers and, when they shorten, the muscle fibers shorten. Muscle bundles are made up of muscle fibers and muscles are made up of muscle bundles. Therefore, when sarcomeres shorten, myofibrils, muscle fibers, muscle bundles, and muscles shorten to produce muscle contractions.

During muscle relaxation, the sarcomeres lengthen. For this to happen, an external force must be applied to a muscle to cause sarcomeres to lengthen, such as forces produced by other muscles or by gravity. For example, contraction of a muscle causes a joint, such as the elbow or knee, to flex. Extension of the joint and lengthening of the muscle result from the contraction of other, antagonistic muscles (see chapter 10).

- 12 Why do the I bands and H zones shorten during muscle contraction but the length of the A band is unchanged?
- 13 How does shortening of sarcomeres explain muscle contraction?

PREDICT 1

Explain the events that influence the width of each band of a sarcomere when a muscle goes through the sequence of being stretched, contracted, and relaxed.

PHYSIOLOGY OF SKELETAL MUSCLE FIBERS

Axons of nerve cells extend from the brain and spinal cord to skeletal muscle fibers. The nervous system controls the contraction of skeletal muscles through these axons. Electrical signals, called **action potentials**, travel from the brain or spinal cord along the axons to muscle fibers and cause them to contract.

Membrane Potentials

Plasma membranes are **polarized**—that is, there is a voltage difference, or electric charge difference, across each plasma membrane. This charge difference across the plasma membrane of an unstimulated cell is called the **resting membrane potential** (figure 9.7). Action potentials cannot be produced without the resting membrane potential. The negative charge at the internal surface of the plasma membrane compared with the outer surface results mainly from the concentration differences of ions and charged molecules across the plasma membrane and to its permeability characteristics.

There is a difference in the ion concentrations across the plasma membrane. The $\text{Na}^+ - \text{K}^+$ pump moves Na^+ to the outside of the cell and K^+ to the inside of the cell. This results in a higher concentration of Na^+ in the extracellular fluid and a lower concentration of Na^+ in the intracellular fluid, and it results in a higher concentration of K^+ in the intracellular fluid and a lower concentration of K^+ in the extracellular fluid.

The plasma membrane is relatively permeable to K^+ and much less permeable to Na^+ and to negatively charged molecules found inside of the cell. Consequently, positively charged K^+ tend to diffuse out of the cell through K^+ leak channels, leaving the negatively charged molecules behind, thus polarizing the membrane. The membrane is at equilibrium when the tendency for K^+ to diffuse out of the cell is resisted by the negative charge of the molecules inside the cell. The details of the resting membrane potential are more fully described in chapter 11.

The resting membrane potential can be measured in units called **millivolts** (mV; $\text{mV} = 1/1000$ volt). The potential differences across the plasma membranes of nerve cells and muscle fibers are between -70 and -90 mV. The potential difference is reported as a negative number because the inner surface of the plasma membrane is negative, compared with the outside.

Ion Channels

The increased permeability of the plasma membrane to K^+ is due to K^+ leak channels. These channels are specific for K^+ and they are open continuously. Once the resting membrane potential is established, action potentials can be produced. An action potential is a reversal of the resting membrane potential such

1. Actin and myosin myofilaments in a relaxed muscle (*right*) and a contracted muscle (*#4 below*) are the same length. Myofilaments do not change length during muscle contraction.

2. During contraction, actin myofilaments at each end of the sarcomere slide past the myosin myofilaments toward each other. As a result, the Z disks are brought closer together, and the sarcomere shortens.

3. As the actin myofilaments slide over the myosin myofilaments, the H zones (yellow) and the I bands (blue) narrow. The A bands, which are equal to the length of the myosin myofilaments, do not narrow, because the length of the myosin myofilaments does not change.

4. In a fully contracted muscle, the ends of the actin myofilaments overlap at the center of the sarcomere and the H zone disappears.

PROCESS FIGURE 9.6 Sarcomere Shortening

FIGURE 9.7 Measuring the Resting Membrane Potential in Skeletal Muscle

The recording electrode is inside the membrane, the reference electrode is outside, and a potential difference of about -85 mV is recorded by the recording device (oscilloscope), with the inside of the membrane negative with respect to the outside of the membrane.

that the inside of the plasma membrane becomes positively charged, compared with the outside. The permeability characteristics of the plasma membrane change as a result of the opening of certain ion channels, when a cell is stimulated. The diffusion of ions through these channels changes the charge across the plasma membrane and produces an action potential. Two types of gated ion channels play important roles in producing action potentials:

1. **Ligand-gated ion channels.** A **ligand** (lī'gand) is a molecule that binds to a receptor. A **receptor** is a protein or glycoprotein that has a receptor site to which a ligand can bind. **Ligand-gated ion channels** are channels that open in response to a ligand binding to a receptor that is part of the ion channel (see figure 3.10). For example, the axons of nerve cells supplying skeletal muscle fibers release ligands, called **neurotransmitters** (noor'ō-trans-mit'erz), which bind to ligand-gated Na^+ channels in the membranes of the muscle fibers. As a result, the Na^+ channels open, allowing Na^+ to enter the cell.
2. **Voltage-gated ion channels.** These channels are gated membrane channels that open and close in response to small voltage (charge) changes across the plasma membrane, or changes in the membrane potential. When a nerve or muscle cell is stimulated, the charge difference changes and that change causes voltage-gated ion channels to open or close. The major voltage-gated channels that play important roles in an action potential are voltage-gated Na^+ and K^+ channels.

Both ligand-gated and voltage-gated ion channels are specific for the type of ion that passes through them. The channels that open determine what ions move across the plasma membrane. For example, opening voltage-gated Na^+ channels allow Na^+ to cross the plasma membrane, whereas opening voltage-gated K^+ channels allow K^+ to cross.

The concentration gradient for an ion determines whether that ion enters or leaves the cell after the ion channel, specific for that ion, opens (see chapter 3). For example, there is a higher concentration of Na^+ outside the cell than inside it. Consequently,

when voltage-gated Na^+ channels open, Na^+ move through them into the cell. In a similar fashion, when gated K^+ channels open, K^+ move out of the cell.

- 14 **Define resting membrane potential.**
- 15 **Describe the differences in Na^+ and K^+ concentrations across the plasma membrane.**
- 16 **Describe the permeability characteristics of the plasma membrane.**
- 17 **List the two major categories of gated ion channels in the plasma membrane.**
- 18 **List the two major types of voltage-gated ion channels that play important roles in the resting membrane potential.**

PREDICT 2

When ligand-gated K^+ channels open, how does this affect the resting membrane potential?

Action Potentials

An action potential takes approximately 1 millisecond to a few milliseconds to occur, and it has two phases, called depolarization and repolarization. Stimulation of a cell can cause depolarization of its plasma membrane (figure 9.8a). Depolarization occurs when the inside of the plasma membrane becomes less negative, which is indicated by movement of the curve upward toward zero. If the depolarization changes the membrane potential to a value called **threshold** (figure 9.8b), an action potential is triggered. The **depolarization phase** of the action potential is a brief period during which further depolarization occurs and the inside of the cell becomes positively charged. The charge difference across the plasma membrane is said to be reversed when the membrane potential becomes a positive value. The **repolarization phase** is the return of the membrane potential to its resting value.

The opening and closing of voltage-gated ion channels change the permeability of the plasma membrane to ions, resulting in depolarization and repolarization. Before a nerve or muscle cell is stimulated, these voltage-gated ion channels are closed (figure 9.9, step 1). When the cell is stimulated, gated Na^+ channels open, and Na^+ diffuse into the cell. The positively charged Na^+ make the inside of the cell membrane less negative. If this depolarization reaches threshold, many voltage-gated Na^+ channels open rapidly, and Na^+ diffuse into the cell until the inside of the membrane becomes positive for a brief time (figure 9.9, step 2). As the inside of the cell becomes positive, this voltage change causes additional permeability changes in the plasma membrane, which stop depolarization and start repolarization. Repolarization results from the closing of voltage-gated Na^+ channels and the opening of voltage-gated K^+ channels (figure 9.9, step 3). Thus, the movement of Na^+ into the cell stops, and the movement of K^+ out of the cell increases. These changes cause the inside of the plasma membrane to become more negative and the outside to become more positive. The action potential ends and the resting membrane potential is reestablished when the voltage-gated K^+ channels close.

- (a) Depolarization is a change of the charge difference across the plasma membrane, making the charge inside of the cell less negative and the outside of the plasma membrane less positive. Once threshold is reached, an action potential is produced.

- (b) During the depolarization phase of the action potential, the membrane potential changes from approximately -85 mV to approximately $+20$ mV. During the repolarization phase, the inside of the plasma membrane changes from approximately $+20$ mV back to -85 mV.

FIGURE 9.8 Depolarization and the Action Potential in Skeletal Muscle

Action potentials occur according to the **all-or-none principle**. If a stimulus is strong enough to produce a depolarization that reaches threshold, or even if it exceeds threshold by a substantial amount, all of the permeability changes responsible for an action potential proceed without stopping. Consequently, all of the action potentials in a given cell are alike (the “all” part). If a stimulus is so weak that the depolarization does not reach

threshold, few of the permeability changes occur. The membrane potential returns to its resting level after a brief period without producing an action potential (the “none” part). An action potential can be compared to the flash system of a camera. Once the shutter is triggered (reaches threshold), the camera flashes (an action potential is produced), and each flash is the same brightness (the “all” part) as the previous flashes. If the shutter is depressed but not triggered (does not reach threshold), no flash results (the “none” part).

An action potential occurs in a very small area of the plasma membrane and does not affect the entire plasma membrane at one time. Action potentials can travel, or **propagate**, across the plasma membrane because an action potential produced at one location in the plasma membrane can stimulate the production of an action potential in an adjacent location (figure 9.10). Note that an action potential does not actually move along the plasma membrane. Rather, an action potential at one location stimulates the production of another action potential in an adjacent location, which in turn stimulates the production of another and so on. It is much like a long row of toppling dominos in which each domino knocks down the next. Each domino falls, but no single domino actually travels the length of the row.

The **action potential frequency** is the number of action potentials produced per unit of time. As the strength of the stimulus applied to a nerve or muscle cell increases (once threshold is reached), the action potential frequency increases as the strength of the stimulus increases. All the action potentials are identical. The action potential frequency can affect the strength of a muscle contraction (see “Stimulus Frequency and Muscle Contraction,” p. 298).

In summary, the resting membrane potential results from a charge difference across the plasma membrane. An action potential, which is a reversal of that charge difference, stimulates cells to respond by contracting. The nervous system controls muscle contractions by sending action potentials along axons to muscle cells and stimulating action potentials in them. An increased frequency of action potentials sent to the muscle cells can result in an increased strength of muscle contraction.

- 19** *What types of gated ion channels are responsible for producing action potentials?*

- 24** *How does the frequency of action potentials affect muscle contractions?*

Neuromuscular Junction

Action potentials carried by motor neurons cause action potentials to be produced in muscle fibers because of events that occur in the neuromuscular junction. Axons of motor neurons carry action

1. Resting membrane potential. In addition to some K^+ leak channels (not shown), which are always open, voltage-gated Na^+ channels (pink) and voltage-gated K^+ channels (purple) are closed. The outside of the plasma membrane is positively charged, compared with the inside.

2. Depolarization. Voltage-gated Na^+ channels are open. Depolarization results because the inward movement of Na^+ makes the inside of the membrane more positive.

3. Repolarization. Voltage-gated Na^+ channels are closed and voltage-gated K^+ channels are open. Na^+ movement into the cell stops and K^+ movement out of the cell increases, causing repolarization.

PROCESS FIGURE 9.9 Gated Ion Channels and the Action Potential

Step 1 illustrates the status of gated Na^+ and K^+ channels in a resting cell. Steps 2 and 3 show how the channels open and close to produce an action potential. Next to each step, the charge difference across the plasma membrane is illustrated.

potentials at a high velocity from the brain and spinal cord to skeletal muscle fibers. The axons branch repeatedly, and each branch projects toward one muscle fiber to innervate it. Thus, each muscle fiber receives a branch of an axon, and each axon innervates more than one muscle fiber (see figure 9.2).

Near the muscle fiber it innervates, each axon branch forms a cluster of enlarged axon terminals that rests in an invagination of the sarcolemma to form a **synapse**, or **neuromuscular junction**, which consists of the axon terminals and the area of the muscle

fiber sarcolemma they innervate. Each axon terminal is the **pre-synaptic** (prē'si-nap'tik) **terminal**. The space between the presynaptic terminal and the muscle fiber is the **synaptic** (si-nap'tik) **cleft**, and the muscle plasma membrane in the area of the junction is the **postsynaptic** (pōst-si-nap'tik) **membrane**, or **motor end-plate** (figure 9.11).

Each presynaptic terminal contains numerous mitochondria and many small, spherical sacs approximately 45 μm in diameter, called **synaptic vesicles**. The vesicles contain **acetylcholine**

1. An action potential in a local area of the plasma membrane is indicated by the orange band. Note the reversal of charge across the membrane.

2. The action potential is a stimulus that causes the production of another action potential in the adjacent plasma membrane.

3. The action potential propagates along the plasma membrane (orange arrow).

(ACh; as-e-til-kō'lēn), an organic molecule composed of acetic acid and choline, which functions as a neurotransmitter. A **neurotransmitter** (noor'ō-trans-mit'er) is a substance released from a presynaptic membrane that diffuses across the synaptic cleft and stimulates (or inhibits) the production of an action potential in the postsynaptic membrane by binding to ligand-gated ion channels.

When an action potential reaches the presynaptic terminal, it causes voltage-gated calcium ion (Ca^{2+}) channels in the plasma membrane of the axon to open; as a result, Ca^{2+} diffuse into the cell (figure 9.12). Once inside the cell, the Ca^{2+} cause the contents of a few synaptic vesicles to be secreted by exocytosis from the presynaptic terminal into the synaptic cleft. The acetylcholine molecules released from the synaptic vesicles then diffuse across the cleft and bind to receptor molecules located within the postsynaptic membrane. This causes ligand-gated Na^+ channels to open, increasing the permeability of the membrane to Na^+ . Sodium ions then diffuse into the cell, causing depolarization. In skeletal muscle, each action potential in the motor neuron causes a depolarization that exceeds threshold, which causes changes in voltage-gated ion channels that result in the production of an action potential in the muscle fiber.

PROCESS FIGURE 9.10 Action Potential Propagation in a Muscle Fiber

FIGURE 9.11 Neuromuscular Junction

(a) Several branches of an axon form the neuromuscular junction with a single muscle fiber. (b) The presynaptic terminal containing synaptic vesicles is separated from the postsynaptic membrane by the synaptic cleft. (c) Photomicrograph of neuromuscular junctions.

1. An action potential (orange arrow) arrives at the presynaptic terminal and causes voltage-gated Ca^{2+} channels in the presynaptic membrane to open.
2. Calcium ions enter the presynaptic terminal and initiate the release of the neurotransmitter acetylcholine (ACh) from synaptic vesicles.
3. ACh is released into the synaptic cleft by exocytosis.
4. ACh diffuses across the synaptic cleft and binds to ligand-gated Na^+ channels on the postsynaptic membrane.
5. Ligand-gated Na^+ channels open and Na^+ enters the postsynaptic cell, causing the postsynaptic membrane to depolarize. If depolarization passes threshold, an action potential is generated along the postsynaptic membrane.
6. ACh unbinds from the ligand-gated Na^+ channels, which then close.
7. The enzyme acetylcholinesterase, which is attached to the postsynaptic membrane, removes acetylcholine from the synaptic cleft by breaking it down into acetic acid and choline.
8. Choline is symported with Na^+ into the presynaptic terminal, where it can be recycled to make ACh. Acetic acid diffuses away from the synaptic cleft.
9. ACh is reformed within the presynaptic terminal using acetic acid generated from metabolism and from choline recycled from the synaptic cleft. ACh is then taken up by synaptic vesicles.

PROCESS FIGURE 9.12 Function of the Neuromuscular Junction

PREDICT 3

Predict the consequence if presynaptic action potentials in an axon could not release sufficient acetylcholine to cause depolarization to threshold in a skeletal muscle fiber.

Acetylcholine released into the synaptic cleft is rapidly broken down to acetic acid and choline by the enzyme **acetylcholinesterase** (as'e-til-kō-lin-es'ter-ās; figure 9.12). Acetylcholinesterase keeps acetylcholine from accumulating within the synaptic cleft,

where it would act as a constant stimulus at the postsynaptic terminal, producing many action potentials and continuous contraction in the muscle fiber. The release of acetylcholine and its rapid degradation in the synaptic cleft ensures that one presynaptic action potential yields only one postsynaptic action potential. Choline molecules are actively reabsorbed by the presynaptic terminal and then combined with the acetic acid produced within the cell to form acetylcholine. Recycling choline molecules requires less energy and is more rapid than completely synthesizing new acetylcholine molecules each time they are released from the

presynaptic terminal. Acetic acid is an intermediate in the process of glucose metabolism (see chapter 25). A variety of cells can take it up and use it after it diffuses from the area of the neuromuscular junction.

25 Describe the neuromuscular junction. How does an action potential in the neuron produce an action potential in the muscle cell?

26 What is the importance of acetylcholinesterase in the synaptic cleft?

Excitation–Contraction Coupling

Action potentials produced in the sarcolemma of a skeletal muscle fiber can lead to contraction of the fiber. The mechanism by which an action potential causes contraction of a muscle fiber is called **excitation–contraction coupling**, and it involves the sarcolemma, T tubules, sarcoplasmic reticulum, Ca^{2+} , and troponin. The sarcolemma has, along its surface, many regularly arranged, tubelike invaginations called **transverse**, or **T, tubules**. T tubules project into the muscle fiber and wrap around sarcomeres in the

region where actin and myosin myofilaments overlap (see figure 9.3; figure 9.13). The lumen of each T tubule is filled with extracellular fluid and is continuous with the exterior of the muscle fiber. Suspended in the sarcoplasm between the T tubules is a highly specialized smooth endoplasmic reticulum called the **sarcoplasmic reticulum** (sar-kō-plaz'mik re-tik'ū-lūm). Near the T tubules, the sarcoplasmic reticulum is enlarged to form **terminal cisternae** (sis-ter'nē). A T tubule and the two adjacent terminal cisternae together are called a **triad** (trī'ad; see figure 9.13). The sarcoplasmic reticulum actively transports Ca^{2+} into its lumen; thus, the concentration of Ca^{2+} is approximately 2000 times higher within the sarcoplasmic reticulum than in the sarcoplasm of a resting muscle.

Excitation–contraction coupling begins at the neuromuscular junction with the production of an action potential in the sarcolemma. The action potential is propagated along the entire sarcolemma of the muscle fiber and into the T tubules. The T tubules carry action potentials into the interior of the muscle fiber, where they cause Ca^{2+} channels in the terminal cisternae of the sarcoplasmic reticulum to open. When the Ca^{2+} channels open, Ca^{2+} rapidly diffuse into the sarcoplasm surrounding the myofibrils (figure 9.14).

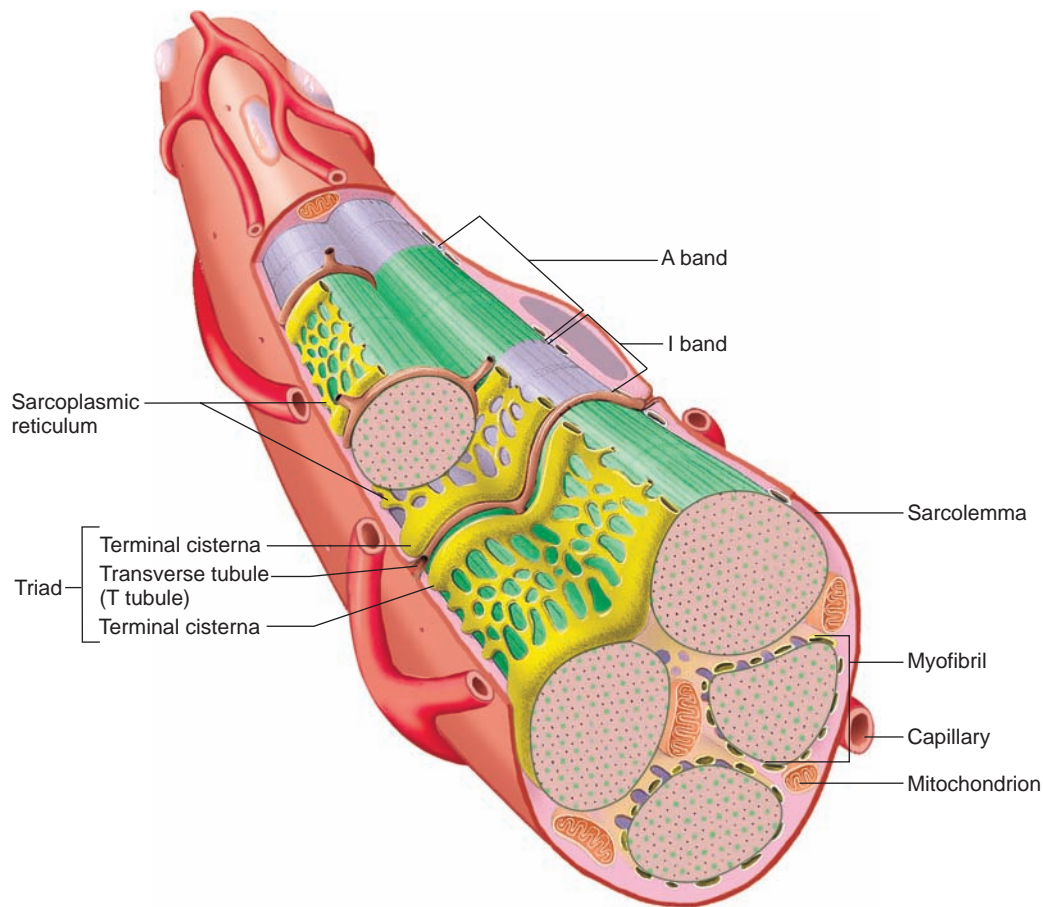

FIGURE 9.13 T Tubules and Sarcoplasmic Reticulum

A T tubule and the sarcoplasmic reticulum on each side of the T tubule form a triad.

1. An action potential produced at the neuromuscular junction is propagated along the sarcolemma of the skeletal muscle. The depolarization also spreads along the membrane of the T tubules.
2. The depolarization of the T tubule causes gated Ca^{2+} channels in the sarcoplasmic reticulum to open, resulting in an increase in the permeability of the sarcoplasmic reticulum to Ca^{2+} , especially in the terminal cisternae. Calcium ions then diffuse from the sarcoplasmic reticulum into the sarcoplasm.
3. Calcium ions released from the sarcoplasmic reticulum bind to troponin molecules. The troponin molecules bound to G actin molecules are released, causing tropomyosin to move, exposing the active sites on G actin.
4. Once active sites on G actin molecules are exposed, the heads of the myosin myofilaments bind to them to form cross-bridges.

PROCESS FIGURE 9.14 Action Potentials and Muscle Contraction

Calcium ions bind to the Ca^{2+} binding sites on the troponin molecules of the actin myofilaments. The combination of Ca^{2+} with troponin causes the troponin–tropomyosin complex to move deeper into the groove between the two F actin strands, which exposes active sites on the actin myofilaments. The heads of the myosin molecules then bind to the exposed active sites to form cross-bridges (see figure 9.14). Movement of the cross-bridges results in contraction.

Cross-Bridge Movement

A cycle of events resulting in contraction proceeds very rapidly when the heads of the myosin molecules bind to actin to form cross-bridges (figure 9.15). The heads of myosin molecules move at their hinged region, resulting in cross-bridge movement, which forces the actin myofilament, to which the heads of the myosin molecules are attached, to slide over the surface of the myosin myofilament. After cross-bridge movement, each myosin head releases from the actin and returns to its original position. It can then form another cross-bridge at a different site on the actin myofilament, followed by movement, release of the cross-bridge, and return to its original position. During a single contraction, each

myosin molecule undergoes the cycle of cross-bridge formation, movement, release, and return to its original position many times. This process is called **cross-bridge cycling**.

The energy from one ATP molecule is required for each cycle of cross-bridge formation, movement, and release. Before a myosin head binds to the active site on an actin myofilament, the head of the myosin molecule is in its resting position, and ADP and phosphate are bound to the head of the myosin molecule (see figure 9.15). Once Ca^{2+} bind to troponin and the tropomyosin moves, the active sites on actin myofilaments are then exposed. The head of a myosin molecule can then bind to an exposed active site, and the phosphate is released from the head of the myosin molecule. Energy stored in the head of the myosin molecule causes the head of the myosin molecule to move. Movement of the head causes the actin myofilament to slide past the myosin myofilament and ADP is released from the myosin head. ATP must then bind to the head of the myosin before the cross-bridge can release. As the ATP molecule binds to the head of the myosin molecule, the ATP is broken down to ADP and phosphate, and the myosin head releases from the active site on actin. The ADP and phosphate remain attached to the head of the myosin molecule, and the head of the myosin returns to its resting position. Energy

1. Exposure of active sites. Before cross-bridges cycle, Ca²⁺ bind to the troponins and the tropomyosins move, causing the exposure of active sites on actin myofilaments.

6. Recovery stroke. The heads of the myosin molecules return to their resting position (*green arrow*), and energy is stored in the heads of the myosin molecules. If Ca²⁺ are still attached to troponins, cross-bridge formation and movement are repeated (return to step 2). This cycle occurs many times during a muscle contraction. Not all cross-bridges form and release simultaneously.

5. Hydrolysis of ATP. The myosin ATPase portion of the myosin heads split ATP in to ADP and phosphate (P), which remain attached to the myosin heads.

4. Cross-bridge release. An ATP molecule binds to each of the myosin heads, causing them to detach from the actin.

2. Cross-bridge formation. The myosin heads bind to the exposed active sites on the actin myofilaments to form cross-bridges, and phosphates are released from the myosin heads.

3. Power stroke. Energy stored in the myosin heads is used to move the myosin heads (*green arrow*), causing the actin myofilaments to slide past the myosin myofilaments (*purple arrow*), and ADP molecules are released from the myosin heads (*black arrow*).

The Effect of Blocking Acetylcholine Receptors and Acetylcholinesterase

Anything that affects the production, release, and degradation of acetylcholine or its ability to bind to its receptor molecule also affects the transmission of action potentials across the neuromuscular junction. For example, some insecticides contain organophosphates that bind to and inhibit the function of acetylcholinesterase. As a result, acetylcholine is not degraded and accumulates in the synaptic cleft, where it acts as a constant stimulus to the muscle fiber. Insects exposed to such insecticides die partly because their muscles contract and cannot relax—a condition called **spastic paralysis** (spas'tik pã-ral'i-sis), which is followed by fatigue of the muscles.

In humans, a similar response to these insecticides occurs. The skeletal muscles responsible for respiration cannot undergo their normal cycle of contraction and relaxation. Instead, they remain in a state of spastic paralysis until they become fatigued. Victims die of respiratory failure. Other organic poisons, such as curare, bind to the acetylcholine receptors, preventing acetylcholine from binding to them. Curare does not allow activation of the receptors, and therefore the muscle is incapable of contracting in response to nervous stimulation—a condition called **flaccid** (flak'sid, flas'id) **paralysis**. Curare is not a poison to which people are commonly exposed, but it has been used to investigate the role of acetylcholine in the neuromuscular synapse and is sometimes used in small doses to relax muscles during certain kinds of surgery.

Myasthenia gravis (mĩ-as-thē'nē-ã grãv'is) results from the production of antibodies that bind to acetylcholine receptors, eventually causing the destruction of the receptor and thus reducing the number of receptors. As a consequence, muscles exhibit a degree of flaccid paralysis or are extremely weak. A class of drugs that includes neostigmine partially blocks the action of acetylcholinesterase and sometimes is used to treat myasthenia gravis. The drugs cause acetylcholine levels to increase in the synaptic cleft and combine more effectively with the remaining acetylcholine receptors.

released from the breakdown of ATP is stored in the head of the myosin molecule.

Movement of the myosin molecule while the cross-bridge is attached is called the **power stroke**, whereas return of the myosin head to its original position after cross-bridge release is called the **recovery stroke**. Many cycles of power and recovery strokes occur during each muscle contraction. While muscle is relaxed, energy stored in the heads of the myosin molecules is held in reserve until the next contraction. When Ca^{2+} are released from the sarcoplasmic reticulum in response to an action potential, the cycle of cross-bridge formation, movement, and release, which results in contraction, begins (see figures 9.14 and 9.15).

Muscle Relaxation

Relaxation occurs as a result of the active transport of Ca^{2+} back into the sarcoplasmic reticulum. As the Ca^{2+} concentration decreases in the sarcoplasm, the ions diffuse away from the troponin molecules. The troponin–tropomyosin complex then reestablishes its position, which blocks the active sites on the actin molecules. As a

consequence, cross-bridges cannot re-form once they have been released, and relaxation occurs.

Energy is needed to make muscles contract, but it is also needed to make muscles relax. The active transport of Ca^{2+} into the sarcoplasmic reticulum requires ATP. The active transport processes that maintain the normal concentrations of Na^+ and K^+ across the sarcolemma also require ATP. The amount of ATP required for cross-bridge formation during contraction is much greater than the other energy requirements in a skeletal muscle. The diffusion of Ca^{2+} from the sarcoplasmic reticulum is rapid, compared with the reuptake of Ca^{2+} into the sarcoplasmic reticulum by active transport. Consequently, a muscle takes at least twice as long to relax as it does to contract.

- 27** How does an action potential produced in the postsynaptic membrane of the neuromuscular junction eventually result in contraction of the muscle fiber?
- 28** Where in the contraction and relaxation processes is ATP required? Define power stroke and recovery stroke.
- 29** What conditions are required for relaxation of the muscle fiber?

PREDICT 4

Predict the consequences of having the following conditions develop in a muscle in response to a stimulus: (a) Na^+ cannot enter the skeletal muscle through voltage-gated Na^+ channels, (b) very little ATP is present in the muscle fiber before a stimulus is applied, and (c) adequate ATP is present within the muscle fiber, but action potentials occur at a frequency so great that calcium is not transported back into the sarcoplasmic reticulum between individual action potentials.

PHYSIOLOGY OF SKELETAL MUSCLE

Muscle Twitch

A **muscle twitch** is the contraction of a muscle in response to a stimulus that causes an action potential in one or more muscle fibers. Even though the normal function of muscles is more complex, an understanding of the muscle twitch makes the function of muscles in living organisms easier to comprehend.

A hypothetical contraction of a single muscle fiber in response to a single action potential is illustrated in figure 9.16. The time between application of the stimulus to the motor neuron and the beginning of contraction is the **lag**, or **latent phase**; the time during which contraction occurs is the **contraction phase**; and the time during which relaxation occurs is the **relaxation phase** (table 9.2). An action potential is an electrochemical event, but contraction is a mechanical event. An action potential is measured in millivolts and is completed in less than 2 milliseconds. Muscle contraction is measured as a force, also called tension. It is reported as the number of grams lifted, or the distance the muscle shortens, and requires up to 1 second to occur.

- 30** Define the phases of a muscle twitch and describe the events responsible for each phase.

FIGURE 9.16 Phases of a Muscle Twitch in a Single Muscle Fiber

There is a short lag phase after stimulus application, followed by a contraction phase and a relaxation phase.

Stimulus Strength and Muscle Contraction

An isolated skeletal muscle fiber produces contractions of equal force in response to each action potential. This relationship, called the **all-or-none law of skeletal muscle contraction**, can be explained on the basis of action potential production in the skeletal muscle fiber. When brief electric stimuli of increasing strength are applied to the muscle fiber sarcolemma, the following events occur: (1) A subthreshold stimulus does not produce an action potential, and no muscle contraction occurs; (2) a threshold stimulus produces an action potential and results in contraction of the muscle cell; or (3) a stronger-than-threshold stimulus produces an action potential of the same magnitude as the threshold stimulus and therefore produces an identical contraction. Thus, for a given condition, once an action potential is generated, the skeletal muscle fiber contracts to produce a constant force. If internal conditions change, the force of contraction can change as well. For example, increasing the amount of calcium available to the muscle cell results in a stronger force of contraction; conversely, muscle fatigue can result in a weaker force of contraction.

Within a given skeletal muscle, such as the biceps brachii (see chapter 10), skeletal muscle fibers form **motor units**, each of

TABLE 9.2 Events That Occur During Each Phase of a Muscle Twitch*

Lag Phase

1. An action potential is propagated to the presynaptic terminal of the motor neuron.
2. The action potential causes voltage-gated Ca^{2+} channels in the presynaptic terminal to open.
3. Calcium ions diffuse into the presynaptic terminal, causing acetylcholine contained within several synaptic vesicles to be released by exocytosis into the synaptic cleft.
4. Acetylcholine released from the presynaptic terminal diffuses across the synaptic cleft and binds to acetylcholine receptor sites on ligand-gated Na^+ channels in the postsynaptic membrane of the sarcolemma.
5. The binding of acetylcholine to its receptor site causes the ligand-gated Na^+ channels to open, and the postsynaptic membrane becomes more permeable to Na^+ .
6. Sodium ions diffuse into the muscle fiber, causing a local depolarization that exceeds threshold and produces an action potential.
7. Acetylcholine is rapidly degraded in the synaptic cleft to acetic acid and choline by acetylcholinesterase, thus limiting the length of time acetylcholine is bound to its receptor site. The result is that one presynaptic action potential produces one postsynaptic action potential in each muscle fiber.
8. The action potential produced in a muscle fiber is propagated from the postsynaptic membrane near the middle of the fiber toward both ends and into the T tubules.
9. The depolarization that occurs in the T tubule in response to the action potential causes gated Ca^{2+} channels of the membrane of the sarcoplasmic reticulum to open, and the membrane of the sarcoplasmic reticulum becomes very permeable to Ca^{2+} .
10. Calcium ions diffuse from the sarcoplasmic reticulum into the sarcoplasm.
11. Calcium ions bind to troponin; the troponin-tropomyosin complex changes its position and exposes active sites on the actin myofilaments.

Contraction Phase

12. Cross-bridges between actin molecules and myosin molecules form, move, release, and re-form many times, causing the sarcomeres to shorten. Energy stored in the heads of the myosin molecules allows cross-bridge formation and movement. After cross-bridge movement has occurred, ATP must bind to the myosin heads. The ATP is broken down to ADP, and some of the energy is used to release the cross-bridges and cause the heads of the myosin molecules to move back to their resting position, where they are ready to form other cross-bridges. Some of the energy from the ATP is stored in the myosin heads and is used for the next cross-bridge formation and movement (see figure 9.15). Energy is also released as heat.

Relaxation Phase

13. Calcium ions are actively transported back into the sarcoplasmic reticulum (requires ATP).
14. The troponin-tropomyosin complexes move to inhibit cross-bridge formation.
15. The muscle fibers lengthen passively.

*Assuming that the process begins with a single action potential in the motor neuron.

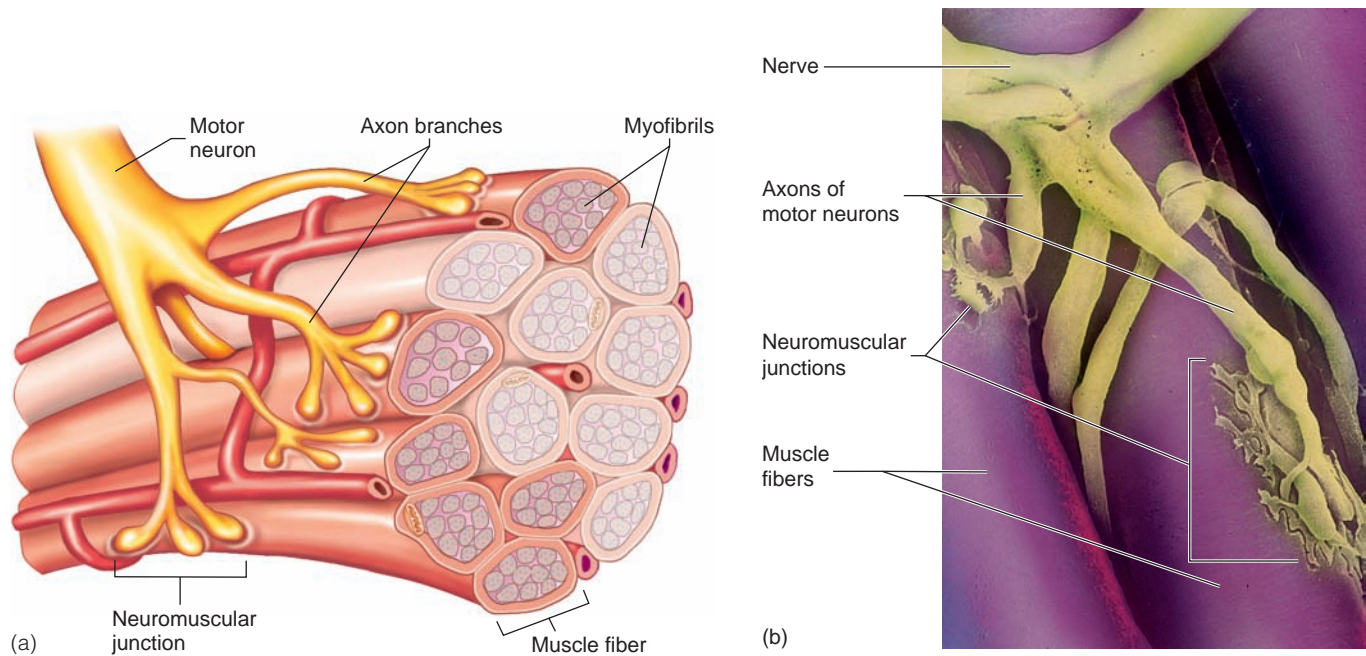

FIGURE 9.17 Motor Unit

(a) A motor unit consists of a single motor neuron and all the muscle fibers its branches innervate. (b) Photomicrograph of motor units.

which consists of a single motor neuron and all of the muscle fibers it innervates (figure 9.17). Motor units respond as a single unit. All the muscle fibers of a motor unit contract to produce a constant force in response to a threshold stimulus because an action potential in a motor neuron initiates an action potential in each of the muscle fibers it innervates.

Whole muscles exhibit characteristics that are more complex than those of individual muscle fibers or motor units. Instead of responding in an all-or-none fashion, whole muscles respond to stimuli in a **graded fashion**, which means that the strength of the contractions can range from weak to strong.

A muscle is composed of many motor units, and the axons of the motor units combine to form a nerve. A whole muscle contracts with either a small force or a large force, depending on the number of motor units stimulated to contract. This relationship is called **multiple motor unit summation** because the force of contraction increases as more and more motor units are stimulated. Multiple motor unit summation resulting in graded responses can be demonstrated by applying brief electric stimuli of increasing strength to the nerve supplying a muscle (figure 9.18). A **subthreshold stimulus** is not strong enough to cause an action potential in any of the axons in a nerve and causes no contraction. As the stimulus strength increases, it eventually becomes a **threshold stimulus**, which is strong enough to produce an action potential in a single motor unit axon, causing all the muscle fibers of that motor unit to contract. Progressively stronger stimuli, called **submaximal stimuli**, produce action potentials in axons of additional motor units. A **maximal stimulus** produces action potentials in the axons of all motor units of that muscle. Consequently, even greater stimulus strengths, or **supramaximal stimuli**, have no additional effect. As the stimulus strength increases between threshold and maximum

values, motor units are **recruited**—the number of motor units responding to the stimuli increases and the force of contraction produced by the muscle increases in a graded fashion.

Motor units in different muscles do not always contain the same number of muscle fibers. Muscles performing delicate and precise movements have motor units with a small number of muscle fibers, whereas muscles performing more powerful but less precise contractions have motor units with many muscle fibers. For example, in very delicate muscles, such as those that move the eye, the number of muscle fibers per motor unit can be less than 10, whereas, in the heavy muscles of the thigh, the number can be several hundred.

- 31** Why does a single muscle fiber either not contract or contract with the same force in response to stimuli of different strengths?
- 32** Why does a motor unit either not contract or contract with the same force in response to stimuli of different strengths?
- 33** How does increasing the strength of a stimulus cause a whole muscle to respond in a graded fashion?
- 34** Define multiple motor unit summation.

PREDICT 5

In patients with poliomyelitis (pō'lē-ō-mī'ē-lī'tis), motor neurons are destroyed, causing loss of muscle function and even flaccid paralysis. Sometimes recovery occurs because of the formation of axon branches from the remaining motor neurons. These branches innervate the paralyzed muscle fibers to produce motor units with many more muscle fibers than usual, resulting in the recovery of muscle function. What effect would this reinnervation of muscle fibers have on the degree of muscle control in a person who has recovered from poliomyelitis?

FIGURE 9.18 Multiple Motor Unit Summation in a Muscle

Multiple motor unit summation occurs as stimuli of increasing strength are applied to a nerve that innervates a muscle. The amount of tension (height of peaks) is influenced by the number of motor units responding.

Stimulus Frequency and Muscle Contraction

An action potential in a single muscle fiber causes it to contract. Although the action potential triggers contraction of the muscle fiber, the action potential is completed long before the contraction phase is completed. In addition, the contractile mechanism in a muscle fiber exhibits no refractory period. That is, relaxation of a muscle fiber is not required before a second action potential can stimulate a second contraction. As the frequency of action potentials in a skeletal muscle fiber increases, the frequency of contraction also increases. In **incomplete tetanus** (tet'ă-nŭs), muscle fibers partially relax between the contractions, but, in **complete tetanus**, action potentials are produced so rapidly in muscle fibers that no muscle relaxation occurs between them. The tension produced by a muscle increases as the frequency of contractions increases. This increased tension is called **multiple-wave summation** (figure 9.19).

Tetanus of a muscle caused by stimuli of increasing frequency can be explained by the effect of the action potentials on Ca^{2+} release from the sarcoplasmic reticulum. The first action potential causes Ca^{2+} release from the sarcoplasmic reticulum, the Ca^{2+} diffuse to the myofibrils, and contraction occurs. Relaxation begins as the Ca^{2+} are pumped back into the sarcoplasmic reticulum. If the next action potential occurs before relaxation is complete, two things happen. First, because not enough time has passed for all the Ca^{2+} to reenter the sarcoplasmic reticulum, Ca^{2+} levels around the myofibrils remain elevated. Second, the next action potential causes the release of additional Ca^{2+} from the sarcoplasmic reticulum. Thus, the elevated Ca^{2+} levels in the sarcoplasm produce continued contraction of the muscle fiber. Action poten-

tials at a high frequency can increase Ca^{2+} concentrations in the sarcoplasm to an extent that the muscle fiber is contracted completely and does not relax at all.

At least two factors play roles in the increased tension observed during multiple-wave summation. First, as the action potential frequency increases, the concentration of Ca^{2+} around the myofibrils becomes greater than during a single muscle twitch, thereby causing a much greater degree of contraction. The additional Ca^{2+} cause the exposure of additional active sites on the actin myofilaments. Second, the sarcoplasm and the connective tissue components of

FIGURE 9.19 Multiple-Wave Summation

Stimuli 1–5 are stimuli of increasing frequency. For each stimulus, the up arrow indicates the start of stimulation, and the down arrow indicates the end of stimulation. Stimulus frequency 1 produces successive muscle twitches with complete relaxation between stimuli. Stimuli frequencies 2–4 do not allow complete relaxation between stimuli. Stimulus frequency 5 causes tetanus—no relaxation between stimuli.

muscle have some elasticity. During each separate muscle twitch, some of the tension produced by the contracting muscle fibers is used to stretch those elastic elements, and the remaining tension is applied to the load to be lifted. In a single muscle twitch, relaxation begins before the elastic components are totally stretched. The maximum tension produced during a single muscle twitch is therefore not applied to the load to be lifted. In a muscle stimulated at a high frequency, the elastic elements are stretched during the very early part of the prolonged contraction. After the elastic components are stretched, all of the tension produced by the muscle is applied to the load to be lifted, and the observed tension produced by the muscle is increased.

Another example of a graded response is **treppe** (trep'eh; staircase), which occurs in muscle that has rested for a prolonged period (figure 9.20). If the muscle is stimulated with a maximal stimulus at a low frequency, which allows complete relaxation between the stimuli, the contraction triggered by the second stimulus produces a slightly greater tension than the first. The contraction triggered by the third stimulus produces a contraction with a greater tension than the second. After only a few stimuli, the levels of tension produced by all the contractions are equal.

A possible explanation for treppe is an increase in Ca^{2+} levels around the myofibrils. The Ca^{2+} released in response to the first stimulus is not taken up completely by the sarcoplasmic reticulum before the second stimulus causes the release of additional Ca^{2+} , even though the muscle completely relaxes between the muscle twitches. As a consequence, during the first few contractions of the muscle, the Ca^{2+} concentration in the sarcoplasm increases slightly, making contraction more efficient because of the increased number of ions available to bind to troponin. Treppe achieved during warm-up exercises can contribute to improved muscle efficiency during athletic events. Factors such as increased blood flow to the muscle and increased muscle temperature probably are involved as well. Increased muscle temperature causes the enzymes responsible for muscle contraction to function at a more rapid rate.

FIGURE 9.20 Treppe

When a rested muscle is stimulated repeatedly with maximal stimuli at a frequency that allows complete relaxation between stimuli, the second contraction produces a slightly greater tension than the first, and the third contraction produces greater tension than the second. After a few contractions, the levels of tension produced by all contractions are equal.

CASE STUDY

Organophosphate Poisoning

John has a number of prize apple trees in his back yard. To prevent them from becoming infested with insects, he sprayed them with an organophosphate insecticide. He was in a rush to spray the trees before leaving town on vacation, and he failed to pay attention to the safety precautions on the packaging. He sprayed the trees without using any skin or respiratory protection. Soon he experienced severe stomach cramps, double vision, difficulty breathing, and spastic contractions of his skeletal muscles. His wife took John to the emergency room where he was diagnosed with organophosphate poisoning. While in the emergency room, his physician administered a drug, and soon many of John's symptoms subsided.

Organophosphate insecticides exert their effects by binding to the enzyme acetylcholinesterase within synaptic clefts, rendering it ineffective. Thus, the organophosphate poison and acetylcholine “compete” for the acetylcholinesterase as the organophosphate poison increases in concentration the enzyme is less effective in degrading acetylcholine. Organophosphate poisons affect synapses in which acetylcholine is the neurotransmitter, including skeletal muscle synapses and some smooth muscle synapses, such as in the walls of the stomach, intestines, and air passageways.

PREDICT 6

Organophosphate insecticides exert their effects by binding to the enzyme acetylcholinesterase within synaptic clefts, rendering it ineffective. Use figure 9.12 to help answer the following question.

- Explain the spastic contractions that occurred in John's skeletal muscles.
- Propose as many mechanisms as you can by which a drug could counteract the effects of organophosphate poisoning.

- How does the lack of a refractory period in skeletal muscle fiber contraction explain multiple-wave summation?
- Define incomplete tetanus and complete tetanus.
- Give two reasons why rapid, repeated stimulation of a muscle fiber increases its force of contraction.
- Describe treppe and explain how it occurs.

TYPES OF MUSCLE CONTRACTIONS

Muscle contractions are classified based on the type of contraction that predominates (table 9.3). In **isometric** (ī-sō-met'rik) **contractions**, the length of the muscle does not change, but the amount of tension increases during the contraction process. Isometric contractions are responsible for the constant length of the postural muscles of the body, such as muscles that hold the spine erect while a person is sitting or standing. In **isotonic** (ī-sō-ton'ik) **contractions**, the amount of tension produced by the

TABLE 9.3 Types of Muscle Contractions

Contraction Types	Characteristics
Multiple motor unit summation	Each motor unit responds in an all-or-none fashion. A whole muscle is capable of producing an increasing amount of tension as the number of motor units stimulated increases.
Multiple-wave summation	Summation results when many action potentials are produced in a muscle fiber. Contraction occurs in response to the first action potential, but there is not enough time for relaxation to occur between action potentials. Because each action potential cause the release of Ca^{2+} from the sarcoplasmic reticulum, the ion levels remain elevated in the sarcoplasm to produce a tetanic contraction. The tension produced as a result of multiple-wave summation is greater than the tension produced by a single muscle twitch. The increased tension results from the greater concentration of Ca^{2+} in the sarcoplasm and the stretch of the elastic components of the muscle early in contraction.
Tetanus of muscles	Tetanus of muscles results from multiple-wave summation. Incomplete tetanus occurs when the action potential frequency is low enough to allow partial relaxation of the muscle fibers. Complete tetanus occurs when the action potential frequency is high enough that no relaxation of the muscle fibers occurs.
Treppe	Tension produced increases for the first few contractions in response to a maximal stimulus at a low frequency in a muscle that has been at rest for some time. Increased tension may result from the accumulation of small amounts of Ca^{2+} in the sarcoplasm for the first few contractions or from an increasing rate of enzyme activity.
Isometric contractions	A muscle produces increasing tension as it remains at a constant length. This type of contraction is characteristic of postural muscles that maintain a constant tension without changing their length.
Isotonic contractions	A muscle produces a constant tension during contraction. A muscle shortens during contraction. This type of contraction is characteristic of finger and hand movements.
Concentric contractions	A muscle produces increasing tension as it shortens.
Eccentric contractions	A muscle produces increasing tension as it lengthens.

muscle is constant during contraction, but the length of the muscle changes. Movements of the upper limbs or fingers are predominantly isotonic contractions. Examples include waving and using a computer keyboard. Most muscle contractions are not strictly isometric or isotonic contractions. For example, both the length and tension of muscles change when a person walks or opens a heavy door. Although some mechanical differences exist, both types of contractions result from the same contractile process within muscle cells.

Concentric (kon-sen'trik) **contractions** are isotonic contractions in which tension in the muscle is great enough to overcome the opposing resistance, and the muscle shortens. Concentric contractions include contractions that result in an increasing tension as the muscle shortens. Many of the movements performed by muscle contractions are concentric contractions. **Eccentric** (ek-sen'trik) **contractions** are isotonic contractions in which tension is maintained in a muscle, but the opposing resistance is great enough to cause the muscle to increase in length (see table 9.3). Eccentric contractions are performed when a person slowly lowers a heavy weight. During eccentric contractions, muscles produce substantial force. During exercise, eccentric contractions often produce greater tension than concentric contractions. Eccentric contractions are of clinical interest because repetitive eccentric contractions, such as seen in the lower limbs of people

who run downhill for long distances, tend to injure muscle fibers and the connective tissue of muscles.

Muscle tone is the constant tension produced by muscles for long periods of time. Muscle tone is responsible for keeping the back and lower limbs straight, the head upright, and the abdomen flat. Muscle tone depends on a small percentage of all the motor units contracting out of phase with one another at any point in time. The same motor units are not contracting all the time, however. A small percentage of motor units is stimulated with a frequency of nerve impulses that causes incomplete tetanus for short periods. The motor units that are contracting are stimulated in such a way that the tension produced by the whole muscle remains constant.

PREDICT 7

Mary Myosin overheard an argument between two students who could not decide if a weight lifter who lifts a weight above the head and then holds it there before lowering it is using isometric, isotonic, concentric, or eccentric muscle contractions. Mary is an expert on muscle contractions, so she settles the debate. What is her explanation?

Movements of the body are usually smooth and occur at widely differing rates—some very slowly and others quite rapidly. Most

movements are produced by muscle contractions, but very few of the movements resemble the rapid contractions of individual muscle twitches. Smooth, slow contractions result from an increasing number of motor units contracting out of phase as the muscles shorten, as well as from a decreasing number of motor units contracting out of phase as muscles lengthen. Each motor unit exhibits either incomplete or complete tetanus, but, because the contractions are out of phase and because the number of motor units activated varies at each point in time, a smooth contraction results. Consequently, muscles are capable of contracting either slowly or rapidly, depending on the number of motor units stimulated and the rate at which that number increases or decreases.

Length Versus Tension

Active tension is the force applied to an object to be lifted when a muscle contracts. The initial length of a muscle has a strong influence on the amount of active tension it produces. As the length of a muscle increases, its active tension also increases, to a point. If the muscle is stretched farther than that optimum length, the active tension it produces begins to decline. The muscle length plotted against the tension produced by the muscle in response to maximal stimuli is the **active tension curve** (figure 9.21).

If a muscle is stretched so that the actin and myosin myofilaments within the sarcomeres do not overlap or overlap to a very small extent, the muscle produces very little active tension when it is stimulated. Also, if the muscle is not stretched at all, the myosin myofilaments touch each of the Z disks in each sarcomere, and very little contraction of the sarcomeres can occur. If the muscle is stretched to its optimum length, optimal overlap of the actin and myosin myofilaments takes place. When the muscle is stimulated, cross-bridge formation results in maximal contraction.

Passive tension is the tension applied to the load when a muscle is stretched but not stimulated. It is similar to the tension produced if the muscle is replaced with an elastic band. Passive tension exists because the muscle and its connective tissue have some elasticity. The sum of active and passive tension is called **total tension**.

- 39** Define *isometric, isotonic, concentric, and eccentric contractions*.
- 40** What is *muscle tone*, and how is it maintained?
- 41** How are *smooth, slow contractions produced in muscles*?
- 42** Draw an *active tension curve*. How does the *overlap of actin and myosin explain the shape of the curve*?

Weight Lifters and Muscle Length

Weight lifters and others who lift heavy objects usually assume positions so that their muscles are stretched close to their optimum length before lifting. For example, the position a weight lifter assumes before power lifting stretches the upper limb and lower limb muscles to a near-optimum length for muscle contraction, and the stance a lineman assumes in a football game stretches most muscle groups in the lower limbs so they are near their optimum length for suddenly moving the body forward.

FATIGUE

Fatigue (fā-tēg') is the decreased capacity to do work and the reduced efficiency of performance that normally follows a period of activity. The rate at which individuals develop fatigue is highly variable, but it is a phenomenon that everyone has experienced. Fatigue can develop at three possible sites: the nervous system, the muscles, and the neuromuscular junction.

Psychologic fatigue, the most common type, involves the central nervous system. The muscles are capable of functioning, but the individual “perceives” that additional muscular work is not possible. A burst of activity in a tired athlete in response to encouragement from spectators shows how psychologic fatigue can be overcome. The onset and duration of psychologic fatigue vary greatly and depend on the emotional state of the individual.

The second most common type of fatigue occurs in the muscle fiber. **Muscular fatigue** results from ATP depletion. Without adequate ATP levels in muscle fibers, cross-bridges and ion transport cannot function normally. As a consequence, the tension that a muscle is capable of producing declines. Fatigue in the lower limbs of marathon runners or in the upper and lower limbs of swimmers are examples.

The least common type of fatigue, called **synaptic fatigue**, occurs in the neuromuscular junction. If the action potential frequency in motor neurons is great enough, the release of acetylcholine from the presynaptic terminals is greater than the rate of acetylcholine synthesis. As a result, the synaptic vesicles become depleted, and insufficient acetylcholine is released to stimulate the muscle fibers. Under normal physiologic conditions, fatigue of neuromuscular junctions is rare; however, it may occur under conditions of extreme exertion.

Muscle Soreness Resulting from Exercise

Pain frequently develops after 1 or 2 days in muscles that are vigorously exercised, and the pain can last for several days. The pain is more common in untrained people who exercise vigorously. In addition, highly repetitive eccentric contractions of muscles produce pain more readily than concentric contractions. The pain is associated with damage to skeletal muscle fibers and with connective tissue surrounding the skeletal muscle fibers. In people with muscle soreness induced by exercise, enzymes that are normally found inside muscle fibers can be detected in the extracellular fluid. Enzymes are able to leave the muscle fibers because injury causes an increase in the permeability or rupture of plasma membranes. In addition, fragments of collagen molecules can be found in the extracellular fluid of muscles. These observations indicate that injury occurs to both muscle fibers and the connective tissue of muscles. The pain produced appears to be the result of inflammation resulting from damage to muscle fibers and the connective tissue. Exercise schedules that alternate exercise with periods of rest, such as lifting weights every other day, provide time for the repair of muscle tissue.

As a result of extreme muscular fatigue, muscles occasionally become incapable of either contracting or relaxing—a condition called **physiologic contracture** (kon-trak'choor), which is caused by a lack of ATP within the muscle fibers. ATP can decline

At the normal resting length of a muscle, the sarcomeres are also at an optimal length. The muscle produces maximum tension in response to a maximal stimulus at this length.

At muscle/sarcomere length 1, the muscle is not stretched, and the tension produced when the muscle contracts is small because there is too much overlap between actin and myosin myofilaments. The myosin myofilaments run into the Z disks and the actin myofilaments interfere with each other at the center of the sarcomere, reducing the number of cross-bridges that can form.

At muscle/sarcomere length 2, the muscle is optimally stretched, and the tension produced when the muscle contracts is maximal because there is optimal overlap of actin and myosin myofilaments, so the number of cross-bridges that can form is maximal.

At muscle/sarcomere length 3, the muscle is stretched severely, and the tension produced when the muscle contracts is small because there is little overlap between actin and myosin myofilaments and few cross-bridges can form.

FIGURE 9.21 Muscle Length and Tension

The length of a muscle before it is stimulated influences the force of contraction of the muscle. As the muscle changes length, the sarcomeres also change length.

to very low levels when a muscle is stimulated strongly, such as under conditions of extreme exercise. When ATP levels are very low, active transport of Ca^{2+} into the sarcoplasmic reticulum slows, Ca^{2+} accumulate within the sarcoplasm, and ATP is unavailable to bind to the myosin molecules that have formed

cross-bridges with the actin myofilaments. As a consequence, the previously formed cross-bridges cannot release, resulting in physiologic contracture.

Rigor mortis (rig'er mōr'tīs), the development of rigid muscles several hours after death, is similar to physiologic contracture.

ATP production stops shortly after death, and ATP levels within muscle fibers decline. Because of low ATP levels, active transport of Ca^{2+} into the sarcoplasmic reticulum stops, and Ca^{2+} leak from the sarcoplasmic reticulum into the sarcoplasm. Calcium ions can also leak from the sarcoplasmic reticulum as a result of the breakdown of the sarcoplasmic reticulum membrane after cell death. As Ca^{2+} levels increase in the sarcoplasm, cross-bridges form. Too little ATP is available to bind to the myosin molecules, however, so the cross-bridges are unable to release and re-form in a cyclic fashion to produce contractions. As a consequence, the muscles remain stiff until tissue degeneration occurs.

43 Define fatigue, and list three locations in which fatigue can develop.

44 Define and explain the cause of physiologic contracture and rigor mortis.

ENERGY SOURCES

ATP is the immediate source of energy for muscle contractions. As long as adequate amounts of ATP are present, muscles can contract repeatedly for a long time. ATP must be synthesized continuously to sustain muscle contractions, and ATP synthesis must be equal to ATP breakdown because the small amount of ATP stored in muscle fibers is sufficient to support vigorous muscle contractions for only a few seconds. The energy required to produce ATP comes from three sources: (1) creatine phosphate, (2) anaerobic respiration, and (3) aerobic respiration (table 9.4). Only the main points of anaerobic respiration and aerobic respiration are considered here (a more detailed discussion can be found in chapter 25).

Creatine Phosphate

During resting conditions, energy from aerobic respiration is used to synthesize **creatine** (krē'ă-tēn, krē'ă-tin) **phosphate**. Creatine phosphate accumulates in muscle cells and functions to store energy, which can be used to synthesize ATP. As ATP levels begin to fall, ADP reacts with creatine phosphate to produce ATP and creatine.

The reaction is catalyzed by the enzyme **creatine kinase**, occurs very rapidly, and is able to maintain ATP levels as long as creatine phosphate is available in the cell. During intense muscular contraction, however, creatine phosphate levels are quickly exhausted. ATP and creatine phosphate present in the cell provide enough energy to sustain maximum contractions for about 8–10 seconds.

Anaerobic Respiration

Anaerobic (an-ār-ō'bik) **respiration** does not require oxygen and results in the breakdown of glucose to yield ATP and lactic acid. For each molecule of glucose metabolized, a net production of two ATP molecules and two molecules of lactic acid occurs. The first part of anaerobic respiration and aerobic respiration share an enzymatic pathway called **glycolysis** (glī-kol'ī-sis). In glycolysis, a glucose molecule is broken down into two molecules of pyruvic

acid. Two molecules of ATP are used in this process, but four molecules of ATP are produced, resulting in a net gain of two ATP molecules for each glucose molecule metabolized. In anaerobic respiration, the pyruvic acid is then converted to lactic acid. Unlike pyruvic acid, much of the lactic acid diffuses out of the muscle fibers into the bloodstream.

Anaerobic respiration is less efficient than aerobic respiration, but it is much faster, especially when oxygen availability limits aerobic respiration. By using many glucose molecules, anaerobic respiration can rapidly produce ATP for a short time. During short periods of intense exercise, such as sprinting, anaerobic respiration combined with the breakdown of creatine phosphate provides enough ATP to support intense muscle contraction for up to 3 minutes. ATP formation from creatine phosphate and anaerobic respiration is limited by the depletion of creatine phosphate and glucose and by the brief time anaerobic respiration can produce ATP.

Aerobic Respiration

Aerobic (ār-ō'bik) **respiration** requires oxygen and breaks down glucose to produce ATP, carbon dioxide, and water. Compared with anaerobic respiration, aerobic respiration is much more efficient. The metabolism of a glucose molecule by anaerobic respiration produces a net gain of 2 ATP molecules for each glucose molecule. In contrast, aerobic respiration can produce up to 38 ATP molecules for each glucose molecule. In addition, aerobic respiration uses a greater variety of molecules as energy sources, such as fatty acids and amino acids. Some glucose is used as an energy source in skeletal muscles, but fatty acids provide a more important source of energy during sustained exercise and during resting conditions.

In aerobic respiration, pyruvic acid is metabolized by chemical reactions within mitochondria. Two closely coupled sequences of reactions in mitochondria, called the citric acid cycle and the electron-transport chain, produce many ATP molecules. Carbon dioxide molecules are produced and, in the last step, oxygen atoms combine with hydrogen atoms to form water. Thus, carbon dioxide, water, and ATP are major end products of aerobic respiration. The following equation represents the aerobic respiration of one molecule of glucose:

Although aerobic respiration produces many more ATP molecules for each glucose molecule metabolized than does anaerobic respiration, the rate at which the ATP molecules are produced is slower. Resting muscles or muscles undergoing long-term exercise, such as long-distance running or other endurance exercises, depend primarily on aerobic respiration for ATP synthesis.

Oxygen Deficit and Recovery Oxygen Consumption

There is a lag time between when exercise begins and when an individual begins to breathe more heavily because of the exercise. After exercise stops, there is a lag time before breathing returns to preexercise levels. These changes in breathing patterns reflect changes in oxygen consumption by muscle cells as they increase their demand for ATP supplied through aerobic respiration. The

TABLE 9.4 Sources of ATP in Muscles

	Creataine Phosphate	Anaerobic Respiration	Aerobic Respiration
Metabolic Process	<p>Creatine phosphate → Creatine → 1 ATP</p>	<p>Glucose → Glycolysis → 2 pyruvic acid → 2 ATP → 2 lactic acid</p>	<p>Glucose → Glycolysis → 2 pyruvic acid → 2 ATP → Citric acid cycle → Electron-transport chain → 36 ATP</p> <p>Fatty acids, Amino acids → Citric acid cycle</p>
Energy Source	Creatine phosphate	Glucose	Glucose, fatty acids, amino acids
Oxygen Required	No	No	Yes
ATP Yield	1 per creatine phosphate	2 per glucose molecule	Up to 38 per glucose molecule
Duration of Energy Supply	Up to 10 seconds	Up to 3 minutes	Hours

lack of increased oxygen consumption relative to increased activity at the onset of exercise creates an **oxygen deficit**, or **debt**. This deficit must be repaid during and after exercise once oxygen consumption catches up with the increased activity level. At the onset of exercise, the ATP required by muscles for the increased level of activity is primarily supplied by the creatine phosphate system and anaerobic respiration: two systems that can supply ATP relatively quickly and without a requirement for oxygen (see table 9.4). The ability of aerobic respiration to supply ATP at the onset of exercise lags behind that of the creatine phosphate system and anaerobic respiration. Consequently, there is a lag between the onset of exercise and the need for increased oxygen consumption.

The elevated oxygen consumption relative to activity level after exercise has ended is called **recovery oxygen consumption**. A portion of the recovery oxygen consumption is used to “repay” the oxygen deficit that was incurred at the onset of exercise, but most of the recovery oxygen consumption is used to support metabolic processes that restore homeostasis after the disturbances that occurred during exercise. Such disturbances include exercise-related increases in body temperature, changes in intra- and extracellular ion concentrations, and changes in metabolite and hormone levels. The duration of the recovery oxygen consumption generally lasts only minutes to hours, and it is dependent on the individual’s physical conditioning and on the length and intensity of the exercise session. In extreme cases, such as following a marathon, recovery oxygen consumption can last as long as 15 hours.

Anaerobic Exercise and Oxygen Deficit

During brief but intense exercise, such as sprinting or lifting a heavy weight, much of the ATP used by exercising muscles comes from the conversion of creatine phosphate to creatine and from anaerobic respiration. Glycogen is broken down to glucose in the skeletal muscle fibers and in the liver. Glucose is released from the liver into the circulatory system and can be taken up by skeletal muscle fibers. Anaerobic respiration within the skeletal muscle fibers converts the glucose molecules to ATP and lactic acid. Increased breathing and elevated aerobic respiration after exercise partially result from the oxygen deficit that occurs during such exercise. The increased aerobic respiration pays back a portion of the oxygen deficit by converting creatine to creatine phosphate and converting the excess lactic acid to glucose, which is once again stored as glycogen in muscles and in the liver. The magnitude of the oxygen deficit depends on the intensity of the exercise, the length of time it was sustained, and the physical condition of the individual. Those who are in poor physical condition do not have as great a capacity as well-trained athletes to perform aerobic respiration.

PREDICT 8

Eric is a highly trained cross-country runner and his brother John is a computer programmer who almost never exercises. While the two brothers were working on a remodeling project in the basement of their house, the doorbell upstairs rang: A package they were both very excited about was being delivered. They raced each other up the stairs to the front door to see which one would get the package first. When they reached the front door, both were breathing heavily. However, John continued to breathe heavily for several minutes while Eric was opening the package. Explain why John continued to breathe heavily longer than Eric, even though they both had run the same distance.

SLOW AND FAST FIBERS

Not all skeletal muscles have identical functional capabilities. They differ in several respects, including having muscle fibers that contain slightly different forms of myosin. The myosin of slow-twitch muscle fibers causes these fibers to contract more slowly, and these cells are more resistant to fatigue, whereas the myosin of fast-twitch muscle fibers cause these fibers to contract quickly and these cells fatigue quickly (table 9.5). The proportion of muscle fiber types differs within individual muscles.

Slow-Twitch Oxidative Muscle Fibers

Slow-twitch oxidative (SO), or type I, muscle fibers contract more slowly, are smaller in diameter, have a better developed blood supply, have more mitochondria, and are more fatigue-resistant than fast-twitch muscle fibers. Slow-twitch muscle fibers respond relatively slowly to nervous stimulation. The enzymes on the myosin heads responsible for the breakdown of ATP are called **myosin ATPase**. Slow-twitch fibers break down ATP slowly because their myosin heads have a slow form of myosin ATPase. The relatively slow breakdown of ATP means that cross-bridge movement occurs slowly, which is what causes the muscle to contract slowly. Aerobic respiration is the primary source for ATP synthesis in slow-twitch muscles, and their capacity to perform aerobic respiration is enhanced by a plentiful blood supply and the presence of numerous mitochondria. They are called oxidative muscle fibers because of their enhanced capacity to carry out aerobic respiration. Slow-twitch fibers also contain large amounts of **myoglobin** (mī-ō-glō’bin), a dark pigment similar to hemoglobin in red blood cells, which binds oxygen and acts as a muscle reservoir for oxygen when the blood does not supply an adequate amount. Myoglobin thus enhances the capacity of the muscle fibers to perform aerobic respiration.

Fast-Twitch Muscle Fibers

Fast-twitch, or type II, muscle fibers respond rapidly to nervous stimulation and their myosin heads have a fast form of myosin ATPase, which allows them to break down ATP more rapidly than slow-twitch muscle fibers. This allows their cross-bridges to release and form more rapidly than those in slow-twitch muscle fibers. Muscles containing a high percentage of these fibers have a less well-developed blood supply than muscles containing a high percentage of slow-twitch muscle fibers. In addition, fast-twitch

TABLE 9.5 Characteristics of Skeletal Muscle Fiber Types

	Slow-Twitch Oxidative (SO) Type I	Fast-Twitch Oxidative Glycolytic (FOG) Type IIa	Fast-Twitch Glycolytic (FG) Type IIb
Fiber Diameter	Smallest	Intermediate	Largest
Myoglobin Content	High	High	Low
Mitochondria	Many	Many	Few
Capillaries	Many	Many	Few
Metabolism	High aerobic capacity Low anaerobic capacity	Intermediate aerobic capacity High anaerobic capacity	Low aerobic capacity Highest anaerobic capacity
Fatigue Resistance	High	Intermediate	Low
Myosin ATPase Activity	Slow	Fast	Fast
Glycogen Concentration	Low	High	High
Location Where Fibers Are Most Abundant	Generally in postural muscles and more in lower limbs than upper limbs	Generally predominate in lower limbs	Generally predominate in upper limbs
Functions	Maintenance of posture and performance in endurance activities	Endurance activities in endurance-trained muscles	Rapid, intense movements of short duration

muscle fibers have very little myoglobin and fewer and smaller mitochondria. Fast-twitch muscle fibers have large deposits of glycogen and are well adapted to perform anaerobic respiration. The anaerobic respiration of fast-twitch muscle fibers, however, is not adapted for supplying a large amount of ATP for a prolonged period. The muscle fibers tend to contract rapidly for a shorter time and fatigue relatively quickly. Fast-twitch muscle fibers come in two forms, which differ mainly in their metabolic capacities. The two types are type IIa, or fast-twitch oxidative glycolytic (FOG) fibers, and type IIb, or fast-twitch glycolytic (FG) fibers (see table 9.5). Type IIa fibers rely on both anaerobic and aerobic ATP production, whereas type IIb fibers rely almost exclusively on anaerobic glycolysis for ATP production.

Distribution of Fast-Twitch and Slow-Twitch Muscle Fibers

The muscles of many animals are composed primarily of either fast-twitch or slow-twitch muscle fibers. The white meat of a chicken or pheasant breast, which is composed mainly of fast-twitch fibers, appears whitish because of its relatively poor blood supply and lack of myoglobin. The muscles are adapted to contract rapidly for a short time but fatigue quickly. The red, or dark, meat of a chicken leg or of a duck breast is composed of slow-twitch fibers and appears darker because of the relatively well-developed blood supply and a large amount of myoglobin. These muscles are adapted to contract slowly for a longer time and to fatigue slowly. The distribution of slow-twitch and fast-twitch muscle fibers is consistent with the behavior of these animals. For example, pheasants can fly relatively fast for short distances, and ducks fly more slowly for long distances.

Humans exhibit no clear separation of slow-twitch and fast-twitch muscle fibers in individual muscles. Most muscles have both types of fibers, although the number of each varies for each muscle. The large postural muscles contain more slow-twitch fibers, whereas the muscles of the upper limbs contain more fast-twitch fibers.

The distribution of slow-twitch and fast-twitch muscle fibers in a given muscle is fairly constant for each individual and apparently is established developmentally. People who are good sprinters have a greater percentage of fast-twitch muscle fibers, whereas good long-distance runners have a higher percentage of slow-twitch muscle fibers in their lower limb muscles. Athletes who are able to perform a variety of anaerobic and aerobic exercises tend to have a more balanced mixture of fast-twitch and slow-twitch muscle fibers.

50 *Contrast the structural and functional differences between slow-twitch and fast-twitch muscle fibers.*

51 *Explain the functions for which each type is best adapted and how they are distributed.*

Effects of Exercise

Neither fast-twitch nor slow-twitch muscle fibers can be easily converted to muscle fibers of the other type without specialized training. Training can increase the size and the capacity of both types of muscle fibers to perform more efficiently. Intense exercise resulting in anaerobic respiration, such as weight lifting, increases muscular strength and mass and results in an enlargement of fast-twitch muscle fibers more than slow-twitch muscle fibers. Aerobic exercise increases the vascularity of muscle and causes an enlargement of slow-twitch muscle fibers. Aerobic exercise training can convert some fast-twitch muscle fibers that fatigue readily (type IIb) to fast-twitch muscle fibers that resist fatigue (type IIa). In addition to changes in myosin, there is an increase in the number of mitochondria in the muscle cells and an increase in their blood supply. Weight training followed by periods of rest can convert some muscle fibers from type IIa to type IIb. However, a type I muscle fiber cannot be converted to a type II fiber, and vice versa. Through specific training, a person with more fast-twitch muscle fibers can run long distances, and a person with more slow-twitch muscle fibers can increase the speed at which he or she runs.

PREDICT 9

Susan recently began racing her bicycle. Her training consists entirely of long rides on her bicycle at a steady pace. When she entered her first race, she was excited to find that she was able to keep pace with the rest of the riders. However, at the final sprint to the finish line, the other riders left her in their dust, and she finished in last place. Why was she unable to keep pace during the finishing sprint? As her coach, what advice would you give Susan about her training to prepare her better for her next race?

A muscle increases in size, or **hypertrophies** (hī-per'trō-fēz), and increases in strength and endurance in response to exercise. Conversely, a muscle that is not used decreases in size, or **atrophies** (at'rō-fēz). The muscular atrophy that occurs in limbs placed in casts for several weeks is an example. Because muscle cell numbers do not change appreciably during most of a person's life, atrophy and hypertrophy of muscles result from changes in the size of individual muscle fibers. As fibers increase in size, the number of myofibrils and sarcomeres increases within each muscle fiber. The number of nuclei in each muscle cell increases in response to exercise, but the nuclei of muscle cells cannot divide. New nuclei are added to muscle fibers because small satellite cells near skeletal muscle cells increase in number in response to exercise and then fuse with the skeletal muscle cells. Other elements, such as blood vessels, connective tissue, and mitochondria, also increase. Atrophy of muscles due to lack of exercise results from a decrease in all of these elements without a decrease in muscle cell number. Severe atrophy, such as occurs in elderly people who cannot readily move their limbs, however, does involve an irreversible decrease in the number of muscle cells and can lead to paralysis.

The increased strength of trained muscle is greater than would be expected if that strength were based only on the change in muscle

Anabolic Steroids and Growth Hormone

Some people take synthetic hormones called **anabolic steroids** (an-ă-bol'ik stēr'oydz, ster'oydz) to increase the size and strength of their muscles. Anabolic steroids are related to testosterone, a reproductive hormone secreted by the testes, except that they have been altered so that the reproductive effects of these compounds are minimized but their effect on skeletal muscles is maintained. Testosterone and anabolic steroids cause skeletal muscle tissue to hypertrophy. People who take large doses of an anabolic steroid exhibit an increase in body weight and total skeletal muscle mass, and many athletes believe that anabolic steroids improve performance that depends on strength. Unfortunately, evidence indicates that harmful side effects are associated with taking anabolic steroids, including periods of irritability, testicular atrophy and sterility, cardiovascular diseases (such as heart attack or stroke), and abnormal liver function. Most athletic organizations prohibit the use of anabolic steroids, and some even analyze urine samples either randomly or periodically for evidence of their use. Penalties exist for athletes who have evidence of anabolic steroid metabolites in their urine.

Some individuals use growth hormone inappropriately to increase muscle size. Growth hormone increases protein synthesis in muscle tissue, although it does not produce the same kinds of side effects as those produced by anabolic steroids. The large doses of growth hormone used by athletes, however, can cause harmful side effects if taken over a long period (see chapter 18).

size. Part of the increase in strength results from the ability of the nervous system to recruit a large number of motor units simultaneously in a trained person to perform movements with better neuromuscular coordination. In addition, trained muscles usually are restricted less by excess fat. Metabolic enzymes increase in hypertrophied muscle fibers, resulting in a greater capacity for nutrient uptake and ATP production. Improved endurance in trained muscles is in part a result of improved metabolism, increased circulation to the exercising muscles, increased numbers of capillaries, more efficient respiration, and a greater capacity for the heart to pump blood.

52 *What factors contribute to an increase in muscle size, strength, and endurance?*

53 *How does anaerobic versus aerobic exercise affect muscles?*

HEAT PRODUCTION

The rate of metabolism in skeletal muscle differs before, during, and after exercise. As chemical reactions occur within cells, some energy is released in the form of heat. Normal body temperature results in large part from this heat. Because the rate of chemical reactions increases in muscle fibers during contraction, the rate of heat production also increases, causing an increase in body temperature. After exercise, elevated metabolism resulting from the oxygen deficit helps keep the body temperature elevated. If the body temperature increases as a result of increased contraction of skeletal muscle, vasodilation of blood vessels in the skin and sweating speed heat loss and keep body temperature within its normal range (see chapter 25).

When body temperature declines below a certain level, the nervous system responds by inducing **shivering**, which involves rapid skeletal muscle contractions that produce shaking rather than coordinated movements. The muscle movement increases heat production up to 18 times that of resting levels, and the heat produced during shivering can exceed that produced during moderate exercise. The elevated heat production during shivering helps raise body temperature to its normal range.

54 *How do muscles contribute to the heat responsible for body temperature before, during, and after exercise? What is accomplished by shivering?*

SMOOTH MUSCLE

Smooth muscle is distributed widely throughout the body and is more variable in function than other muscle types. Smooth muscle cells (figure 9.22) are smaller than skeletal muscle cells, ranging from 15 to 500 μm in length and from 5 to 10 μm in diameter. They are spindle-shaped, with a single nucleus located in the middle of the cell. Compared with skeletal muscle, fewer actin and myosin myofilaments are present, and there are more actin than myosin myofilaments. The actin and myosin myofilaments overlap, but they are organized as loose bundles. Consequently, smooth muscle does not have a striated appearance. Actin myofilaments are attached to **dense bodies**, which are scattered through the cell cytoplasm, and to **dense areas**, which are in the plasma membrane. Dense bodies and dense areas are considered to be equivalent to the Z disks in skeletal muscle. Noncontractile **intermediate filaments** also attach to the

Nuclei of smooth muscle cells

FIGURE 9.22 Smooth Muscle Histology

Smooth muscle tissue is made up of sheets or bundles of spindle-shaped cells, with a single nucleus located in the middle of each cell.

dense bodies. The intermediate filaments and dense bodies form an intracellular cytoskeleton, which has a longitudinal or spiral organization. The smooth muscle cells shorten when the actin and myosin slide over one another during contraction (figure 9.23).

Sarcoplasmic reticulum is present in smooth muscle cells, but no T tubule system exists. Some shallow invaginated areas called **caveolae** (kav-ē-ō'lē) are along the surface of the plasma membrane. The function of caveolae is not well known, but it may be similar to that of both the T tubules and the sarcoplasmic reticulum of skeletal muscle.

Some of the Ca^{2+} required to initiate contractions in smooth muscle enters the cell from the extracellular fluid and from the sarcoplasmic reticulum. The greater distance that Ca^{2+} must diffuse, the rate at which action potentials are propagated between smooth muscle cells, and the slower rate of cross-bridge formation between actin and myosin myofilaments are responsible for the slower contraction of smooth muscle, compared with skeletal muscle.

Calcium ions regulate contraction in smooth muscle cells (figure 9.24). The role of Ca^{2+} in smooth muscle differs from that in skeletal muscle cells because there are no troponin molecules associated with actin fibers of smooth muscle cells. Calcium ions that enter the cytoplasm bind to a protein called **calmodulin** (kal-mod'ū-lin). Calmodulin molecules with Ca^{2+} bound to them activate an enzyme called **myosin kinase** (kī'nās), which transfers a phosphate group

FIGURE 9.23 Contractile Proteins in a Smooth Muscle Cell

Bundles of contractile myofilaments containing actin and myosin are anchored at one end to dense areas in the plasma membrane and at the other end, through dense bodies, to intermediate filament. The contractile myofilaments are oriented with the long axis of the cell; when actin and myosin slide over one another during contraction, the cell shortens.

from ATP to light myosin molecules on the heads of myosin molecules. Cross-bridge formation occurs when myosin myofilaments have phosphate groups bound to them. The enzymes responsible for cross-bridge cycling are slower than the enzymes in skeletal muscle, resulting in slower cross-bridge formation. Once activated, cross-bridge formation has energy requirements very similar to those for cross-bridge formation in skeletal muscle fibers.

Relaxation of smooth muscle results because of the activity of another enzyme, called **myosin phosphatase** (fos'fā-tās). This enzyme removes the phosphate group from the myosin molecules (see figure 9.24). If the phosphate is removed from myosin while the cross-bridges are attached to actin, the cross-bridges release very slowly. This explains how smooth muscle is able to sustain tension for long periods and without extensive energy expenditure. This is often called the **latch state** of smooth muscle contraction. If myosin phosphatase removes the phosphate from myosin molecules while the cross-bridges are not attached, relaxation occurs much more rapidly.

Elevated Ca^{2+} levels in the sarcoplasm of smooth muscle cells result in the activation of myosin molecules and cross-bridge formation. Also, the action of myosin phosphatase results in a high percentage of myosin molecules having their phosphates removed while bound to actin. This process favors sustained contractions, or the latch state, and a low rate of energy consumption because of the slow release of cross-bridges. As long as Ca^{2+} are present, cross-bridges re-form quickly after they are released. Consequently, many cross-bridges are intact at any given time in contracted smooth muscle.

Calcium ion levels in the sarcoplasm of smooth muscle are reduced as Ca^{2+} are actively transported across the plasma membrane, including the plasma membrane of caveolae, and into the sarcoplasmic reticulum. Relaxation occurs in response to lower intracellular levels of Ca^{2+} .

PROCESS FIGURE 9.24 Smooth Muscle Contraction

Types of Smooth Muscle

Smooth muscle can be either visceral or multiunit. **Visceral** (vis'er-äl), or **unitary, smooth muscle** is more common than multiunit smooth muscle. It occurs in sheets and includes smooth muscle of the digestive, reproductive, and urinary tracts. Visceral smooth muscle has numerous gap junctions (see chapter 4), which

allow action potentials to pass directly from one cell to another. As a consequence, sheets of smooth muscle cells function as a unit, and a wave of contraction traverses the entire smooth muscle sheet. Visceral smooth muscle is often autorhythmic, but some contracts only when stimulated. For example, visceral smooth muscles of the digestive tract contract spontaneously and at relatively regular

intervals, whereas the visceral smooth muscle of the urinary bladder contracts when stimulated by the nervous system.

Multiunit smooth muscle occurs as sheets, such as in the walls of blood vessels; as small bundles, such as in the arrector pili muscles and the iris of the eye; and as single cells, such as in the capsule of the spleen. Multiunit smooth muscle has fewer gap junctions than visceral smooth muscle, and cells or groups of cells act as independent units. It normally contracts only when stimulated by nerves or hormones.

Visceral smooth muscle tissue has a different arrangement between neurons and smooth muscle fibers than in skeletal muscle tissue. The synapses are more diffuse than in skeletal muscle. Axons of nerve cells terminate in a series of dilations along the branching axons within the connective tissue among the smooth muscle cells. These dilations have vesicles containing neurotransmitter molecules. Once released, the neurotransmitter molecules diffuse among the smooth muscle cells and bind to receptors on their surfaces. Multiunit smooth muscle has synapses more like those found in skeletal muscle tissue.

55 Describe a typical smooth muscle cell. How does its structure and its contraction process differ from those of a skeletal muscle cell?

56 Compare visceral smooth muscle and multiunit smooth muscle. Explain why visceral smooth muscle contracts as a single unit.

Electrical Properties of Smooth Muscle

The resting membrane potential of smooth muscle cells is usually not as negative as that of skeletal muscle fibers. It normally ranges from -55 to -60 mV, compared with approximately -85 mV in skeletal muscle fibers. Furthermore, the resting membrane potential of some smooth muscle types fluctuates, with slow depolarization and repolarization phases occurring in many visceral smooth muscle cells. These slow waves of depolarization and repolarization are propagated from cell to cell for short distances (figure 9.25a). More “classic” action potentials can be triggered by the slow waves of depolarization and usually are propagated for longer distances (figure 9.25b). In addition, some smooth muscle types have action potentials with a plateau, or prolonged, depolarization (figure 9.25c). The slow waves in the resting membrane potential may result from a spontaneous and progressive increase in the permeability of the plasma membrane to Na^+ and Ca^{2+} , or they may be controlled by neurons. Sodium ions and Ca^{2+} diffuse into the cell through their respective channels and produce the depolarization.

Smooth muscle does not respond in an all-or-none fashion to action potentials. A series of action potentials in smooth muscle can result in a single, slow contraction followed by slow relaxation instead of individual contractions in response to each action potential, as occurs in skeletal muscle. A slow wave of depolarization that has one to several more classic-appearing action potentials superimposed on it is common in many types of smooth muscle. After the wave of depolarization, the smooth muscle undergoes contraction. Action potentials with plateaus are common in smooth muscle that exhibits periods of sustained contraction.

Spontaneously generated action potentials that lead to contractions are characteristic of visceral smooth muscle in the uterus, the ureter, and the digestive tract. Certain smooth muscle cells in

(a) Slow waves of depolarization

(b) Action potentials in smooth muscle superimposed on a slow wave of depolarization

(c) Action potential with prolonged depolarization (plateau)

FIGURE 9.25 Membrane Potential from a Smooth Muscle Preparation

these organs function as **pacemaker cells**, which tend to develop action potentials more rapidly than other cells.

The nervous system can regulate smooth muscle contractions by increasing or decreasing action potentials carried by nerve cell axons to smooth muscle. Responses of smooth muscle cells result in depolarization and increased contraction or hyperpolarization and decreased contraction. The nervous system can also regulate the pacemaker cells.

Hormones and ligands produced locally in tissues can bind to receptors on some smooth muscle plasma membranes. The combination of a hormone or other ligands with a receptor causes ligand-gated Ca^{2+} channels in the plasma membrane to open (see figure 9.24). Calcium ions then enter the cell and cause smooth muscle contractions to occur without a major change in the membrane potential. For example, some smooth muscles contract when exposed to the hormone epinephrine because epinephrine combines with epinephrine receptors. Epinephrine combined with its receptors activates G proteins in the plasma membrane (see figure 9.24). The α subunit of the G complex can produce intracellular mediator molecules, which open the ligand-gated Ca^{2+} channels in the plasma membrane or sarcoplasmic reticulum.

PREDICT 10

Explain how a ligand could bind to a membrane-bound receptor in a smooth muscle cell and cause a sustained contraction of the smooth muscle cell for a prolonged period without a large increase in ATP breakdown.

Functional Properties of Smooth Muscle

Smooth muscle has four functional properties not seen in skeletal muscle: (1) Some visceral smooth muscle exhibits autorhythmic contractions; (2) smooth muscle tends to contract in response to being stretched but a slow increase in length produces less of a response than a more rapid increase in length; (3) smooth muscle exhibits a relatively constant tension, called **smooth muscle tone**, over a long period and maintains that same tension in response to a gradual increase in the smooth muscle length; (4) the amplitude of contraction produced by smooth muscle also remains constant, although the muscle length varies. Smooth muscle is therefore well adapted for lining the walls of hollow organs, such as the stomach and the urinary bladder. As the volume of the stomach or urinary bladder increases, only a small increase develops in the tension applied to its contents. Also, as the volume of the large and small intestines increases, the contractions that move food through them do not change dramatically in amplitude.

Regulation of Smooth Muscle

Nerves that innervate smooth muscle are part of the autonomic division of the nervous system, whereas skeletal muscle is innervated by the somatic motor nervous system (see chapter 11). The regulation of smooth muscle is therefore involuntary, and the regulation of skeletal muscle is voluntary.

The most important neurotransmitters released from nerves that innervate smooth muscle cells are acetylcholine and norepinephrine. Acetylcholine stimulates some smooth muscle types to contract and inhibits others.

Hormones are also important in regulating smooth muscle. Epinephrine, a hormone from the adrenal medulla, stimulates some smooth muscles, such as those in the blood vessels of the intestine, and inhibits other smooth muscles, such as those in the intestinal wall. Oxytocin stimulates contractions of uterine smooth muscle, especially during delivery of a baby. These and other hormones are discussed more thoroughly in chapters 17 and 18. Other

chemical substances produced locally by surrounding tissues—such as histamine, prostaglandins, and by-products of metabolism—also influence smooth muscle function. For example, blood flow through capillaries is dramatically influenced by these substances (see chapter 21).

The type of receptors present on the plasma membrane to which the neurotransmitters or hormones bind determines the response of the smooth muscle. Some smooth muscle types have receptors to which acetylcholine binds, and the receptor's response is to stimulate contractions; other smooth muscle types have receptors to which acetylcholine binds, and the receptor's response is to inhibit contractions. A similar relationship exists for smooth muscle receptors for norepinephrine and certain hormones.

The receptor molecules that result in stimulation of smooth muscle contractions often open either Na^+ or Ca^{2+} channels. When these channels open, Na^+ and Ca^{2+} pass through their respective channels into the cell and cause depolarization of the plasma membrane. It is also possible for the receptor to open Ca^{2+} channels in the plasma membrane and sarcoplasmic reticulum. As a result, Ca^{2+} can diffuse into the cytoplasm of the smooth muscle cells without depolarization of the membrane potential to its threshold level and therefore not produce action potentials.

The receptor molecules that result in the inhibition of smooth muscle contractions often close Na^+ and Ca^{2+} channels or open K^+ channels. The result is hyperpolarization of the smooth muscle cells and inhibition. It is also possible for the receptors to increase the activity of the Ca^{2+} pump that transports Ca^{2+} out of the cell or into the sarcoplasmic reticulum. As a result, relaxation may occur without a change in the resting membrane potential.

The response of specific smooth muscle types to either neurotransmitters or hormones is presented in chapters dealing with the smooth muscle types.

- 58 *List four functional properties of smooth muscle that are not seen in skeletal muscle. Can smooth muscle develop an oxygen deficit?*
- 59 *How do the nervous system and hormones regulate smooth muscle contraction? How are ion channels affected by receptors that stimulate smooth muscle contractions? How are ion channels affected by receptors that inhibit smooth muscle contractions?*

CARDIAC MUSCLE

Cardiac muscle is found only in the heart; it is discussed in detail in chapter 20. Cardiac muscle tissue is striated, like skeletal muscle, but each cell usually contains one nucleus located near the center. Adjacent cells join together to form branching fibers by specialized cell-to-cell attachments called **intercalated disks**, which have gap junctions that allow action potentials to pass from cell to cell. Some cardiac muscle cells are autorhythmic, and one part of the heart normally acts as the pacemaker. The action potentials of cardiac muscle are similar to those of nerve and skeletal muscle but have a much longer duration and refractory period. The depolarization of cardiac muscle results from the

CLINICAL FOCUS

Disorders of Muscle Tissue

Muscle disorders are caused by disruption of normal innervation, degeneration and replacement of muscle cells, injury, lack of use, and disease.

ATROPHY

Muscular atrophy is a decrease in the size of muscles. Individual muscle fibers decrease in size, and a progressive loss of myofibrils occurs.

Disuse atrophy is muscular atrophy that results from a lack of muscle use. Bedridden people, people with limbs in casts, and those who are inactive for other reasons experience disuse atrophy in the unused muscles. Disuse atrophy is temporary if a muscle is exercised after it is taken out of a cast. Extreme disuse of a muscle, however, results in muscular atrophy in which skeletal muscle fibers are permanently lost and replaced by connective tissue. Immobility that occurs in bedridden elderly people can lead to permanent and severe muscular atrophy.

Denervation (dē-ner-vā'shūn) **atrophy** results when nerves that supply skeletal muscles are severed. When motor neurons innervating skeletal muscle fibers are severed, the result is flaccid paralysis. If the muscle is reinnervated,

muscle function is restored, and atrophy is stopped. If skeletal muscle is permanently denervated, however, it atrophies and exhibits its permanent flaccid paralysis. Eventually, muscle fibers are replaced by connective tissue and the condition cannot be reversed.

Transcutaneous stimulators are used to supply electric stimuli to muscles that have had their nerves temporarily damaged or to muscles that are put in casts for a prolonged period. The electric stimuli keep the muscles functioning and prevent them from permanently atrophying while the nerves resupply the muscles or until the cast is removed.

FIBROSIS

Fibrosis (fī-brō'sis), or scarring, is the replacement of damaged cardiac muscle or skeletal muscle by connective tissue. Fibrosis is associated with severe trauma to skeletal muscle and with heart attack (myocardial infarction) in cardiac muscle.

FIBROSITIS

Fibrositis (fī-brō-sī'tis) is an inflammation of fibrous connective tissue, resulting in stiff-

ness, pain, or soreness. It is not progressive, nor does it lead to tissue destruction. Fibrositis can be caused by repeated muscular strain or prolonged muscular tension.

CRAMPS

Cramps are painful, spastic contractions of muscles that usually result from an irritation within a muscle that causes a reflex contraction (see chapter 12). Local inflammation resulting from a buildup of lactic acid and fibrositis causes reflex contraction of muscle fibers surrounding the irritated region.

Fibromyalgia (fī-brō-mī-al'ja), or chronic muscle pain syndrome, has muscle pain as its main symptom. Fibromyalgia has no known cure, but it is not progressive, crippling, or life-threatening. The pain occurs in muscles or where muscles join their tendons, but not in joints. The pain is chronic, widespread, and distinguished from other causes of chronic pain by the identification of tender points in muscles, by the length of time the pain persists, and by failure to identify any other cause of the condition.

influx of both Na^+ and Ca^{2+} across the plasma membrane. The regulation of contraction in cardiac muscle by Ca^{2+} is similar to that of skeletal muscle.

60 *Compare the structural and functional characteristics of cardiac muscle with those of skeletal muscle.*

EFFECTS OF AGING ON SKELETAL MUSCLE

Several changes occur in aging skeletal muscle that reduce muscle mass, increase the time that muscle takes to contract in response to nervous stimuli, reduce stamina, and increase recovery time. There is a loss of muscle fibers as aging occurs, and the loss begins as early as 25 years of age. By 80 years of age, 50% of the muscle mass is gone, and this is due mainly to the loss of muscle fibers. Weight-lifting exercises help slow the loss of muscle mass, but they do not prevent the loss of muscle fibers. In addition, fast-twitch muscle fibers decrease in number more rapidly than slow-twitch fibers. Most of the loss of strength and speed is due

to the loss of fast-twitch muscle fibers. Also, the surface area of the synapse decreases. Consequently, action potentials in neurons stimulate action potential production in muscle cells more slowly, and action potentials may not be produced in muscle cells consistently. The number of motor neurons also decreases. Some of the muscle fibers that lose their innervation when a neuron dies are reinnervated by a branch of another motor neuron. This makes motor units in skeletal muscle fewer in number, with a greater number of muscle fibers for each neuron. This may result in less precise control of muscles. Aging is associated with a decrease in the density of capillaries in skeletal muscles, and after exercise a longer period of time is required to recover.

Many of the age-related changes in skeletal muscle can be dramatically slowed if people remain physically active. As people age, they often assume a sedentary lifestyle. Age-related changes develop more rapidly in these people. It has been demonstrated that elderly people who are sedentary can become stronger and more mobile in response to exercise.

61 *Describe the changes in muscle mass and response time that occur in aging skeletal muscle.*

SYSTEMS PATHOLOGY

Duchenne Muscular Dystrophy

A couple became concerned about their 3-year-old son when they noticed that he was much weaker than other boys his age. The differences appeared to become more pronounced as time passed. Eventually, the boy had difficulty sitting, standing, and walking. He seemed clumsy and fell often. He had difficulty climbing stairs, and he often moved from a sitting position on the floor to a standing position by using his hands and arms to climb up his legs. His muscles appeared to be poorly developed. The couple took their son to a physician and, after several tests, they were informed that he had Duchenne muscular dystrophy.

BACKGROUND INFORMATION

Duchenne muscular dystrophy (DMD) is usually identified in children around 3 years of age when their parents notice slow motor development with progressive weakness and muscle wasting (atrophy). Typically, muscular weakness begins in the hip muscles, which causes a waddling gait. Temporary enlargement of the calf muscles is apparent in 80% of cases. The enlargement is paradoxical because the muscle fibers are actually getting smaller, but there is an increase in fibrous connective tissue and fat between the muscle fibers (figures A and B). Rising from the floor by climbing up the legs is characteristic and is caused by weakness of the lumbar and hip muscles (figure C). Muscles of the shoulder are affected by 6–8 years of age. Wasting of the muscles with replacement by connective tissue results in shortened, inflexible muscles called contractures. The contractures limit movements and can cause severe deformities of the skeleton. People with DMD are usually unable to walk by 10–12 years of age, and few live beyond age 20. No effective treatment exists to prevent the progressive deterioration of muscles in DMD. Therapy primarily involves exercises to help strengthen muscles and prevent contractures. Braces and corrective surgery sometimes help correct abnormal posture caused by the advanced disease. There are other types of muscular dystrophies that are less severe than DMD. Most of these are also inherited conditions, and all are characterized by degeneration of muscle fibers, leading to atrophy and

FIGURE A

Normal appearance of skeletal muscle in cross section. The muscle fibers are of normal size, and a small amount of connective tissue is located between them.

FIGURE B

Skeletal muscle biopsy of a patient with DMD demonstrates muscle fibers of varying sizes, most of them smaller than normal (atrophic). An abundance of fibrous connective tissue and fat fills the spaces previously occupied by muscle tissue.

FIGURE C

DMD is characterized by progressive muscle weakness. Rising from the floor to a standing position becomes difficult and use of the arms to push against the thighs while rising is common.

replacement by connective tissues. Research is directed at identifying the genes responsible for all types of muscular dystrophy, exploring

the mechanism that leads to the disease condition, and finding an effective treatment once the mechanism is known.

Continued

CLINICAL GENETICS

Mutations in the *dystrophin* (dis-trō'-fin; *DMD*) gene on the X chromosome are responsible for Duchenne muscular dystrophy. The dystrophin gene is responsible for producing a protein called **dystrophin**. Dystrophin plays a role in attaching actin myofilaments of myofibrils to, and regulating the activity of, other proteins in the sarcolemma (figure D). Dystrophin is thought to protect muscle fibers against mechanical stress in a normal individual. In DMD, part of the dystrophin gene is missing, and the protein it produces is non-functional, resulting in progressive muscular weakness and muscle contractures. DMD is an X-linked recessive disorder. Thus, although the gene is carried by females, DMD affects males almost exclusively.

FIGURE D

The protein dystrophin links actin myofilaments within myofibrils to integral proteins in the sarcolemma of the muscle fiber and to linking proteins.

PREDICT 11

A boy with advanced Duchenne muscular dystrophy developed pulmonary edema, which is an accumulation of fluid in the lungs, and pneumonia caused by a bacterial infection.

His physician diagnosed the condition in the following way: The pulmonary edema was the result of heart failure and the increased fluid in the lungs acted as a site where bacteria invaded and grew. The fact that the boy could not breathe deeply or cough effectively

made the condition worse. How would the muscle tissues in a boy with advanced DMD with heart failure and ineffective respiratory movements differ from the muscle tissues in a boy with less advanced DMD?

SYSTEM INTERACTIONS	Effect of Duchenne Muscular Dystrophy on Other Systems
SYSTEM	INTERACTION
Skeletal	The shortened, inflexible muscles (contractures) cause severe deformities of the skeletal system. Kyphoscoliosis, severe curvature of the spinal column laterally and anteriorly, can be so severe that normal respiratory movements are impaired. Surgery is sometimes required to prevent contractures from making it impossible for the individual to sit in a wheelchair.
Nervous	Some degree of mental retardation occurs in a large percentage of people with DMD, although the specific cause is unknown. Research suggests that dystrophin is important in the formation of synapses between nerve cells.
Cardiovascular	Cardiac muscle is affected by DMD; consequently, heart failure occurs in a large number of people with advanced DMD. Cardiac involvement becomes serious in as many as 95% of cases and is one of the leading causes of death for individuals with DMD.
Lymphatic and immune	No obvious direct effects occur to the lymphatic system, but damaged muscle fibers are phagocytized by macrophages.
Respiratory	Deformity of the thorax and increasing weakness of the respiratory muscles result in inadequate respiratory movements, which causes an increase in respiratory infections, such as pneumonia. Insufficient movement of air into and out of the lungs due to weak respiratory muscles is a major contributing factor in many deaths.
Digestive	Smooth muscle tissue is affected by DMD and the reduced ability of smooth muscle to contract can result in disorders of the digestive system. Digestive system disorders include an enlarged colon diameter and twisting of the small intestine, resulting in intestinal obstruction, cramping, and reduced absorption of nutrients.
Urinary	Reduced smooth muscle function and wheelchair dependency increase the frequency of urinary tract infections.

SUMMARY

Functions of the Muscular System (p. 279)

Muscle is responsible for movement of the arms, legs, heart, and other parts of the body; maintenance of posture; respiration; production of body heat; communication; contraction of organs and vessels; and heart beat.

General Functional Characteristics of Muscle (p. 279)

Properties of Muscle

1. Muscle exhibits contractility (shortens forcefully), excitability (responds to stimuli), extensibility (can be stretched and still contract), and elasticity (recoils to resting length).
2. Muscle tissue shortens forcefully but lengthens passively.

Types of Muscle Tissue

1. The three types of muscle are skeletal, smooth, and cardiac.
2. Skeletal muscle is responsible for most body movements, smooth muscle is found in the wall of hollow organs and tubes and moves substances through them, and cardiac muscle is found in the heart and pumps blood.

Skeletal Muscle Structure (p. 279)

Skeletal muscle fibers are multinucleated and appear striated.

Connective Tissue Coverings of Muscle

1. The connective tissue of muscle is bound firmly to the connective tissue of tendons and bone.
2. Endomysium surrounds each muscle fiber.
3. Muscle fibers are covered by the external lamina and the endomysium.
4. Muscle fasciculi, bundles of muscle fibers, are covered by the perimysium.
5. Muscle consisting of fasciculi is covered by the epimysium, or muscular fascia.

Nerves and Blood Vessels

1. Motor neurons extend together with arteries and veins through the connective tissue of skeletal muscles.
2. At the level of the perimysium, axons of motor neurons branch and each branch projects to a muscle fiber to form a synapse.

Muscle Fibers

1. A muscle fiber is a single cell consisting of a plasma membrane (sarcolemma), cytoplasm (sarcoplasm), several nuclei, and myofibrils.
2. Myofibrils are composed of two major protein fibers: actin and myosin.
 - Actin myofilaments consist of a double helix of F actin (composed of G actin monomers), tropomyosin, and troponin.
 - Myosin molecules, consisting of two globular heads and a rodlike portion, constitute myosin myofilaments.
 - A cross-bridge is formed when the myosin binds to the actin.
3. Actin and myosin are organized to form sarcomeres.
 - Sarcomeres are bound by Z disks that hold actin myofilaments.
 - Six actin myofilaments (thin filaments) surround a myosin myofilament (thick filament).
 - Myofibrils appear striated because of A bands and I bands.

Sliding Filament Model (p. 285)

1. Actin and myosin myofilaments do not change in length during contraction.
2. Actin and myosin myofilaments slide past one another in a way that causes sarcomeres to shorten.
3. The I band and H zones become narrower during contraction, and the A band remains constant in length.

Physiology of Skeletal Muscle Fibers (p. 285)

Membrane Potentials

Plasma membranes are polarized, which means there is a charge difference, called the resting membrane potential, across the plasma membrane. The membrane becomes polarized because the tendency for K^+ to diffuse out of the cell is resisted by the negative charges of ions and molecules inside the cell.

Ion Channels

1. An action potential is a reversal of the resting membrane potential so that the inside of the plasma membrane becomes positive.
2. Ion channels are responsible for producing action potentials.
3. Two types of membrane channels produce action potentials, ligand-gated and voltage-gated channels.

Action Potentials

1. The charge difference across the plasma membrane of cells is the resting membrane potential.
2. Depolarization results from an increase in the permeability of the plasma membrane to Na^+ .
3. An all-or-none action potential is produced if depolarization reaches threshold.
4. The depolarization phase of the action potential results from many Na^+ channels opening in an all-or-none fashion.
5. The repolarization phase of the action potential occurs when the Na^+ channels close and K^+ channels open briefly.
6. Propagation of action potentials along the plasma membrane of neurons and skeletal muscle fibers occurs in an all-or-none fashion.

Neuromuscular Junction

1. The presynaptic terminal of the axon is separated from the postsynaptic membrane of the muscle fiber by the synaptic cleft.
2. Acetylcholine released from the presynaptic terminal binds to receptors of the postsynaptic membrane, thereby changing membrane permeability and producing an action potential.
3. After an action potential occurs, acetylcholinesterase splits acetylcholine into acetic acid and choline. Choline is reabsorbed into the presynaptic terminal to re-form acetylcholine.

Excitation–Contraction Coupling

1. Invaginations of the sarcolemma form T tubules, which wrap around the sarcomeres.
2. A triad is a T tubule and two terminal cisternae (an enlarged area of sarcoplasmic reticulum).
3. Action potentials move into the T tubule system, causing Ca^{2+} channels to open to release Ca^{2+} from the sarcoplasmic reticulum.
4. Calcium ions diffuse from the sarcoplasmic reticulum to the myofilaments and bind to troponin, causing tropomyosin to move and expose active sites on actin to myosin.

5. Contraction occurs when myosin heads bind to active sites on actin, myosin changes shape, and actin is pulled past the myosin.
6. Relaxation occurs when calcium is taken up by the sarcoplasmic reticulum, ATP binds to myosin, and tropomyosin moves back so that active sites on actin are no longer exposed to myosin.

Cross-Bridge Movement

1. ATP is required for the cycle of cross-bridge formation, movement, and release.
2. ATP is also required to transport Ca^{2+} into the sarcoplasmic reticulum and to maintain normal concentration gradients across the plasma membrane.

Muscle Relaxation

1. Calcium ions are transported into the sarcoplasmic reticulum.
2. Calcium ions diffuse away from troponin, preventing further cross-bridge formation.

Physiology of Skeletal Muscle (p. 295)

Muscle Twitch

1. A muscle twitch is the contraction of a single muscle fiber or a whole muscle in response to a stimulus.
2. A muscle twitch has lag, contraction, and relaxation phases.

Stimulus Strength and Muscle Contraction

1. For a given condition, a muscle fiber or motor unit contracts with a consistent force in response to each action potential, which is called the all-or-none law of skeletal muscle contraction.
2. For a whole muscle, a stimulus of increasing magnitude results in graded contractions of increased force as more motor units are recruited (multiple motor unit summation).

Stimulus Frequency and Muscle Contraction

1. A stimulus of increasing frequency increases the force of contraction (multiple-wave summation).
2. Incomplete tetanus is partial relaxation between contractions, and complete tetanus is no relaxation between contractions.
3. The force of contraction of a whole muscle increases with increased frequency of stimulation because of an increasing concentration of Ca^{2+} around the myofibrils and because of complete stretching of muscle elastic elements.
4. Treppe is an increase in the force of contraction during the first few contractions of a rested muscle.

Types of Muscle Contractions (p. 299)

1. Isometric contractions cause a change in muscle tension but no change in muscle length.
2. Isotonic contractions cause a change in muscle length but no change in muscle tension.
3. Concentric contractions cause muscles to shorten and tension to increase.
4. Eccentric contractions cause muscles to increase in length and the tension to decrease gradually.
5. Muscle tone is maintenance of a steady tension for long periods.
6. Asynchronous contractions of motor units produce smooth, steady muscle contractions.

Length Versus Tension

Muscle contracts with less than maximum force if its initial length is shorter or longer than optimum.

Fatigue (p. 301)

Fatigue, the decreased ability to do work, can be caused by the central nervous system, depletion of ATP in muscles, or depletion of acetylcholine in the neuromuscular synapse. Physiologic contracture (the inability of muscles to contract or relax) and rigor mortis (stiff muscles after death) result from inadequate amounts of ATP.

Energy Sources (p. 303)

Energy for muscle contraction comes from ATP.

Creatine Phosphate

ATP can be synthesized when ADP reacts with creatine phosphate to form creatine and ATP. ATP from this source provides energy for a short time during intense exercise.

Anaerobic Respiration

ATP is synthesized by anaerobic respiration and is used to provide energy for a short time during intense exercise. Anaerobic respiration produces ATP less efficiently but more rapidly than aerobic respiration. Lactic acid levels increase because of anaerobic respiration.

Aerobic Respiration

ATP is synthesized by aerobic respiration. Although ATP is produced more efficiently, it is produced more slowly. Aerobic respiration produces energy for muscle contractions under resting conditions or during exercises such as long-distance running.

Oxygen Deficit and Recovery Oxygen Consumption

After anaerobic respiration, aerobic respiration is higher than normal, as the imbalances of homeostasis that occurred during exercise become rectified.

Slow and Fast Fibers (p. 305)

Slow-Twitch Oxidative Muscle Fibers

Slow-twitch muscle fibers split ATP slowly and have a well-developed blood supply, many mitochondria, and myoglobin.

Fast-Twitch Muscle Fibers

Fast-twitch muscle fibers split ATP rapidly.

1. Type IIa fibers have a well-developed blood supply, more mitochondria, and more myoglobin.
2. Type IIb fibers have large amounts of glycogen, a poor blood supply, fewer mitochondria, and little myoglobin.

Distribution of Fast-Twitch and Slow-Twitch Muscle Fibers

People who are good sprinters have a greater percentage of fast-twitch muscle fibers, and people who are good long-distance runners have a higher percentage of slow-twitch muscle fibers in their leg muscles.

Effects of Exercise

1. Muscles increase (hypertrophy) or decrease (atrophy) in size because of a change in the size of muscle fibers.
2. Anaerobic exercise develops Type IIb fibers. Aerobic exercise develops Type I fibers and changes Type IIb fibers into Type IIa fast-twitch fibers.

Heat Production (p. 307)

1. Heat is produced as a by-product of chemical reactions in muscles.
2. Shivering produces heat to maintain body temperature.

Smooth Muscle (p. 307)

- Smooth muscle cells are spindle-shaped with a single nucleus. They have actin myofilaments and myosin myofilaments but are not striated.
- The sarcoplasmic reticulum is poorly developed, and caveolae may function as a T tubule system.
- Calcium ions enter the cell to initiate contraction; calmodulin binds to Ca^{2+} and activates an enzyme that transfers a phosphate group from ATP to myosin. When phosphate groups are attached to myosin, cross-bridges form.
- Relaxation results when myosin phosphatase removes a phosphate group from the myosin molecule.
 - If phosphate is removed while the cross-bridges are attached, relaxation occurs very slowly, and this is referred to as the catch phase.
 - If phosphate is removed while the cross-bridges are not attached, relaxation occurs rapidly.

Types of Smooth Muscle

- Visceral smooth muscle fibers contract slowly, have gap junctions (and thus function as a single unit), and can be autorhythmic.
- Multiunit smooth muscle fibers contract rapidly in response to stimulation by neurons and function independently.

Electrical Properties of Smooth Muscle

- Spontaneous contractions result from Na^+ and Ca^{2+} leakage into cells; Na^+ and Ca^{2+} movement into the cell is involved in depolarization.
- The autonomic nervous system, hormones, and chemicals produced locally can inhibit or stimulate action potentials (and thus contractions). Hormones can also stimulate or inhibit contractions without affecting membrane potentials.

Functional Properties of Smooth Muscle

- Smooth muscle can contract autorhythmically in response to stretch or when stimulated by the autonomic nervous system or hormones.
- Smooth muscle maintains a steady tension for long periods.
- The force of smooth muscle contraction remains nearly constant, despite changes in muscle length.
- Smooth muscle does not develop an oxygen deficit.

Regulation of Smooth Muscle

- Smooth muscle is innervated by the autonomic nervous system and is involuntary.
- Hormones are important in regulating smooth muscle. Some hormones can increase the Ca^{2+} permeability of some smooth muscle membranes and therefore cause contraction without a change in the resting membrane potential.

Cardiac Muscle (p. 311)

Cardiac muscle fibers are striated, have a single nucleus, are connected by intercalated disks (thus function as a single unit), and are capable of autorhythmicity.

Effects of Aging on Skeletal Muscle (p. 312)

- Aging skeletal muscle is associated with reduced muscle mass, increased response time, and increased time that muscle takes to contract in response to nervous stimuli.
- Muscle fibers decrease in number, motor units decrease in number, and recovery time increases.

REVIEW AND COMPREHENSION

- Which of these is true of skeletal muscle?
 - spindle-shaped cells
 - under involuntary control
 - many peripherally located nuclei per muscle cell
 - forms the walls of hollow internal organs
 - may be autorhythmic
- Which of these is *not* a major functional characteristic of muscle?
 - contractility
 - elasticity
 - excitability
 - extensibility
 - secretability
- The connective tissue sheath that surrounds a muscle fasciculus is the
 - perimysium.
 - endomysium.
 - epimysium.
 - hypomysium.
 - external lamina.
- Given these structures:
 - whole muscle
 - muscle fiber (cell)
 - myofilament
 - myofibril
 - muscle fasciculus

Choose the arrangement that lists the structures in the correct order from the largest to the smallest structure.

 - 1,2,5,3,4
 - 1,2,5,4,3
 - 1,5,2,3,4
 - 1,5,2,4,3
 - 1,5,4,2,3
- Each myofibril
 - is made up of many muscle fibers.
 - contains sarcoplasmic reticulum.
 - is made up of many sarcomeres.
 - contains T tubules.
 - is the same thing as a muscle fiber.
- Myosin myofilaments are
 - attached to the Z disk.
 - found primarily in the I band.
 - thinner than actin myofilaments.
 - absent from the H zone.
 - attached to filaments that form the M line.
- Which of these statements about the molecular structure of myofilaments is true?
 - Tropomyosin has a binding site for Ca^{2+} .
 - The head of the myosin molecule binds to an active site on G actin.
 - ATPase is found on troponin.
 - Troponin binds to the rodlike portion of myosin.
 - Actin molecules have a hingelike portion, which bends and straightens during contraction.
- The part of the sarcolemma that invaginates into the interior of the skeletal muscle cells is the
 - T tubule system.
 - sarcoplasmic reticulum.
 - myofibrils.
 - terminal cisternae.
 - mitochondria.
- During the depolarization phase of an action potential, the permeability of the plasma membrane to
 - Ca^{2+} increases.
 - Na^+ increases.
 - K^+ increases.
 - Ca^{2+} decreases.
 - Na^+ decreases.
- During depolarization, the inside of the membrane
 - becomes more negative than the outside of the membrane.
 - becomes more positive than the outside of the membrane.
 - is unchanged.

11. During repolarization of the plasma membrane,
- Na^+ move to the inside of the cell.
 - Na^+ move to the outside of the cell.
 - K^+ move to the inside of the cell.
 - K^+ move to the outside of the cell.
12. Given these events:
- Acetylcholine is broken down into acetic acid and choline.
 - Acetylcholine diffuses across the synaptic cleft.
 - Action potential reaches the terminal branch of the motor neuron.
 - Acetylcholine combines with a ligand-gated ion channel.
 - Action potential is produced on the muscle fiber's plasma membrane.
- Choose the arrangement that lists the events in the order they occur at a neuromuscular junction.
- 2,3,4,1,5
 - 3,2,4,5,1
 - 3,4,2,1,5
 - 4,5,2,1,3
 - 5,1,2,4,3
13. Acetylcholinesterase is an important molecule in the neuromuscular junction because it
- stimulates receptors on the presynaptic terminal.
 - synthesizes acetylcholine from acetic acid and choline.
 - stimulates receptors within the postsynaptic membrane.
 - breaks down acetylcholine.
 - causes the release of Ca^{2+} from the sarcoplasmic reticulum.
14. Given these events:
- Sarcoplasmic reticulum releases Ca^{2+} .
 - Sarcoplasmic reticulum takes up Ca^{2+} .
 - Calcium ions diffuse into myofibrils.
 - Action potential moves down the T tubule.
 - Sarcomere shortens.
 - Muscle relaxes.
- Choose the arrangement that lists the events in the order they occur following a single stimulation of a skeletal muscle cell.
- 1,3,4,5,2,6
 - 2,3,5,4,6,1
 - 4,1,3,5,2,6
 - 4,2,3,5,1,6
 - 5,1,4,3,2,6
15. Given these events:
- Calcium ions combine with tropomyosin.
 - Calcium ions combine with troponin.
 - Tropomyosin pulls away from actin.
 - Troponin pulls away from actin.
 - Tropomyosin pulls away from myosin.
 - Troponin pulls away from myosin.
 - Myosin binds to actin.
- Choose the arrangement that lists the events in the order they occur during muscle contraction.
- 1,4,7
 - 2,5,6
 - 1,3,7
 - 2,4,7
 - 2,3,7
16. Which of these regions shortens during skeletal muscle contraction?
- A band
 - I band
 - H zone
 - both a and b
 - both b and c
17. With stimuli of increasing strength, which of these is capable of a graded response?
- nerve axon
 - muscle fiber
 - motor unit
 - whole muscle
18. Considering the force of contraction of a skeletal muscle cell, multiple-wave summation occurs because of
- increased strength of action potentials on the plasma membrane.
 - a decreased number of cross-bridges formed.
 - an increase in Ca^{2+} concentration around the myofibrils.
 - an increased number of motor units recruited.
 - increased permeability of the sarcolemma to Ca^{2+} .
19. Which of these events occurs during the lag (latent) phase of muscle contraction?
- cross-bridge movement
 - active transport of Ca^{2+} into the sarcoplasmic reticulum
 - Ca^{2+} binding to troponin
 - sarcomere shortening
 - ATP broken down to ADP
20. A weight lifter attempts to lift a weight from the floor, but the weight is so heavy that he is unable to move it. The type of muscle contraction the weight lifter is using is mostly
- isometric.
 - isotonic.
 - isokinetic.
 - concentric.
 - eccentric.
21. An active tension curve illustrates
- how isometric contractions occur.
 - that the greatest force of contraction occurs if a muscle is not stretched at all.
 - that passive tension can create active tension.
 - that optimal overlap of actin and myosin produces the greatest force of contraction.
 - that the greatest force of contraction occurs with little or no overlap of actin and myosin.
22. Which of these types of fatigue is the most common?
- muscular fatigue
 - psychological fatigue
 - synaptic fatigue
 - army fatigue
23. Given these conditions:
- low ATP levels
 - little or no transport of Ca^{2+} into the sarcoplasmic reticulum
 - release of cross-bridges
 - Na^+ accumulation in the sarcoplasm
 - formation of cross-bridges
- Choose the conditions that occur in both physiologic contracture and rigor mortis.
- 1,2,3
 - 1,2,5
 - 1,2,3,4
 - 1,2,4,5
 - 1,2,3,4,5
24. Jerry Jogger's 3-mile run every morning takes about 30 minutes. Which of these sources provides most of the energy for his run?
- aerobic respiration
 - anaerobic respiration
 - creatine phosphate
 - stored ATP
25. Which of these conditions would one expect to find within the leg muscle cells of a world-class marathon runner?
- myoglobin-poor
 - contract very quickly
 - primarily anaerobic
 - numerous mitochondria
 - large deposits of glycogen
26. Which of these increases the least as a result of muscle hypertrophy?
- number of sarcomeres
 - number of myofibrils
 - number of fibers
 - blood vessels and mitochondria
 - connective tissue
27. Relaxation in smooth muscle occurs when
- myosin kinase attaches phosphate to the myosin head.
 - Ca^{2+} bind to calmodulin.
 - myosin phosphatase removes phosphate from myosin.
 - Ca^{2+} channels open.
 - Ca^{2+} are released from the sarcoplasmic reticulum.

28. Compared with skeletal muscle, visceral smooth muscle
 - a. has the same ability to be stretched.
 - b. when stretched loses the ability to contract forcefully.
 - c. maintains about the same tension, even when stretched.
 - d. cannot maintain long, steady contractions.
 - e. can accumulate a substantial oxygen deficit.
29. Which of these often has spontaneous contractions?
 - a. multiunit smooth muscle
 - b. visceral smooth muscle
 - c. skeletal muscle
 - d. both a and b
 - e. both b and c
30. Which of these statements concerning aging and skeletal muscle is correct?
 - a. There is a loss of muscle fibers with aging.
 - b. Slow-twitch fibers decrease in number faster than fast-twitch fibers.
 - c. Loss of strength and speed is due mainly to loss of neuromuscular junctions.
 - d. There is an increase in density of capillaries in skeletal muscle.
 - e. The number of motor neurons remains constant.

Answers in Appendix E

CRITICAL THINKING

1. Bob Canner improperly canned some homegrown vegetables. As a result, he contracted botulism poisoning after eating the vegetables. His symptoms included difficulty in swallowing and breathing. Eventually, he died of respiratory failure (his respiratory muscles relaxed and would not contract). Assuming that botulism toxin affects the neuromuscular synapse, propose the ways that the toxin produced the observed symptoms.
2. A patient is thought to be suffering from either muscular dystrophy or myasthenia gravis. How would you distinguish between the two conditions?
3. Under certain circumstances, the actin and myosin myofilaments can be extracted from muscle cells and placed in a beaker. They subsequently bind together to form long filaments of actin and myosin. The addition of what cell organelle or molecule to the beaker would make the actin and myosin myofilaments unbind?
4. Explain the effect of a lower than normal temperature on each of the processes that occur in the lag phase of muscle contraction.
5. Design an experiment to test the following hypothesis: Muscle A has the same number of motor units as muscle B. Assume you could stimulate the nerves that innervate skeletal muscles with an electronic stimulator and monitor the tension produced by the muscles.
6. Explain what is happening at the level of individual sarcomeres when an individual is using his or her biceps brachii muscle to hold a weight in a constant position. Contrast this with what is happening at the level of individual sarcomeres when an individual lowers the weight, as well as when the individual raises the weight.
7. Predict the shape of an active tension curve for visceral smooth muscle. How does it differ from the active tension curve for skeletal muscle?
8. A researcher is investigating the composition of muscle tissue in the gastrocnemius muscles (in the calf of the leg) of athletes. A needle biopsy is taken from the muscle, and the concentration (or enzyme activity) of several substances is determined. Describe the major differences this researcher sees when comparing the muscles from athletes who perform in the following events: 100 m dash, weight lifting, and 10,000 m run.
9. Harvey Leche milked cows by hand each morning before school. One morning, he slept later than usual and had to hurry to get to school on time. As he was milking the cows as fast as he could, his hands became very tired, and for a short time he could neither release his grip nor squeeze harder. Explain what happened.
10. Explain how the force produced by smooth muscle contractions in the stomach change between 5 minutes after eating a meal and 1 hour after eating a meal.
11. Shorty McFleet noticed that his rate of respiration was elevated after running a 100 m race but was not as elevated after running slowly for a much longer distance. How would you explain this?
12. High blood K^+ concentrations cause depolarization of the resting membrane potential. Predict the effect of high blood K^+ levels on smooth muscle function. Explain.
13. Predict and explain the response if the ATP concentration in a muscle that was exhibiting rigor mortis could be instantly increased.
14. A hormone stimulates the smooth muscle of a blood vessel to contract. Although the hormone causes a small change in membrane potential, the smooth muscle contracts substantially. Explain.
15. Experiments were performed in an anatomy and physiology laboratory. The rate and depth of respiration for a resting student were determined. In experiment A, students ran in place for 30 seconds and then immediately sat down and relaxed, and respiration rate and depth were again determined. Experiment B was just like experiment A, except that the students held their breath while running in place. What differences in respiration would you expect for the two different experiments? Explain the basis for your predictions.
16. After learning about muscle fiber types in his anatomy and physiology class, Alex started to notice differences in the color of the meat in the turkey he ate for lunch. Some of the meat was very white and some of it was much darker. From the color of the meat, Alex guessed which muscles the bird used for maintenance of posture and/or slow movements such as walking, and which muscles were used for quicker movements, such as running or flying. What type of muscle fiber predominates in white meat and in dark meat? Explain how the color of the meat relates to the function of the muscle.

Muscular System

Gross Anatomy

Mannequins are rigid, expressionless, immobile recreations of the human form. They cannot walk or talk. One of the major characteristics of a living human being is our ability to move about. Without muscles, humans would be little more than mannequins. We would not be able to hold this book. We would not be able to blink, so our eyes would dry out. None of these inconveniences would bother us for long because we would not be able to breathe, either.

We use our skeletal muscles all the time—even when we are not “moving.” Postural muscles are constantly contracting to keep us sitting or standing upright. Respiratory muscles are constantly functioning to keep us breathing, even when we sleep. Communication of any kind requires skeletal muscles, whether we are writing, typing, or speaking. Even silent communication with hand signals or facial expression requires skeletal muscle function.

This chapter explains the *general principles* (p. 321) of the muscular system and describes in detail the *head muscles* (p. 327), *trunk muscles* (p. 340), *upper limb muscles* (p. 346), and *lower limb muscles* (p. 359).

Colorized SEM of skeletal muscle.

Muscular System

GENERAL PRINCIPLES

This chapter is devoted to the description of the major named skeletal muscles. The structure and function of cardiac and smooth muscle are considered in other chapters. Most skeletal muscles extend from one bone to another and cross at least one joint. Muscle contraction causes most body movements by pulling one of the bones toward the other across a movable joint. The **action** of a muscle is the movement accomplished when it contracts. Some muscles are not attached to bone at both ends. For example, some facial muscles attach to the skin, which moves as the muscles contract.

The two points of attachment of each muscle are its origin and insertion. The **origin**, also called the **fixed end** or the **head**, is usually the most stationary, usually proximal end of the muscle. The **insertion**, also called the **mobile end**, is usually the distal end of the muscle attached to the bone undergoing the greatest movement. The part of the muscle between the origin and the insertion is the **belly** (figure 10.1). Some muscles, such as the biceps brachii with two heads and the triceps brachii with three heads, have multiple origins, or heads. At the attachment point, each muscle is connected to bone by **tendons**. Tendons are long, cablelike structures; broad, sheetlike structures called **aponeuroses** (ap'ō-noo-rō'sēz); or short, almost nonexistent structures.

Muscles are typically grouped so that the action of one muscle or group of muscles is opposed by that of another muscle or group of muscles. For example, the biceps brachii flexes the elbow and

the triceps brachii extends the elbow. A muscle that accomplishes a certain movement, such as flexion, is called the **agonist** (ag'ō-nist; a contest). A muscle acting in opposition to an agonist is called an **antagonist** (an-tag'ō-nist). The biceps brachii is the agonist in elbow flexion, whereas the triceps brachii is the antagonist, which extends the elbow.

Muscles also tend to function in groups to accomplish specific movements. For example, the deltoid, biceps brachii, and pectoralis major all help flex the shoulder. Furthermore, many muscles are members of more than one group, depending on the type of movement being considered. For example, the anterior part of the deltoid muscle functions with the flexors of the shoulder, whereas the posterior part functions with the extensors of the shoulder. Members of a group of muscles working together to produce a movement are called **synergists** (sin'er-jistz). For example, the biceps brachii and brachialis are synergists in elbow flexion. Among a group of synergists, if one muscle plays the major role in accomplishing the desired movement, it is the **prime mover**. The brachialis is the prime mover in flexing the elbow. **Fixators** are muscles that hold one bone in place relative to the body while a usually more distal bone is moved. The origin of a prime mover is often stabilized by fixators so that its action occurs at its point of insertion. The muscles of the scapula act as fixators to hold the scapula in place while other muscles contract to move the humerus.

1 Define origin and insertion; agonist and antagonist; and synergist, prime mover, and fixator.

FIGURE 10.1 Muscle Attachment

Muscles are attached to bones by tendons. The biceps brachii has two heads, which originate on the scapula. The triceps brachii has three heads, which originate on the scapula and humerus. The biceps brachii inserts onto the radial tuberosity and onto nearby connective tissue. The triceps brachii inserts onto the olecranon process of the ulna.

Muscle Shapes

Muscles come in a wide variety of shapes. The shape and size of any given muscle greatly influence the degree to which it can contract and the amount of force it can generate. Muscle shapes are grouped into three classes, according to the orientation of the fasciculi: pennate, straight, and orbicular.

Some muscles have their fasciculi (bundles of muscle fibers that can be distinguished by the unaided eye) arranged like the barbs of a feather on two sides of a common tendon and therefore are called **pennate** (pen'at; *pennatus* is Latin, meaning feather), or **bipennate**, muscles. A muscle with all fasciculi on one side of the tendon is **semipennate**, or **unipennate**, and a muscle with fasciculi arranged at many places around the central tendon is **multipennate** (figure 10.2a). The long tendons of pennate muscles can extend for some distance between a muscle belly and its insertion. The pennate arrangement allows a large number of fasciculi to attach to a single tendon with the force of contraction concentrated at the tendon. The muscles that extend the knee are multipennate muscles.

In other muscles, called **straight** muscles, fasciculi are organized parallel to the long axis of the muscle (figure 10.2b). As a consequence, the muscles shorten to a greater degree than do pennate muscles because the fasciculi are in a direct line with the tendon; however, they contract with less force because fewer total fascicles are attached to the tendon. The hyoid muscles are an example of straight muscles.

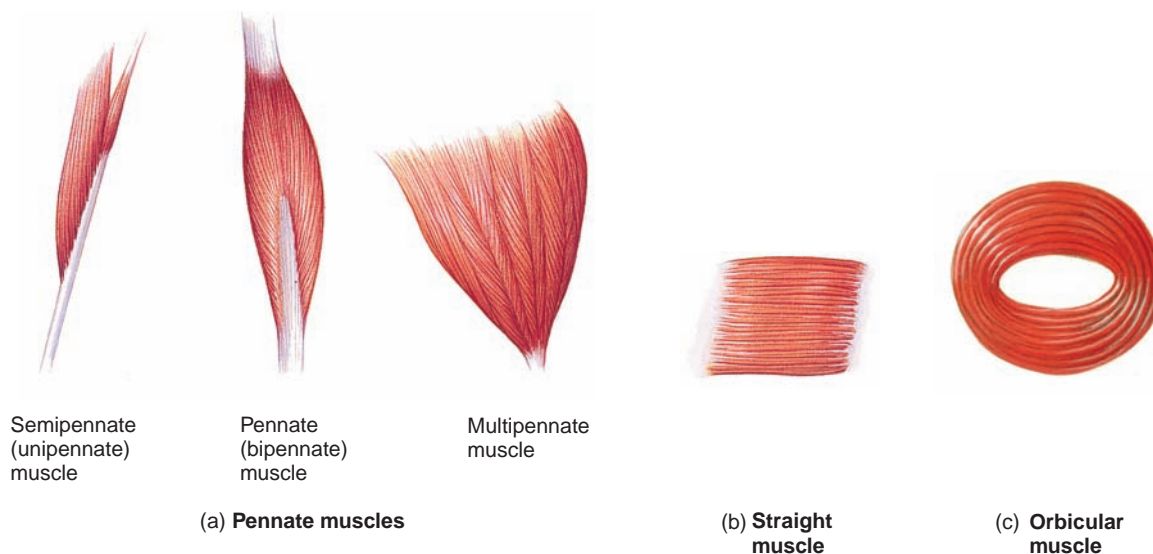

FIGURE 10.2 Examples of Muscle Types

Three classes of muscle shapes based on fasciculi arrangement.

Orbicular, or **circular**, muscles, such as the orbicularis oris and orbicularis oculi (figure 10.2c) have their fasciculi arranged in a circle around an opening and act as sphincters to close the opening.

Muscles can also have specific shapes, such as quadratus, triangular, trapezium, rhomboidal, or fusiform (figure 10.3a). Muscles also can have multiple components, such as two bellies or two heads. A digastric muscle has two bellies separated by a tendon, whereas a bicipital muscle has two origins (heads) and a single insertion (figure 10.3b).

2 Describe the different shapes of muscles. How are the shapes related to the muscle's force of contraction and the range of movement the contraction produces?

Nomenclature

Muscles are named according to their location, size, shape, orientation of fasciculi, origin and insertion, number of heads, and function. Recognizing the descriptive nature of muscle names makes learning those names much easier.

1. **Location.** A pectoralis (chest) muscle is located in the chest, a gluteus (buttock) muscle is located in the buttock, and a brachial (arm) muscle is located in the arm.
2. **Size.** The gluteus maximus (large) is the largest muscle of the buttock, and the gluteus minimus (small) is the smallest. A longus (long) muscle is longer than a brevis (short) muscle.

3. **Shape.** The deltoid (triangular) muscle is triangular, a quadratus (quadratus) muscle is rectangular, and a teres (round) muscle is round.
4. **Orientation of fasciculi.** A rectus (straight) muscle has muscle fasciculi running straight with the axis of the structure to which the muscle is associated, whereas the fasciculi of an oblique muscle lie oblique to the longitudinal axis of the structure.
5. **Origin and insertion.** The sternocleidomastoid originates on the sternum and clavicle and inserts onto the mastoid process of the temporal bone. The brachioradialis originates in the arm (brachium) and inserts onto the radius.
6. **Number of heads.** A biceps muscle has two heads, and a triceps muscle has three heads.
7. **Function.** An abductor moves a structure away from the midline, and an adductor moves a structure toward the midline. The masseter (a chewer) is a chewing muscle.

3 List the criteria used to name muscles, and give an example of each.

Movements Accomplished by Muscles

When muscles contract, the **pull** (P), or force, of muscle contraction is applied to levers, such as bones, resulting in movement of the levers (figure 10.4). A **lever** is a rigid shaft capable of turning about a hinge, or pivot point, called a **fulcrum** (F) and transferring a force applied at one point along the lever to a **weight** (W), or resistance, placed at another point along the lever. The joints

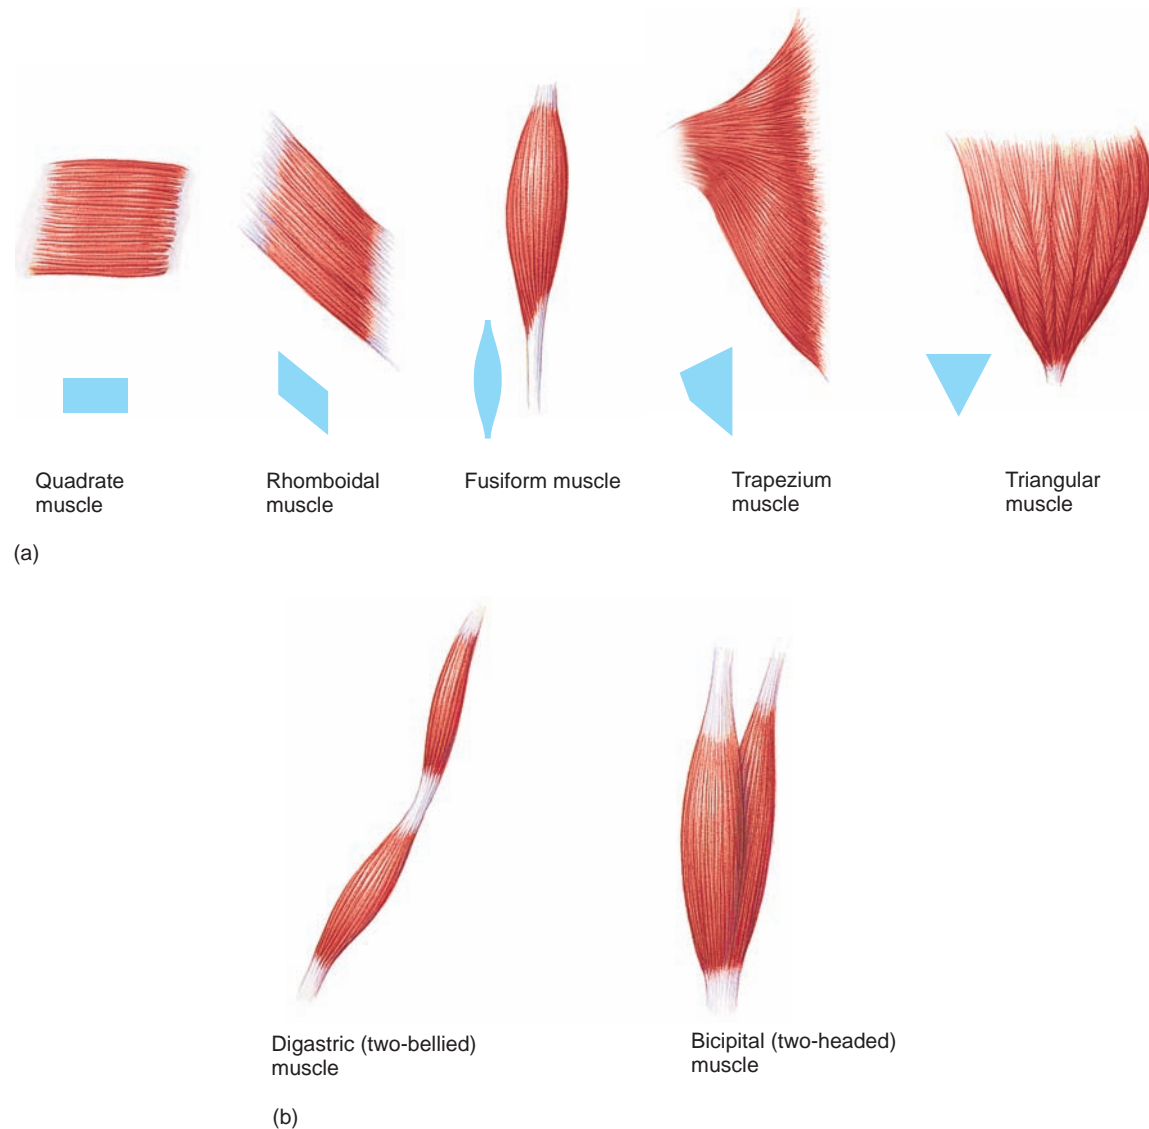

FIGURE 10.3 Examples of Muscle Shapes

(a) Muscles with various shapes: quadratus (four-sided with right angles), rhomboidal (four-sided with no right angles), fusiform (spindle-shaped), trapezium (four-sided with no right angles and no parallel sides), and triangular (three-sided). (b) Muscles with various components: digastric (two bellied) and bicipital (two headed).

function as fulcrums, the bones function as levers, and the muscles provide the pull to move the levers. Three classes of levers exist based on the relative positions of the levers, weights, fulcrums, and forces.

Class I Lever

In a **class I lever system**, the fulcrum is located between the pull and the weight (see figure 10.4a). A child's seesaw is an example of this type of lever. The children on the seesaw alternate between being the weight and the pull across a fulcrum in the center of the

board. The head is an example of this type of lever in the body. The atlanto-occipital joint is the fulcrum, the posterior neck muscles provide the pull depressing the back of the head, and the face, which is elevated, is the weight. With the weight balanced over the fulcrum, only a small amount of pull is required to lift a weight. For example, only a very small shift in weight is needed for one child to lift the other on a seesaw. This system is quite limited, however, as to how much weight can be lifted and how high it can be lifted. For example, consider what happens when the child on one end of the seesaw is much larger than the child on the other end.

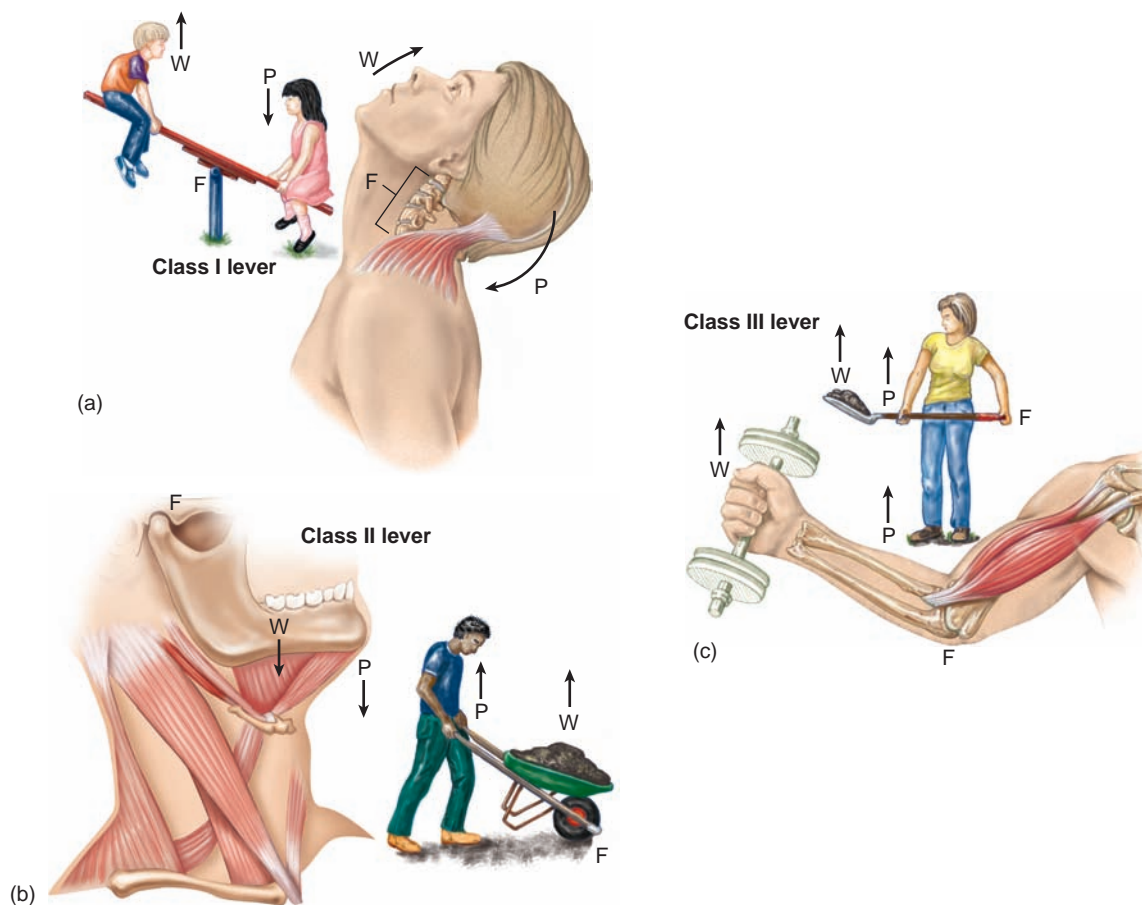

FIGURE 10.4 Lever Classes

(a) **Class I:** The fulcrum (F) is located between the weight (W) and the pull (P), or force. The pull is directed downward, and the weight, on the opposite side of the fulcrum, is lifted. In the example in the body, the fulcrum extends through several cervical vertebrae. (b) **Class II:** The weight (W) is located between the fulcrum (F) and the pull (P), or force. The upward pull lifts the weight. The movement of the mandible is easier to compare to a wheelbarrow if the head is considered upside down. (c) **Class III:** The pull (P), or force, is located between the fulcrum (F) and the weight (W). The upward pull lifts the weight.

Class II Lever

In a **class II lever system**, the weight is located between the fulcrum and the pull (see figure 10.4b). An example is a wheelbarrow; the wheel is the fulcrum and the person lifting on the handles provides the pull. The weight, or load, carried in the wheelbarrow is placed between the wheel and the operator. In the body, an example of a class II lever is depression of the mandible (as in opening the mouth; in this case, the whole system, the wheelbarrow and the person lifting it, is upside down).

Class III Lever

In a **class III lever system**, the most common type in the body, the pull is located between the fulcrum and the weight (see figure 10.4c). An example is a person using a shovel. The hand placed on the part of the handle closest to the blade provides the pull to lift the weight, such as a shovelful of dirt, and

the hand placed near the end of the handle acts as the fulcrum. In the body, the action of the biceps brachii muscle (force) pulling on the radius (lever) to flex the elbow (fulcrum) and elevate the hand (weight) is an example of a class III lever. This type of lever system does not allow as great a weight to be lifted, but the weight can be lifted a greater distance.

4 *Using the terms fulcrum, lever, and force, explain how contraction of a muscle results in movement. Define the three classes of levers, and give an example of each in the body.*

Muscle Anatomy

An overview of the superficial skeletal muscles is presented in figure 10.5. Muscles of the head, neck, trunk, and limbs are described in the following sections.

(a) Anterior view

FIGURE 10.5 General Overview of the Superficial Body Musculature

(b) Posterior view

FIGURE 10.5 (continued)

HEAD MUSCLES

Head and Neck Muscles

The muscles of the neck are listed in table 10.1 and are illustrated in figures 10.6–10.8. The anterior superficial neck muscles are illustrated in figure 10.6. Most of the flexors of the head and neck lie deep within the neck along the anterior margins of the vertebral bodies (not illustrated). Extension of the neck is accomplished by the posterior neck muscles that attach to the occipital bone and mastoid process of the temporal bone (see figures 10.7 and 10.8) and function as the force of a class I lever system. They also rotate and laterally flex the neck.

The muscular ridge seen superficially in the posterior part of the neck and lateral to the midline is composed of the trapezius muscle overlying the splenius capitis (see figures 10.6b

and 10.7b). The fasciculi of the trapezius muscles are shorter at the base of the neck and leave a diamond-shaped area over the inferior cervical and superior thoracic vertebral spines (see figure 10.7b).

Rotation and lateral flexion of the neck are accomplished by muscles of both the lateral and posterior groups (see table 10.1). The **sternocleidomastoid** (ster'nō-klī'dō-mas'toyd) muscle is the prime mover of the lateral group. It is easily seen on the anterior and lateral sides of the neck, especially if the head is extended slightly and rotated to one side (see figure 10.6b). If the sternocleidomastoid muscle on only one side of the neck contracts, the neck is rotated toward the opposite side. If both contract together, they flex the neck. Lateral flexion of the neck (moving the head back to the midline after it has been tilted to one side) is accomplished by the lateral flexors of the opposite side.

TABLE 10.1* Muscles Moving the Head (See Figures 10.6–10.8)

Muscle	Origin	Insertion	Nerve	Action
Anterior				
Longus capitis (lon'gūs ka'pi-tis) (not illustrated)	C3–C6	Occipital bone	C1–C3	Flexes neck
Rectus capitis anterior (rek'tūs ka'pi-tis) (not illustrated)	Atlas	Occipital bone	C1–C2	Flexes neck
Posterior				
Longissimus capitis (lon-gis'ī-mūs kā'pi-tis)	Upper thoracic and lower cervical vertebrae	Mastoid process	Dorsal rami of cervical nerves	Extends, rotates, and laterally flexes neck
Oblique capitis superior (ka'pi-tis)	Atlas	Occipital bone (inferior nuchal line)	Dorsal ramus of C1	Extends and laterally flexes neck
Rectus capitis posterior (rek'tūs ka'pi-tis)	Axis, atlas	Occipital bone	Dorsal ramus of C1	Extends and rotates neck
Semispinalis capitis	C4–T6	Occipital bone	Dorsal rami of cervical nerves	Extends and rotates neck
Splenius capitis	C4–T6	Superior nuchal line and mastoid process	Dorsal rami of cervical nerves	Extends, rotates, and laterally flexes neck
Trapezius	Occipital protuberance, nuchal ligament, spinous processes of C7–T12	Clavicle, acromion process, and scapular spine	Accessory (cranial nerve XI)	Extends and laterally flexes neck
Lateral				
Rectus capitis lateralis (not illustrated)	Atlas	Occipital bone	C1	Laterally flexes neck
Sternocleidomastoid	Manubrium and medial clavicle	Mastoid process and superior nuchal line	Accessory (cranial nerve XI)	One contracting alone: rotates and extends neck Both contracting together: flex neck and elevate face

*The tables in this chapter are to be used as references. As you study the muscular system, first locate the muscle on the figure, and then find its description in the corresponding table.

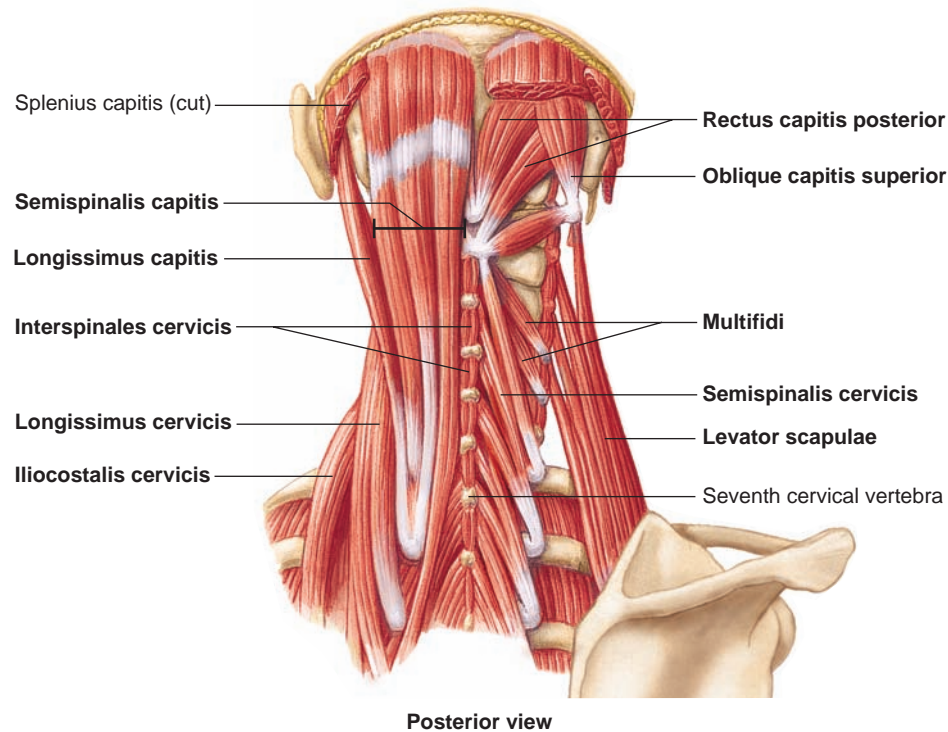

FIGURE 10.8 Posterior Deep Neck Muscles

Torticollis

Torticollis (tōr-ti-kol'is; twisted neck or wry neck) may result from damage to one of the sternocleidomastoid muscles or the accessory nerve (cranial nerve XI) supplying it. Torticollis may also result from a tumor forming in a baby's sternocleidomastoid before birth. Damage to an infant's neck muscles during a difficult birth sometimes causes torticollis and can usually be corrected by exercising the muscle. **Spasmodic torticollis** can occur in adults. It is characterized by intermittent contraction of neck muscles, especially the sternocleidomastoid and trapezius, resulting in rotation, flexion, and extension of the neck and elevation of the shoulder.

PREDICT 1

Shortening of the right sternocleidomastoid muscle rotates the head in which direction?

- 5 Name the major movements of the head caused by contraction of the anterior, posterior, and lateral neck muscles.
- 6 Name the movements of the head and neck caused by contraction of the sternocleidomastoid muscle. What is torticollis (wry neck)?

Facial Expression

The skeletal muscles of the face (table 10.2 and figure 10.9) are cutaneous muscles attached to the skin. Many animals have cutaneous muscles over the trunk that allow the skin to twitch

to remove irritants, such as insects. In humans, facial expressions are important components of nonverbal communication, and the cutaneous muscles are confined primarily to the face and neck.

Several muscles act on the skin around the eyes and eyebrows (figure 10.10; see figure 10.9). The **occipitofrontalis** (ok-sip'i-tō-frūn-tā'lis) raises the eyebrows and furrows the skin of the forehead. The **orbicularis oculi** (ōr-bik'ū-lā'ris ok'ū-lī) closes the eyelids and causes “crow’s-feet” wrinkles in the skin at the lateral corners of the eyes. The **levator palpebrae** (le-vā'ter, lē-vā'tōr pal-pē'brē; the palpebral fissure is the opening between the eyelids) **superioris** raises the upper lids (see figure 10.10a). A droopy eyelid on one side, called **ptosis** (tō'sis), usually indicates that the nerve to the levator palpebrae superioris, or the part of the brain controlling that nerve, has been damaged. The **corrugator supercillii** (kōr'ū-gā'ter, kōr'ū-gā'tōr soo'per-sil'ē-ī) draws the eyebrows inferiorly and medially, producing vertical corrugations (furrows) in the skin between the eyes (see figures 10.9 and 10.10c).

Several muscles function in moving the lips and the skin surrounding the mouth (see figures 10.9 and 10.10). The **orbicularis oris** (ōr-bik'ū-lā'ris ōr'is) and **buccinator** (buk'si-nā-tōr), the kissing muscles, pucker the mouth. Smiling is accomplished by the **zygomaticus** (zī'gō-mat'i-kūs) **major** and **minor**, the **levator anguli oris**, and the **risorius** (rī-sōr'ē-ūs). Sneering is accomplished by the **levator labii superioris** and frowning or pouting by the **depressor anguli oris**, the **depressor labii inferioris**, and the **mentalis** (men-tā'lis). If the mentalis muscles are well developed on each side of the chin, a chin dimple, where

TABLE 10.2 Muscles of Facial Expression (See Figure 10.9)

Muscle	Origin	Insertion	Nerve	Action
Auricularis (aw-rik'ū-lār'is)				
Anterior	Aponeurosis over head	Cartilage of auricle	Facial	Draws auricle superiorly and anteriorly
Posterior	Mastoid process	Posterior root of auricle	Facial	Draws auricle posteriorly
Superior	Aponeurosis over head	Cartilage of auricle	Facial	Draws auricle superiorly and posteriorly
Buccinator (buk'sī-nā'tōr)	Mandible and maxilla	Orbicularis oris at angle of mouth	Facial	Retracts angle of mouth; flattens cheek
Corrugator supercillii (kōr'ū'gā'ter, soo'per-sil'ē-ī)	Nasal bridge and orbicularis oculi	Skin of eyebrow	Facial	Depresses medial portion of eyebrow; draws eyebrows together, as in frowning
Depressor anguli oris (dē-pres'ōr ang'gū-lī ōr'ūs)	Lower border of mandible	Skin of lip near angle of mouth	Facial	Depresses angle of mouth
Depressor labii inferioris (dē-pres'ōr lā'bē-ī in-fēr'ē-ōr-is)	Lower border of mandible	Skin of lower lip and orbicularis oris	Facial	Depresses lower lip
Levator anguli oris (lē-vā'tor, le-vā'ter ang'gū-lī ōr'ūs)	Maxilla	Skin at angle of mouth and orbicularis oris	Facial	Elevates angle of mouth
Levator labii superioris (lē-vā'tor, le-vā'ter lā'bē-ī sū-pēr'ē-ōr-is)	Maxilla	Skin and orbicularis oris of upper lip	Facial	Elevates upper lip
Levator labii superioris alaeque nasi (lē-vā'tor, le-vā'ter lā'bē-ī sū-pēr'ē-ōr-is ā-lak'ā nā'zī)	Maxilla	Ala at nose and upper lip	Facial	Elevates ala of nose and upper lip
Levator palpebrae superioris (lē-vā'tor, le-vā'ter pal-pēr'brē sū-pēr'ē-ōr-is)	Lesser wing of sphenoid	Skin of eyelid	Oculomotor	Elevates upper eyelid
Mentalis (men-tā'lis)	Mandible	Skin of chin	Facial	Elevates and wrinkles skin over chin; protrudes lower lip
Nasalis (nā'zā-lis)	Maxilla	Bridge and ala of nose	Facial	Dilates nostril
Occipitofrontalis (ok-sip'i-tō-frūn'tā'lis)	Occipital bone	Skin of eyebrow and nose	Facial	Moves scalp; elevates eyebrows
Orbicularis oculi (ōr-bik'ū-lā'ris ok'ū-lī)	Maxilla and frontal bones	Circles orbit and inserts near origin	Facial	Closes eye
Orbicularis oris (ōr-bik'ū-lā'ris ōr'is)	Nasal septum, maxilla, and mandible	Fascia and other muscles of lips	Facial	Closes lip
Platysma (plā-tiz'mā)	Fascia of deltoid and pectoralis major	Skin over inferior border of mandible	Facial	Depresses lower lip; wrinkles skin of neck and upper chest
Procerus (prō-sēr'ūs)	Bridge of nose	Frontalis	Facial	Creates horizontal wrinkles between eyes, as in frowning
Risorius (ri-sōr'ē-ūs)	Platysma and masseter fascia	Orbicularis oris and skin at corner of mouth	Facial	Abducts angle of mouth
Zygomaticus major (zī'gō-mat'i-kūs)	Zygomatic bone	Angle of mouth	Facial	Elevates and abducts upper lip
Zygomaticus minor (zī'gō-mat'i-kūs)	Zygomatic bone	Orbicularis oris of upper lip	Facial	Elevates and abducts upper lip

FIGURE 10.9 Muscles of Facial Expression

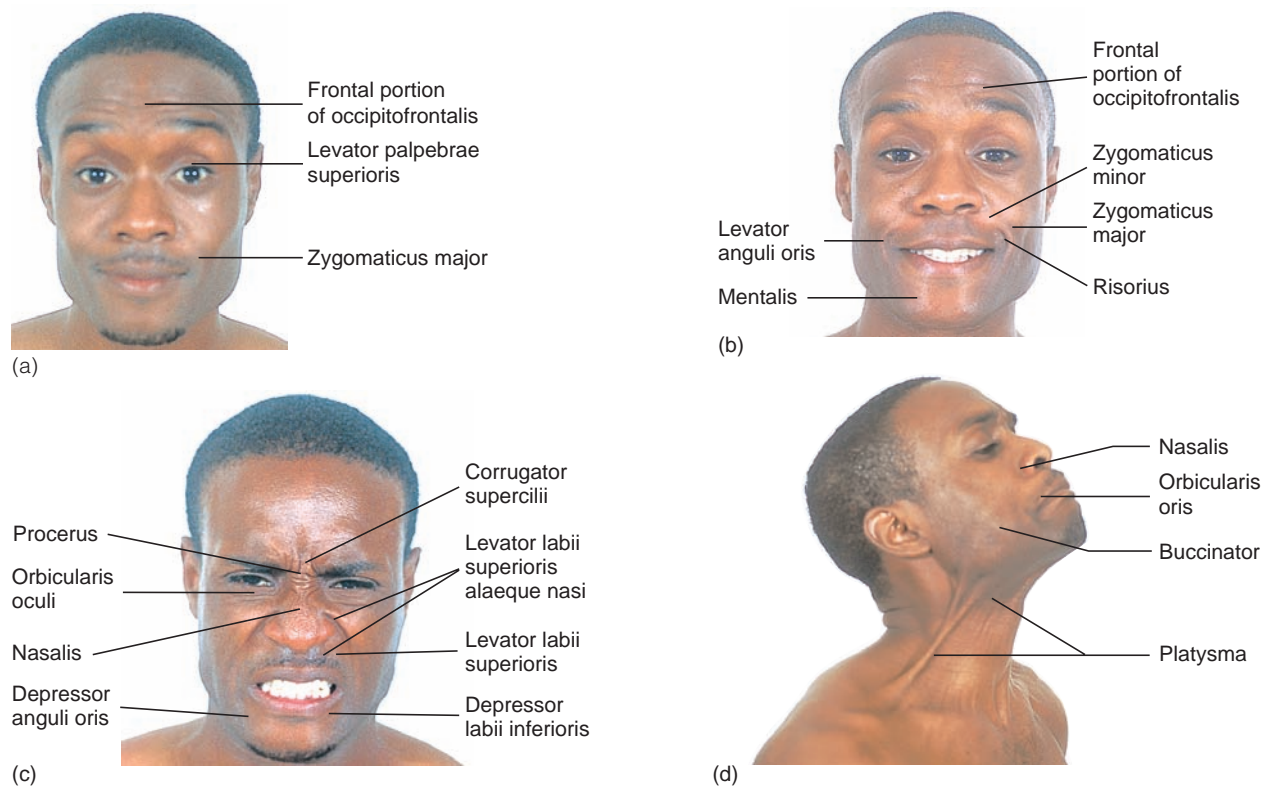

FIGURE 10.10 Surface Anatomy, Muscles of Facial Expression

the skin is tightly attached to the underlying bone or other connective tissue, may appear between the two muscles.

- 7** *What is unusual about the insertion (and sometimes the origin) of facial muscles?*
- 8** *Which muscles are responsible for moving the ears, the eyebrows, the eyelids, and the nose? For puckering the lips, smiling, sneering, and frowning? What causes a dimple on the chin? What usually causes ptosis on one side?*

PREDICT 2

Harry Wolf, a notorious flirt, on seeing Sally Gorgeous, raises his eyebrows, winks, whistles, and smiles. Name the facial muscles he uses to carry out this communication. Sally, thoroughly displeased with this exhibition, frowns and flares her nostrils in disgust. What muscles does she use?

Mastication

Chewing, or **mastication** (mas-ti-kā'shŭn), involves forcefully closing the mouth (elevating the mandible: temporalis, masseter, and medial pterygoid) and grinding food between the teeth (medial and lateral excursion of the mandible; involving all muscles of mastication). The **muscles of mastication** and the **hyoid muscles**

move the mandible (tables 10.3 and 10.4; figures 10.11 and 10.12). The elevators of the mandible are some of the strongest muscles of the body and bring the mandibular teeth forcefully against the maxillary teeth to crush food. Slight mandibular depression involves relaxation of the mandibular elevators and the pull of gravity. Opening the mouth wide requires the action of the depressors of the mandible (lateral pterygoid, digastric, geniohyoid, mylohyoid); even though the muscles of the tongue and the buccinator (see table 10.2; table 10.5) are not involved in chewing, they help move the food in the mouth and hold it in place between the teeth.

- 9** *Name the muscles responsible for opening and closing the jaw and for lateral and medial excursion of the jaw.*

Tongue Movements

The tongue is very important in mastication and speech: (1) It moves food around in the mouth; (2) with the buccinator, it holds food in place while the teeth grind it; (3) it pushes food up to the palate and back toward the pharynx to initiate swallowing; and (4) it changes shape to modify sound during speech. The tongue consists of a mass of **intrinsic muscles** (entirely within the tongue), which are involved in changing the shape of the tongue, and **extrinsic muscles** (outside of the tongue but attached to it), which help change the shape and move the tongue

TABLE 10.3 Muscles of Mastication (See Figures 10.9 and 10.11)

Muscle	Origin	Insertion	Nerve	Action
Temporalis (tem-pō-rā'lis)	Temporal fossa	Anterior portion of mandibular ramus and coronoid process	Mandibular division of trigeminal	Elevates and retracts mandible; involved in excursion
Masseter (ma'se-ter)	Zygomatic arch	Lateral side of mandibular ramus	Mandibular division of trigeminal	Elevates and protracts mandible; involved in excursion
Pterygoids (ter'i-goydz)				
Lateral	Lateral side of lateral pterygoid plate and greater wing of sphenoid	Condylar process of mandible and articular disk	Mandibular division of trigeminal	Protracts and depresses mandible; involved in excursion
Medial	Medial side of lateral pterygoid plate and tuberosity of maxilla	Medial surface of mandible	Mandibular division of trigeminal	Protracts and elevates mandible; involved in excursion

TABLE 10.4 Hyoid Muscles (See Figure 10.12)

Muscle	Origin	Insertion	Nerve	Action
Suprahyoid Muscles				
Digastric (dī-gas'trik)	Mastoid process (posterior belly)	Mandible near midline (anterior belly)	Posterior belly—facial; anterior belly—mandibular division of trigeminal	Depresses and retracts mandible; elevates hyoid
Geniohyoid (jē-nī-ō-hī'oyd)	Genu of mandible	Body of hyoid	Fibers of C1 and C2 with hypoglossal	Protracts hyoid; depresses mandible
Mylohyoid (mī-lō-hī'oyd)	Body of mandible	Hyoid	Mandibular division of trigeminal	Elevates floor of mouth and tongue; depresses mandible when hyoid is fixed
Stylohyoid (stī-lō-hī'oyd)	Styloid process	Hyoid	Facial	Elevates hyoid
Infrahyoid Muscles				
Omoxyoid (ō-mō-hī'oyd)	Superior border of scapula	Hyoid	Upper cervical through ansa cervicalis	Depresses hyoid; fixes hyoid in mandibular depression
Sternohyoid (ster'nō-hī'oyd)	Manubrium and first costal cartilage	Hyoid	Upper cervical through ansa cervicalis	Depresses hyoid; fixes hyoid in mandibular depression
Sternothyroid (ster'nō-thī'royd)	Manubrium and first or second costal cartilage	Thyroid cartilage	Upper cervical through ansa cervicalis	Depresses larynx; fixes hyoid in mandibular depression
Thyrohyoid (thī-rō-hī'oyd)	Thyroid cartilage	Hyoid	Upper cervical, passing with hypoglossal	Depresses hyoid and elevates thyroid cartilage of larynx; fixes hyoid in mandibular depression

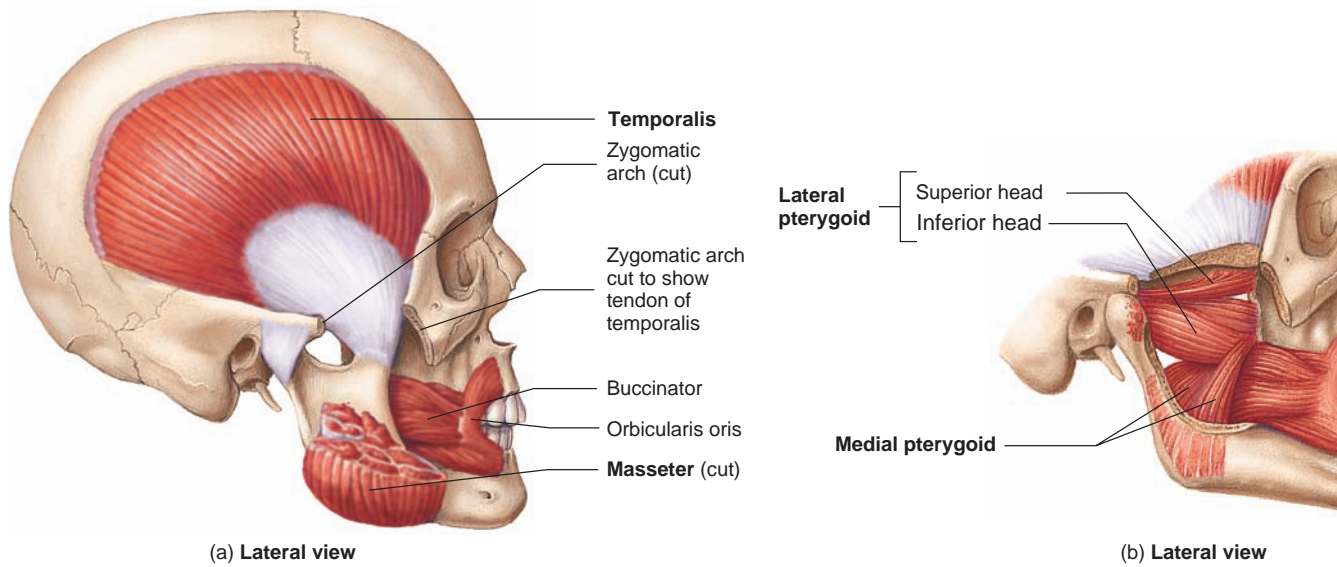

FIGURE 10.11 Muscles of Mastication

(a) Masseter and zygomatic arch are cut away to expose the temporalis. (b) Masseter and temporalis muscles are removed, and the zygomatic arch and part of the mandible are cut away to reveal the deeper muscles. (c) Frontal section of the head, showing the pterygoid muscles.

(c) Anterolateral view

FIGURE 10.12 (continued)

TABLE 10.5 Tongue Muscles

Muscle	Origin	Insertion	Nerve	Action
Intrinsic Muscles				
Longitudinal, transverse, and vertical (not illustrated)	Within tongue	Within tongue	Hypoglossal	Change tongue shape
Extrinsic Muscles				
Genioglossus (jĕ'nĭ-ō-glos'ūs)	Genu of mandible	Tongue	Hypoglossal	Depresses and protrudes tongue
Hyoglossus (hĭ'ō-glos'ūs)	Hyoid	Side of tongue	Hypoglossal	Retracts and depresses side of tongue
Styloglossus (stĭ'lō-glos'ūs)	Styloid process of temporal bone	Tongue (lateral and inferior)	Hypoglossal	Retracts tongue
Palatoglossus (pal-ă-tō-glos'ūs)	Soft palate	Tongue	Pharyngeal plexus	Elevates posterior tongue

(see table 10.5; figure 10.13). The intrinsic muscles are named for their fiber orientation in the tongue. The extrinsic muscles are named for their origin and insertion.

Tongue Rolling

Everyone can change the shape of the tongue, but not everyone can roll the tongue into the shape of a tube. This ability apparently is partially controlled genetically, but other factors are involved. In some cases, one of a pair of identical twins can roll the tongue but the other twin cannot. It is not known exactly what tongue muscles are involved in **tongue rolling**, and no anatomical differences are reported between tongue rollers and nonrollers.

10 Contrast the movements produced by the extrinsic and intrinsic tongue muscles.

Swallowing and the Larynx

The hyoid muscles (see table 10.4 and figures 10.12 and 10.13) are divided into a **suprahyoid group** superior to the hyoid bone and an **infrahyoid group** inferior to it. When the hyoid bone is fixed by the infrahyoid muscles so that the bone is stabilized from below, the suprahyoid muscles can help depress the mandible. If the suprahyoid muscles fix the hyoid and thus stabilize it from above, the thyrohyoid muscle (an infrahyoid muscle) can elevate the larynx. To observe this effect, place your hand on your larynx (Adam's apple) and swallow.

The soft palate, pharynx, and larynx contain several muscles involved in swallowing and speech (table 10.6 and figure 10.14). The muscles of the soft palate close the posterior opening to the nasal cavity during swallowing.

FIGURE 10.13 Tongue Muscles

As seen from the right side.

TABLE 10.6 Muscles of Swallowing and the Larynx (See Figure 10.14)

Muscle	Origin	Insertion	Nerve	Action
Larynx				
Arytenoids (ar-i-tē'noydz)				
Oblique (not illustrated)	Arytenoid cartilage	Opposite arytenoid cartilage	Recurrent laryngeal	Narrows opening to larynx
Transverse (not illustrated)	Arytenoid cartilage	Opposite arytenoid cartilage	Recurrent laryngeal	Narrows opening to larynx
Cricoarytenoids (krī'kō-ar-i-tē'noydz)				
Lateral (not illustrated)	Lateral side of cricoid cartilage	Arytenoid cartilage	Recurrent laryngeal	Narrows opening to larynx
Posterior (not illustrated)	Posterior side of cricoid cartilage	Arytenoid cartilage	Recurrent laryngeal	Widens opening of larynx
Cricothyroid (krī-kō-thī'royd)	Anterior cricoid cartilage	Thyroid cartilage	Superior laryngeal	Lengthens (tenses) vocal cords
Thyroarytenoid (thī'rō-ar'i-tē'noyd) (not illustrated)	Thyroid cartilage	Arytenoid cartilage	Recurrent laryngeal	Shortens (relaxes) vocal cords
Vocalis (vō-kal'is) (not illustrated)	Thyroid cartilage	Arytenoid cartilage	Recurrent laryngeal	Shortens (relaxes) vocal cords
Soft Palate				
Levator veli palatini (lē-vā'tor, le-vā'ter vel'ī pal'ā-tē'nī)	Temporal bone and pharyngotympanic	Soft palate	Pharyngeal plexus	Elevates soft palate
Palatoglossus (pal-ā-tō-glos'ūs)	Soft palate	Tongue	Pharyngeal plexus	Narrows fauces; elevates posterior tongue
Palatopharyngeus (pal'ā-tō-far-in-jē'ūs)	Soft palate	Pharynx	Pharyngeal plexus	Narrows fauces; depresses palate; elevates pharynx
Tensor veli palatini (ten'sōr vel'ī pal'ā-tē'nī)	Sphenoid and auditory tube	Soft palate division of auditory tube	Mandibular, division of trigeminal	Tenses soft palate; opens auditory tube
Uvulae (ū'vū-lē)	Posterior nasal spine	Uvula	Pharyngeal plexus	Elevates uvula
Pharynx				
Pharyngeal constrictors (fā-rin'jē-āl)				
Inferior	Thyroid and cricoid cartilages	Pharyngeal raphe	Pharyngeal plexus and external laryngeal nerve	Narrows inferior portion of pharynx in swallowing
Middle	Stylohyoid ligament and hyoid	Pharyngeal raphe	Pharyngeal plexus	Narrows pharynx in swallowing
Superior	Medial pterygoid plate, mandible, floor of mouth, and side of tongue	Pharyngeal raphe	Pharyngeal plexus	Narrows superior portion of pharynx in swallowing
Salpingopharyngeus (sal-ping'gō-far-in-jē'ūs)	Auditory tube	Pharynx	Pharyngeal plexus	Elevates pharynx; opens auditory tube in swallowing
Stylopharyngeus (stī'lō-far-in-jē'ūs)	Styloid process	Pharynx	Glossopharyngeus	Elevates pharynx

FIGURE 10.14 Muscles of the Palate, Pharynx, and Larynx

(a) Anterior-inferior view of the palate. Palatoglossus and part of the palatopharyngeus muscles are cut on one side to reveal the deeper muscles. (b) Lateral view of the palate, pharynx, and larynx. Part of the mandible is removed to reveal the deeper structures.

Swallowing (see chapter 24) is accomplished by elevation of the pharynx, which in turn is accomplished by elevation of the larynx, to which the pharynx is attached, and constriction of the **palatopharyngeus** (pal'ă-tō-far-in-jē'ūs) and **salpingopharyngeus** (sal-pin'gō-far-in-jē'ūs; *salpingo* means trumpet and refers to the trumpet-shaped opening of the pharyngotympanic, or auditory, tube). The pharyngeal constrictor muscles then constrict from superior to inferior, forcing food into the esophagus.

The salpingopharyngeus also opens the pharyngotympanic tube, which connects the middle ear with the pharynx. Opening the pharyngotympanic tube equalizes the pressure between the middle ear and the atmosphere; this is why it is sometimes helpful to chew gum or swallow when ascending or descending a mountain in a car or when changing altitudes in an airplane.

The muscles of the larynx are listed in table 10.6 and are illustrated in figure 10.14b. Most of the laryngeal muscles help narrow or close the laryngeal opening so food does not enter the larynx when a person swallows. The remaining muscles shorten (relax)

the vocal cords to lower the pitch of the voice or lengthen (tense) the vocal cords to raise the pitch of the voice.

Snoring and Laryngospasm

Snoring is a rough, raspy noise that can occur when a sleeping person inhales through the mouth and nose. The noise usually is made by vibration of the soft palate but also may occur as a result of vocal cord vibration.

Laryngospasm is a tetanic contraction of the muscles that narrows the opening of the larynx (arytenoids, lateral cricoarytenoids). In severe cases, the opening is closed completely, air can no longer pass through the larynx into the lungs, and the victim may die of asphyxiation. Laryngospasm can develop as a result of severe allergic reactions, tetanus infections, or hypocalcemia.

Movements of the Eyeball

The eyeball rotates within the orbit to allow vision in a wide range of directions. The movements of each eye are accomplished by six

TABLE 10.7 Muscles Moving the Eye (See Figure 10.15)

Muscle	Origin	Insertion	Nerve	Action
Oblique				
Inferior	Orbital plate of maxilla	Sclera of eye	Oculomotor	Elevates and laterally deviates gaze
Superior	Common tendinous ring	Sclera of eye	Trochlear	Depresses and laterally deviates gaze
Rectus				
Inferior	Common tendinous ring	Sclera of eye	Oculomotor	Depresses and medially deviates gaze
Lateral	Common tendinous ring	Sclera of eye	Abducent	Laterally deviates gaze
Medial	Common tendinous ring	Sclera of eye	Oculomotor	Medially deviates gaze
Superior	Common tendinous ring	Sclera of eye	Oculomotor	Elevates and medially deviates gaze

muscles named for the orientation of their fasciculi relative to the spherical eye (table 10.7; figure 10.15).

Each rectus muscle (so-named because the fibers are nearly straight with the axis of the eye) attaches to the eyeball anterior to the center of the sphere. The superior rectus rotates the anterior portion of the eyeball superiorly so that the pupil, and thus the gaze, is directed superiorly (looking up). The inferior rectus depresses the gaze, the lateral rectus laterally deviates (abducts) the gaze (looking

to the side), and the medial rectus medially deviates (adducts) the gaze (looking toward the nose). The superior rectus and inferior rectus are not completely straight in their orientation to the eye; thus, they also medially deviate the gaze as they contract.

The oblique muscles (so-named because their fibers are oriented obliquely to the axis of the eye) insert onto the posterolateral margin of the eyeball so that both muscles laterally deviate the gaze as they contract (see chapter 15, figure 15.10). The superior oblique

FIGURE 10.15 Muscles Moving the Right Eyeball

elevates the posterior part of the eye, thus directing the pupil inferiorly and depressing the gaze. The inferior oblique elevates the gaze.

11 Explain the interaction of the suprahyoid and infrahyoid muscles to depress the mandible and to elevate the larynx.

12 Which muscles open and close the openings to the auditory tube and larynx?

13 Describe the muscles of the eye and the movements they cause.

PREDICT 3

Strabismus (stra-biz'mūs) is a condition in which one or both eyes deviate in a medial or lateral direction. In some cases, the condition is caused by a weakness in either the medial or the lateral rectus muscle. If the lateral rectus of the right eye is weak, in which direction does the eye deviate?

TRUNK MUSCLES

Muscles Moving the Vertebral Column

The muscles that extend, laterally flex, and rotate the vertebral column are divided into superficial and deep groups (table 10.8). In general, the muscles of the deep group extend from vertebra to vertebra, whereas the muscles of the superficial group extend from the vertebrae to the ribs. In humans, these back muscles are very strong to maintain erect posture. Comparable muscles in cattle are relatively delicate, although quite large. The **erector spinae** (spī'nē) group of muscles on each side of the back consists of three subgroups: the **iliocostalis** (il'ē-ō-kos-tā'lis), the **longissimus** (lon-gis'i-mūs), and the **spinalis** (sp-ī-nā'lis). The longissimus group accounts for most of the muscle mass in the lower back (figure 10.16). The deepest

TABLE 10.8 Muscles Acting on the Vertebral Column (See Figures 10.7, 10.8, 10.16, and 10.17)

Muscle	Origin	Insertion	Nerve	Action
Superficial				
Erector spinae (ē-rek'tōr, ē-rek'tōr spī'nē; divides into three columns)				
Iliocostalis (il'ē-ō-kos-tā'lis)	Sacrum, ilium, and lumbar spines	Ribs and vertebrae	Dorsal rami of spinal nerves	Extends vertebral column
Cervicis (ser-vī'sis)	Superior six ribs	Transverse processes of middle cervical vertebrae	Dorsal rami of thoracic nerves	Extends, laterally flexes, and rotates vertebral column
Thoracis (thō-ra'sis)	Inferior six ribs	Superior six ribs	Dorsal rami of thoracic nerves	Extends, laterally flexes, and rotates vertebral column
Lumborum (lum-bōr'ūm)	Sacrum, ilium, and lumbar vertebrae	Inferior six ribs	Dorsal rami of thoracic and lumbar nerves	Extends, laterally flexes, and rotates vertebral column
Longissimus (lon-gis'i-mūs)				
Capitis (ka'pī-tis)	Upper thoracic and lower cervical vertebrae	Mastoid process	Dorsal rami of cervical nerves	Extends head
Cervicis (ser-vī'sis)	Upper thoracic vertebrae	Transverse processes of upper cervical vertebrae	Dorsal rami of cervical nerves	Extends neck
Thoracis (thō-ra'sis)	Ribs and lower thoracic vertebrae	Transverse processes of upper lumbar vertebrae and ribs	Dorsal rami of thoracic and lumbar nerves	Extends vertebral column
Spinalis (spī-nā'lis)				
Cervicis (ser-vī'sis) (not illustrated)	C6–C7	Spinous processes of C2–C3	Dorsal rami of cervical nerves	Extends neck
Thoracis (thō-ra'sis)	T11–L2	Spinous processes of middle and upper thoracic vertebrae	Dorsal rami of thoracic nerves	Extends vertebral column
Semispinalis (sem'ē-spī-nā'lis)				
Cervicis (ser-vī'sis)	Transverse processes of T2–T5	Spinous processes of C2–C5	Dorsal rami of cervical nerves	Extends neck
Thoracis (thō-ra'sis)	Transverse processes of T5–T11	Spinous processes of C5–T4	Dorsal rami of thoracic nerves	Extends vertebral column
Splenius cervicis (splē'nē-ūs ser-vī'sis)	Spinous processes of C3–C5	Transverse processes of C1–C3	Dorsal rami of cervical nerves	Rotates and extends neck
Longus colli (lon'gūs kō'li) (not illustrated)	Bodies of C3–T3	Bodies of C1–C6	Ventral rami of cervical nerves	Flexes neck

TABLE 10.8 Muscles Acting on the Vertebral Column—Continued

Muscle	Origin	Insertion	Nerve	Action
Deep				
Interspinales (in-ter-spī-nā'lēz)	Spinous processes of all vertebrae	Next superior spinous process	Dorsal rami of spinal nerves	Extends back and neck
Intertransversarii (in-ter-trans'ver-sār'ē-ī)	Transverse processes of all vertebrae	Next superior transverse process	Dorsal rami of spinal nerves	Laterally flexes vertebral column
Multifidus (mūl-tif'i-dūs)	Transverse processes of vertebrae; posterior surface of sacrum and ilium	Spinous processes of superior vertebrae	Dorsal rami of spinal nerves	Extends and rotates vertebral column
Psoas minor (sō'as mī'ner)	T12–L1	Pectineal line near pubic crest	L1	Flexes vertebral column
Rotatores (rō-tā'tōrz)	Transverse processes of all vertebrae	Base of spinous process of superior vertebrae	Dorsal rami of spinal nerves	Extends and rotates vertebral column

**FIGURE 10.16** Deep Back Muscles

On the right, the erector spinae group of muscles is shown. On the left, these muscles are removed to reveal the deeper back muscles.

muscles of the back attach between the spinous and transverse processes of individual vertebra (figure 10.17).

- 14** List the actions of the group of back muscles that attaches to the vertebrae or ribs (or both). What is the name of the superficial group?

Back Pain
Low back pain can result from poor posture, from being overweight, or from having a poor fitness level. A few changes may help: sitting and standing up straight; using a low-back support when sitting; losing weight; exercising, especially the back and abdominal muscles; and sleeping on your side on a firm mattress. Sleeping on your side all night, however, may be difficult because most people change position over 40 times during the night.

Thoracic Muscles

The muscles of the thorax are involved mainly in the process of breathing (see chapter 23). Four major groups of muscles are associated with the rib cage (table 10.9 and figure 10.18). The **scalene** (skā'lēn) muscles elevate the first two ribs during inspiration. The **external intercostals** (in-ter-kos'tälz) also

FIGURE 10.17 Deep Muscles Associated with the Vertebrae

TABLE 10.9 Muscles of the Thorax (See Figure 10.18)				
Muscle	Origin	Insertion	Nerve	Action
Diaphragm	Interior of ribs, sternum, and lumbar vertebrae	Central tendon of diaphragm	Phrenic	Inspiration; depresses floor of thorax
Intercostalis (in'ter-kos-ta'lis)				
External	Inferior margin of each rib	Superior border of next rib below	Intercostal	Inspiration; elevates ribs
Internal	Superior margin of each rib	Inferior border of next rib above	Intercostal	Expiration; depresses ribs
Scalenus (skā-lē'nūs)				
Anterior	Transverse processes of C3–C6	First rib	Cervical plexus	Elevates first rib
Medial	Transverse processes of C2–C6	First rib	Cervical plexus	Elevates first rib
Posterior	Transverse processes of C4–C6	Second rib	Cervical and brachial plexuses	Elevates second rib
Serratus posterior (sēr-ā'tūs)				
Inferior (not illustrated)	Spinous processes of T11–L2	Inferior four ribs	Ninth to eleventh intercostals and subcostal	Depresses inferior ribs and extends vertebral column
Superior (not illustrated)	Spinous processes of C6–T2	Second to fifth ribs	First to fourth intercostals	Elevates superior ribs
Transversus thoracis (trans-ver'sus thō-ra'sis) (not illustrated)	Sternum and xiphoid process	Second to sixth costal cartilages	Intercostal	Decreases diameter of thorax

FIGURE 10.18 Muscles of the Thorax

elevate the ribs during inspiration. The **internal intercostals** and **transversus thoracis** (thō-ra'sis) muscles depress the ribs during forced expiration.

The **diaphragm** (dī'ă-fram; see figure 10.18a) causes the major movement produced during quiet breathing. It is a dome-shaped structure and, when it contracts, the dome flattens slightly, causing the volume of the thoracic cavity to increase, resulting in inspiration. If this dome of skeletal muscle or the phrenic nerve supplying it is severely damaged, the amount of air moving into and out of the lungs may be so small that the individual is likely to die without the aid of an artificial respirator.

15 *Name the muscle that is mainly responsible for respiratory movements. How do other muscles aid this movement?*

Abdominal Wall

The muscles of the anterior abdominal wall (table 10.10 and figures 10.19 and 10.20) flex and rotate the vertebral column.

Contraction of the abdominal muscles when the vertebral column is fixed decreases the volume of the abdominal cavity and the thoracic cavity and can aid in such functions as forced expiration, vomiting, defecation, urination, and childbirth. The crossing pattern of the abdominal muscles creates a strong anterior wall, which holds in and protects the abdominal viscera.

In a relatively muscular person with little fat, a vertical line is visible, extending from the area of the xiphoid process of the sternum through the navel to the pubis. This tendinous area of the abdominal wall is devoid of muscle; the **linea alba** (lin'ē-ă al'bă), or white line, is so-named because it consists of white connective tissue rather than muscle (see figure 10.19). On each side of the linea alba is the **rectus abdominis** (see figures 10.19 and 10.20), surrounded by a **rectus sheath**. **Tendinous intersections** (tendinous inscriptions) transect the rectus abdominis at three, or sometimes more, locations, causing the abdominal wall of a well-muscled person to appear segmented. Lateral to the rectus abdominis is the **linea semilunaris** (sem-ē-loo-nar'is; a crescent- or half-moon-shaped line); lateral to it are three layers of muscle

TABLE 10.10 Muscles of the Abdominal Wall (See Figures 10.5a, 10.19, and 10.20)

Muscle	Origin	Insertion	Nerve	Action
Anterior				
Rectus abdominis (rek'tūs ab-dom'i-nis)	Pubic crest and symphysis pubis	Xiphoid process and inferior ribs	Branches of lower thoracic	Flexes vertebral column; compresses abdomen
External abdominal oblique	Fifth to twelfth ribs	Iliac crest, inguinal ligament, and rectus sheath	Branches of lower thoracic	Flexes and rotates vertebral column; compresses abdomen; depresses thorax
Internal abdominal oblique	Iliac crest, inguinal ligament, and lumbar fascia	Tenth to twelfth ribs and rectus sheath	Lower thoracic	Flexes and rotates vertebral column; compresses abdomen; depresses thorax
Transversus abdominis (trans-ver'sūs ab-dom'i-nis)	Seventh to twelfth costal cartilages, lumbar fascia, iliac crest, and inguinal ligament	Xiphoid process, linea alba, and pubic tubercle	Lower thoracic	Compresses abdomen
Posterior				
Quadratus lumborum (kwah-drā'tūs lūm-bōr'ūm)	Iliac crest and lower lumbar vertebrae	Twelfth rib and upper lumbar vertebrae	Upper lumbar	Laterally flexes vertebral column and depresses twelfth rib

(a) Anterior view

(b) Anterior view

FIGURE 10.19 Anterior Abdominal Wall Muscles

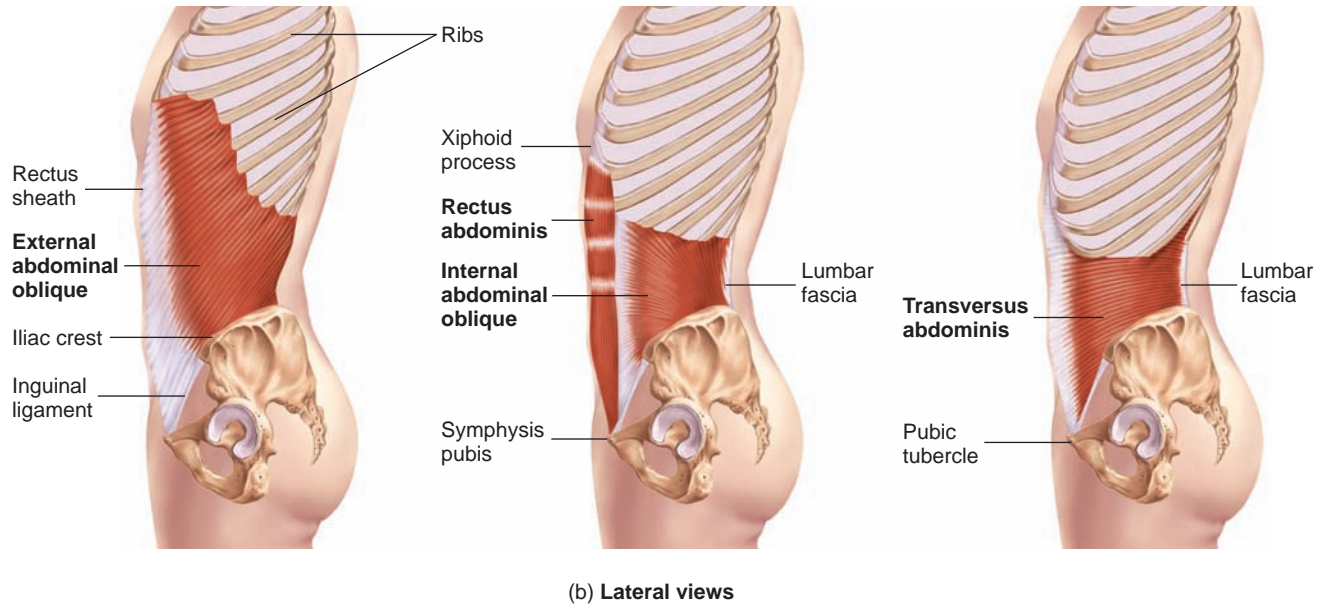

(a) Anterior abdominal muscles. Windows in the side reveal the various muscle layers. (b) Surface anatomy of anterior abdominal muscle.

(see figures 10.19 and 10.20). From superficial to deep, these muscles are the **external abdominal oblique**, **internal abdominal oblique**, and **transversus abdominis**.

16 Explain the anatomical basis for the segments (“cuts”) seen on a well-muscled individual’s abdomen. What are the functions of the abdominal muscles? List the muscles of the anterior abdominal wall.

Pelvic Floor and Perineum

The pelvis is a ring of bone (see chapter 7) with an inferior opening that is closed by a muscular wall, through which the anus and the urogenital openings penetrate (table 10.11). Most of the pelvic floor is formed by the **coccygeus** (kok-si'jē-ŭs) muscle and the **levator ani** (a'nī) muscle, referred to jointly as the **pelvic diaphragm**. The area inferior to the pelvic floor is the **perineum**.

**FIGURE 10.20** Anterior Abdominal Wall Muscles

(a) Cross section superior to the umbilicus. (b) Abdominal muscles shown individually.

TABLE 10.11 Muscles of the Pelvic Floor and Perineum

Muscle	Origin	Insertion	Nerve	Action
Bulbospongiosus (bul' bō-spŭn'jē-ō'sūs)	Male—central tendon of perineum and median raphe of penis	Dorsal surface of penis and bulb of penis	Pudendal	Constricts urethra; erects penis
	Female—central tendon of perineum	Base of clitoris	Pudendal	Erects clitoris
Coccygeus (kok-si'jē-ŭs) (not illustrated)	Ischial spine	Coccyx	S3 and S4	Elevates and supports pelvic floor
Ischiocavernosus (ish'ē-ō-kav'er-nō'sūs)	Ischial ramus	Corpus cavernosum	Perineal	Compresses base of penis or clitoris
Levator ani (lē-vā'tor, le-vā'ter ā'nī)	Posterior pubis and ischial spine	Sacrum and coccyx	Fourth sacral	Elevates anus; supports pelvic viscera
External anal sphincter (ā'nāl sfing'k'ter)	Coccyx	Central tendon of perineum	Fourth sacral and pudenda	Keeps orifice of anal canal closed
External urethral sphincter (ū-rē'thrāl sfing'k'ter) (not illustrated)	Pubic ramus	Median raphe	Pudendal	Constricts urethra
Transverse perinei (pēr'i-nē'ī)				
	Deep	Ischial ramus	Median raphe	Pudendal
Superficial	Ischial ramus	Central perineal	Pudendal	Fixes central tendon

FIGURE 10.21 Muscles of the Pelvic Floor and Perineum

(per'i-nē'ŭm), which is somewhat diamond-shaped (figure 10.21). The anterior half of the diamond is the urogenital triangle, and the posterior half is the anal triangle (see chapter 28). The urogenital triangle contains the **urogenital diaphragm**, which forms a “sub-floor” to the pelvis in that area and consists of the **deep transverse perineal** (pēr'i-nē'äl) muscle and the **external urethral sphincter** muscle. During pregnancy, the muscles of the pelvic diaphragm and urogenital diaphragm may be stretched by the extra weight of the fetus, and specific exercises are designed to strengthen them.

17 *What openings penetrate the pelvic floor muscles? Name the area inferior to the pelvic floor.*

UPPER LIMB MUSCLES

The muscles of the upper limb include those that move the scapula and those that move the arm, forearm, and hand.

Scapular Movements

The major connection of the upper limb to the body is accomplished by muscles (table 10.12 and figure 10.22). The muscles attaching the scapula to the thorax include the **trapezius**, **levator scapulae** (skap'ŭ-lē), **rhomboideus** (rom-bō-id'ē-ŭs) **major** and **minor**, **serratus** (sēr-ā'tŭs) **anterior**, and **pectoralis** (pek'tō-ra'lis) **minor**.

TABLE 10.12 Muscles Acting on the Scapula (See Figure 10.22)

Muscle	Origin	Insertion	Nerve	Action
Levator scapulae (lē-vā'tor, le-vā'ter skap'ŭ-lē)	Transverse processes of C1–C4	Superior angle of scapula	Dorsal scapular	Elevates, retracts, and rotates scapula; laterally flexes neck
Pectoralis minor (pek'tō-ra'lis)	Third to fifth ribs	Coracoid process of scapula	Medial pectoral	Depresses scapula or elevates ribs
Rhomboideus (rom-bō-id'ē-ŭs)				
Major	Spinous processes of T1–T4	Medial border of scapula	Dorsal scapular	Retracts, rotates, and fixes scapula
Minor	Spinous processes of C6–C7	Medial border of scapula	Dorsal scapular	Retracts, slightly elevates, rotates, and fixes scapula
Serratus anterior (ser-ā'tŭs)	First to eighth or ninth ribs	Medial border of scapula	Long thoracic	Rotates and protracts scapula; elevates ribs
Subclavius (sŭb-klā'vē-ŭs)	First rib	Clavicle	Subclavian	Fixes clavicle or elevates first rib
Trapezius (tra-pē'zē-ŭs)	External occipital protuberance, ligamentum nuchae, and spinous processes of C7–T12	Clavicle, acromion process, and scapular spine	Accessory and cervical plexus	Elevates, depresses, retracts, rotates, and fixes scapula; extends neck

FIGURE 10.22 Muscles Acting on the Scapula

(a) The trapezius is removed on the right to reveal the deeper muscles. (b) The pectoralis major is removed on both sides. The pectoralis minor is also removed on the right side. (c) The serratus anterior.

TABLE 10.13 Muscles Acting on the Arm (See Figures 10.22–10.24)

Muscle	Origin	Insertion	Nerve	Action
Coracobrachialis (kōr'ă-kō-brā-kē-ă'lis)	Coracoid process of scapula	Midshaft of humerus	Musculocutaneous	Adducts arm and flexes shoulder
Deltoid (del'toyd)	Clavicle, acromion process, and scapular spine	Deltoid tuberosity	Axillary	Flexes and extends shoulder; abducts and medially and laterally rotates arm
Latissimus dorsi (lă-tis'i-mūs dōr'sī)	Spinous processes of T7–L5; sacrum and iliac crest; inferior angle of scapula in some people	Medial crest of intertubercular groove	Thoracodorsal	Adducts and medially rotates arm; extends shoulder
Pectoralis major (pek'tō-rā'lis)	Clavicle, sternum, superior six costal cartilages, and abdominal aponeurosis	Lateral crest of intertubercular groove	Medial and lateral pectoral	Flexes shoulder; adducts and medially rotates arm; extends shoulder from flexed position
Teres major (ter'ēz, tēr-ēz)	Lateral border of scapula	Medial crest of intertubercular groove	Lower subscapular C5 and C6	Extends shoulder; adducts and medially rotates arm
Rotator Cuff				
Infraspinatus (in-fră-spī-nă'tūs)	Infraspinous fossa of scapula	Greater tubercle of humerus	Suprascapular C5 and C6	Laterally rotates arm; holds head of humerus in place
Subscapularis (sūb-skap-ū-lă'ris)	Subscapular fossa	Lesser tubercle of humerus	Upper and lower subscapular C5 and C6	Medially rotates arm; holds head of humerus in place
Supraspinatus (soo-pră-spī-nă'tūs)	Supraspinous fossa	Greater tubercle of humerus	Suprascapular C5 and C6	Abducts arm; holds head of humerus in place
Teres minor (ter'ēz, tēr-ēz)	Lateral border of scapula	Greater tubercle of humerus	Axillary C5 and C6	Laterally rotates and adducts arm; holds head of humerus in place

These muscles move the scapula, permitting a wide range of movements of the upper limb, or act as fixators to hold the scapula firmly in position when the arm muscles contract. The superficial muscles that act on the scapula can easily be seen on a living person (see figure 10.7*b*): The trapezius forms the upper line from each shoulder to the neck, and the origin of the serratus anterior from the first eight or nine ribs can be seen along the lateral thorax. The serratus anterior inserts onto the medial border of the scapula (see figure 10.22*c*).

Arm Movements

The arm is attached to the thorax by several muscles, including the **pectoralis major** and the **latissimus dorsi** (lă-tis'i-mūs dōr'sī) muscles (table 10.13 and figures 10.23 and 10.24; see figure 10.22*b*). Notice that the pectoralis major muscle is listed in table 10.13 as both a flexor and an extensor. The muscle flexes the extended shoulder and extends the flexed shoulder. Try these

FIGURE 10.25 Right Rotator Cuff Muscles

movements and notice the position and action of the muscle. The **deltoid** (deltoideus) muscle (see figure 10.23) also is listed in table 10.13 as a flexor and an extensor. The deltoid muscle is like three muscles in one: The anterior fibers flex the shoulder, the lateral fibers abduct the arm, and the posterior fibers extend the shoulder. The deltoid muscle is part of the group of muscles that binds the humerus to the scapula. The primary muscles holding the head of the humerus in the glenoid cavity, however, are called the **rotator cuff** muscles (listed separately in table 10.13) because they form a cuff or cap over the proximal humerus (figure 10.25).

A rotator cuff injury involves damage to one or more of these muscles or their tendons, usually the supraspinatus muscle. The muscles moving the arm are involved in flexion, extension, abduction, adduction, rotation, and circumduction (table 10.14).

Raising the upper limb so as to place the hand above the head can be accomplished by abduction of the arm and then rotation of the scapula. Abduction of the arm from the anatomical position through 90 degrees (to the point at which the hand is level to the shoulder) involves movement of the humerus and is accomplished by the deltoid muscle assisted by the rotator cuff muscles, which hold the head of the humerus tightly in place. In the initial phase of abduction (first 15 degrees), the deltoid is assisted by the supraspinatus. Place your hand on your deltoid and feel it contract as you abduct 90 degrees. Moving the arm from 90 degrees to 180 degrees, so that the hand is held high above the head, primarily involves rotation of the scapula, which is accomplished by the trapezius and serratus anterior muscles. Feel the inferior angle of your scapula as you abduct the arm to 90 degrees and then rotate to 180 degrees. Do you notice a big difference? Movement of the arm from 90 degrees to 180 degrees, however, cannot occur unless the head of the humerus is held tightly in the glenoid cavity by the rotator cuff muscles, especially the supraspinatus. Damage to the supraspinatus muscle can prevent abduction past 90 degrees.

PREDICT 4

A tennis player complains of pain in the shoulder when abducting the arm in attempting to serve or when attempting an overhead volley (during extreme abduction). In extreme abduction, the supraspinatus muscle rises superiorly and may be damaged by compression against what bony structure?

Several muscles acting on the arm can be seen very clearly in the living individual (see figures 10.23c and 10.24c). The pectoralis major forms the upper chest, and the deltoids are prominent over the shoulders. The deltoid is a common site for administering injections.

TABLE 10.14 Summary of Muscle Actions on the Shoulder and Arm

Flexion	Extension	Abduction	Adduction	Medial Rotation	Lateral rotation
Deltoid	Deltoid	Deltoid	Pectoralis major	Pectoralis major	Deltoid
Pectoralis major	Teres major	Supraspinatus	Latissimus dorsi	Teres major	Infraspinatus
Coracobrachialis	Lattissimus dorsi		Teres major	Lattissimus dorsi	Teres minor
Biceps brachii	Pectoralis major		Teres minor	Deltoid	
	Triceps brachii		Triceps brachii	Subscapularis	
			Coracobrachialis		

TABLE 10.15 Muscles Acting on the Forearm (See Figures 10.26 and 10.27)

Muscle	Origin	Insertion	Nerve	Action
Arm				
Biceps brachii (bī'seps brā'kē-ī)	Long head—supraglenoid tubercle	Radial tuberosity and aponeurosis of biceps brachii	Musculocutaneous	Flexes shoulder and elbow; supinates forearm and hand
	Short head—coracoid process			
Brachialis (brā'kē-al'is)	Anterior surface of humerus	Ulnar tuberosity and coronoid process of ulna	Musculocutaneous and radial	Flexes elbow
Triceps brachii (trī'seps brā'kē-ī)	Long head—infraglenoid tubercle on the lateral border of scapula	Olecranon process of ulna	Radial	Extends elbow; extends shoulder and adducts arm
	Lateral head—lateral and posterior surface of humerus			
	Medial head—posterior humerus			
Forearm				
Anconeus (ang-kō'nē-ūs)	Lateral epicondyle of humerus	Olecranon process and posterior ulna	Radial	Extends elbow
Brachioradialis (brā'kē-ō-rā'dē-al'is)	Lateral supracondylar ridge of humerus	Styloid process of radius	Radial	Flexes elbow
Pronator quadratus (prō-nā-ter, prō-nā-tōr kwah-drā'tūs)	Distal ulna	Distal radius	Anterior interosseous	Pronates forearm (and hand)
Pronator teres (prō-nā-tōr ter'ēz, tēr-ēz)	Medial epicondyle of humerus and coronoid process of ulna	Radius	Median	Pronates forearm (and hand)
Supinator (soo'pi-nā-ter, soo'pi-nā-tōr)	Lateral epicondyle of humerus and ulna	Radius	Radial	Supinates forearm (and hand)

Shoulder Pain

Baseball pitchers, because they throw very hard, may tear their rotator cuffs. Such tears result in pain in the anterosuperior part of the shoulder. Older people may also develop such pain because of **degenerative tendonitis** of the rotator cuff. The supraspinatus tendon is the most commonly affected part of the rotator cuff in either trauma or degeneration, probably because it has a relatively poor blood supply.

Pain in the shoulder can also result from **subacromial bursitis**, which is inflammation of the subacromial bursa. **Biceps tendinitis**, inflammation of the biceps brachii long head tendon, can also cause shoulder pain. This inflammation is also commonly caused by throwing a baseball or football.

- 18** Name seven muscles that attach the humerus to the scapula. What two muscles attach the humerus directly to the trunk?
- 19** List the muscles forming the rotator cuff, and describe their function.
- 20** What muscles cause flexion and extension of the shoulder? Abduction and adduction of the arm? What muscle is involved in abduction of the arm to 90 degrees? Above 90 degrees? What muscles cause rotation of the arm?

- 21** List the muscles that cause flexion and extension of the elbow. Where are these muscles located?

Forearm Movements

Extension and Flexion of the Elbow

Extension of the elbow is accomplished by the **triceps brachii** (brā'kē-ī) and **anconeus** (ang-kō'nē-ūs); flexion of the elbow is accomplished by the **brachialis** (brā'-kē-al'is), **biceps brachii**, and **brachioradialis** (brā'kē-ō-rā'dē-al'is; table 10.15; figures 10.26 and 10.27). The triceps brachii constitute the main mass visible on the posterior aspect of the arm (see figures 10.24c and 10.26c). The biceps brachii is readily visible on the anterior aspect of the arm (see figures 10.23c and 10.26c). The brachialis lies deep to the biceps brachii and can be seen only as a mass on the medial and lateral sides of the arm. The brachioradialis forms a bulge on the anterolateral side of the forearm just distal to the elbow (see figure 10.26a; figure 10.28b and d). If the elbow is forcefully flexed in the midprone position (midway between pronation and supination), the brachioradialis stands out clearly on the forearm (see figure 10.28d).

(c) Right forearm (deeper than a or b). Brachioradialis, pronator teres, flexor carpi radialis and ulnaris, palmaris longus, and flexor digitorum superficialis muscles are removed. (d) Surface anatomy of anterior forearm muscles.

Supination and Pronation

Supination of the forearm and hand is accomplished by the **supinator** and the **biceps brachii** (see figure 10.27; figure 10.28c and figure 10.29b). Pronation is a function of the **pronator quadratus** (kwah-drā'tūs) and the **pronator teres** (ter'ēz, tēr-ēz; figure 10.28a; see figures 10.27 and 10.28c).

22 *Supination and pronation of the forearm and hand are produced by what muscles? Where are these muscles located?*

PREDICT 5

Explain the difference between doing chin-ups with the forearm supinated versus pronated. The action of which muscle predominates in each type of chin-up? Which type is easier? Why?

Wrist, Hand, and Finger Movements

The forearm muscles are divided into anterior and posterior groups (table 10.16; see figures 10.28 and 10.29). Most of the anterior forearm muscles are responsible for flexion of the wrist and fingers. Most of the posterior forearm muscles cause extension of the wrist and fingers.

Extrinsic Hand Muscles

The **extrinsic hand muscles** are in the forearm but have tendons that extend into the hand. A strong band of fibrous connective tissue, the **retinaculum** (ret-i-nak'ū-lūm; bracelet), covers the flexor and extensor tendons and holds them in place around the wrist so that they do not “bowstring” during muscle contraction (see figures 10.29a and c).

Two major anterior muscles, the **flexor carpi radialis** (kar'pī-rā-dē-ā'lis) and the **flexor carpi ulnaris** (ūl-nā'ris), flex the wrist; and three posterior muscles, the **extensor carpi radialis longus**, the **extensor carpi radialis brevis**, and the **extensor carpi ulnaris**, extend the wrist. The wrist flexors and extensors are visible on the anterior and posterior surfaces of the forearm (see figures 10.28d and 10.29d). The tendon of the flexor carpi radialis is an important landmark because the radial pulse can be felt just lateral to the tendon (see figure 10.28d).

Tennis Elbow

Forceful, repetitive use of the forearm extensor muscles can damage them where they attach to the lateral epicondyle. This condition is often called **tennis elbow** because it can result from playing tennis. It is also called **lateral epicondylitis** because it can result from other sports and activities, such as shoveling snow.

TABLE 10.16 Muscles of the Forearm Acting on the Wrist, Hand, and Fingers
(See Figures 10.28 and 10.29)

Muscle	Origin	Insertion	Nerve	Action
Anterior Forearm				
Flexor carpi radialis (kar'pī rā-dē-ā'lis)	Medial epicondyle of humerus	Second and third metacarpals	Median	Flexes and abducts wrist
Flexor carpi ulnaris (kar'pī ūl-nā'ris)	Medial epicondyle of humerus and ulna	Pisiform, hamate, and fifth metacarpal	Ulnar	Flexes and adducts wrist
Flexor digitorum profundus (dij'i-tōr'ūm prō-fūn'dūs)	Ulna	Distal phalanges of digits 2–5	Ulnar and median	Flexes fingers at metacarpal-phalangeal joints and interphalangeal joints and wrist
Flexor digitorum superficialis (dij'i-tōr'ūm soo'per-fish-ē-ā'lis)	Medial epicondyle of humerus, coronoid process, and radius	Middle phalanges of digits 2–5	Median	Flexes fingers at interphalangeal joints and wrist
Flexor pollicis longus (pol'i-sis lon'gūs)	Radius	Distal phalanx of thumb	Median	Flexes thumb
Palmaris longus (pawl-mār'is lon'gūs)	Medial epicondyle of humerus	Palmar fascia	Median	Tenses palmar fascia; flexes wrist
Posterior Forearm				
Abductor pollicis longus (pol'i-sis lon'gūs)	Posterior ulna and radius and interosseous membrane	Base of first metacarpal	Radial	Abducts and extends thumb; abducts wrist
Extensor carpi radialis brevis (kar'pī rā-dē-ā'lis brev'is)	Lateral epicondyle of humerus	Base of third metacarpal	Radial	Extends and abducts wrist
Extensor carpi radialis longus (kar'pī rā-dē-ā'lis lon'gus)	Lateral supracondylar ridge of humerus	Base of second metacarpal	Radial	Extends and abducts wrist
Extensor carpi ulnaris (kar'pī ūl-nā'ris)	Lateral epicondyle of humerus and ulna	Base of fifth metacarpal	Radial	Extends and adducts wrist
Extensor digiti minimi (dij'i-tī mī'nī-mī)	Lateral epicondyle of humerus	Phalanges of fifth digit	Radial	Extends little finger and wrist
Extensor digitorum (dij'i-tōr'ūm)	Lateral epicondyle of humerus	Extensor tendon expansion over phalanges of digits 2–5	Radial	Extends fingers and wrist
Extensor indicis (in'di-sis)	Ulna	Extensor tendon expansion over second digit	Radial	Extends forefinger and wrist
Extensor pollicis brevis (pol'i-sis brev'is)	Radius	Proximal phalanx of thumb	Radial	Extends and abducts thumb; abducts wrist
Extensor pollicis longus (pol'i-sis lon'gūs)	Ulna	Distal phalanx of thumb	Radial	Extends thumb

TABLE 10.17 Intrinsic Hand Muscles (See Figure 10.30)

Muscle	Origin	Insertion	Nerve	Action
Midpalmar Muscles				
Interossei (in'ter-os'e-ī)				
Dorsal	Sides of metacarpal bones	Proximal phalanges of second, third, and fourth digits	Ulnar	Abducts second, third, and fourth digits
Palmar	Second, fourth, and fifth metacarpals	Second, fourth, and fifth digits	Ulnar	Adducts second, fourth, and fifth digits
Lumbricals (lum'brā-kälz)	Tendons of flexor digitorum profundis	Second through fifth digits	Two on radial side—median; two on ulnar side—ulnar	Flexes proximal and extends middle and distal phalanges
Thenar Muscles				
Abductor pollicis brevis (ab-dük-ter, ab-dük-tör pol'i-sis brev'is)	Flexor retinaculum, trapezium, and scaphoid	Proximal phalanx of thumb	Median	Abducts thumb
Adductor pollicis (ab-dük-ter, ab-dük-tör pol'i-sis)	Third metacarpal, second metacarpal, trapezoid, and capitate	Proximal phalanx of thumb	Ulnar	Adducts thumb
Flexor pollicis brevis (pol'i-sis brev'is)	Flexor retinaculum and first metacarpal	Proximal phalanx of thumb	Median and ulnar	Flexes thumb
Opponens pollicis (ö-pō'nens pol'i-sis)	Trapezium and flexor retinaculum	First metacarpal	Median	Opposes thumb
Hypothenar Muscles				
Abductor digiti minimi (ab-dük-ter, ab-dük-tör dij'i-tī min'imī)	Pisiform	Base of fifth digit	Ulnar	Abducts and flexes little finger
Flexor digiti minimi brevis (dij'i-tī min'ī-mī brev'is)	Hamate	Base of proximal phalanx of fifth digit	Ulnar	Flexes little finger
Opponens digiti minimi (ö-pō'nens dij'i-tī min'imī)	Hamate and flexor retinaculum	Fifth metacarpal	Ulnar	Opposes little finger

Flexion of the four medial digits is a function of the **flexor digitorum** (dij'i-tor'üm) **superficialis** and **flexor digitorum profundus** (prō-fün'dūs; deep). Extension is accomplished by the **extensor digitorum**. The tendons of this muscle are very visible on the dorsum of the hand (see figure 10.29*d*). The little finger has an additional extensor, the **extensor digiti minimi** (dij'i-tī min'imī). The index finger also has an additional extensor, the **extensor indicis** (in'di-sis).

Movement of the thumb is caused in part by the **abductor pollicis** (pol'i-sis) **longus**, the **extensor pollicis longus**, and the **extensor pollicis brevis**. These tendons form the sides of a depression on the posterolateral side of the wrist called the “anatomical snuffbox” (see figure 10.29). When snuff was in use, a small pinch could be placed into the anatomical snuffbox and inhaled through the nose.

Intrinsic Hand Muscles

The **intrinsic hand muscles** are entirely within the hand (table 10.17 and figure 10.30). Abduction of the fingers is accomplished by the **dorsal interossei** (in'ter-os'e-ī) and the **abductor digiti minimi**, whereas adduction is a function of the **palmar interossei**.

The **flexor pollicis brevis**, the **abductor pollicis brevis**, and the **opponens pollicis** form a fleshy prominence at the base of the thumb called the **thenar** (thē'nar) **eminence** (see figure 10.30). The **abductor digiti minimi**, **flexor digiti minimi brevis**, and **opponens digiti minimi** constitute the **hypothenar eminence** on the ulnar side of the hand. The thenar and hypothenar muscles are involved in the control of the thumb and little finger.

FIGURE 10.30 Right Hand Muscles

(a) Superficial muscles of the right hand. Abductor pollicis brevis is cut. (b) Deep muscles of the right hand. Flexor digitorum tendons are cut. (c) Surface anatomy of the palmar surface of the hand.

TABLE 10.18 Muscles Acting on the Thigh (See Figures 10.31–10.35)

Muscle	Origin	Insertion	Nerve	Action
Anterior				
Iliopsoas (il'ē-ō-sō'as)				
Iliacus (il-ī'ā-kus)	Iliac fossa	Lesser trochanter of femur and capsule of hip joint	Lumbar plexus	Flexes hip
Psoas major (sō'as)	T12–L5	Lesser trochanter of femur	Lumbar plexus	Flexes hip
Posterior and Lateral				
Gluteus maximus (gloo-tē'ūs mak'si-mūs)	Posterior surface of ilium, sacrum, and coccyx	Gluteal tuberosity of femur and iliotibial tract	Inferior gluteal	Extends hip; abducts and laterally rotates thigh
Gluteus medius (gloo-tē'ūs mē'dē-ūs)	Posterior surface of ilium	Greater trochanter of femur	Superior gluteal	Abducts and medially rotates thigh; tilts pelvis toward supported side
Gluteus minimus (gloo-tē'ūs min-i-mūs)	Posterior surface of ilium	Greater trochanter of femur	Superior gluteal	Abducts and medially rotates thigh; tilts pelvis toward supported side
Tensor fasciae latae (ten'sōr fash'ē-ē lā'tē)	Anterior superior iliac spine	Through iliotibial tract to lateral condyle of tibia	Superior gluteal	Tenses lateral fascia and stabilizes femur on tibia when standing; flexes hip; abducts and medially rotates thigh; tilts pelvis
Deep Thigh Rotators				
Gemellus (jē-mel'ūs)				
Inferior	Ischial tuberosity	Obturator internus tendon	L5 and S1	Laterally rotates and abducts thigh
Superior	Ischial spine	Obturator internus tendon	L5 and S1	Laterally rotates and abducts thigh
Obturator (ob'too-rā-tōr)				
Externus (eks-ter'nūs)	Inferior margin of obturator foramen	Greater trochanter of femur	Obturator	Laterally rotates thigh
Internus (in-ter'nūs)	Interior margin of obturator foramen	Greater trochanter of femur	L5 and S1	Laterally rotates thigh
Piriformis (pir'i-fōr'mis)	Sacrum and ilium	Greater trochanter of femur	S1 and S2	Laterally rotates and abducts thigh
Quadratus femoris (kwah'-drā'tūs fem'ō-ris)	Ischial tuberosity	Intertrochanteric ridge of femur	L5 and S1	Laterally rotates thigh

- 23** Describe the muscle groups that cause flexion and extension of the wrist.
- 24** Contrast the location and actions of the extrinsic and intrinsic hand muscles. What is the retinaculum? What is the location and action of the thenar and hypothenar muscles?
- 25** Describe the muscles that move the thumb. The tendons of what muscles form the anatomical snuffbox?

LOWER LIMB MUSCLES

Thigh Movements

Several hip muscles originate on the coxal bone and insert onto the femur (table 10.18 and figures 10.31–10.35). These muscles are divided into three groups: anterior, posterolateral, and deep.

The anterior muscles (see figure 10.31), the **iliacus** (il-ī'ā-kūs) and the **psoas** (sō'as) **major**, flex the hip. Because these muscles share an insertion and produce the same movement, they often are referred to as the **iliopsoas** (il'ē-ō-sō'as). When the thigh is fixed, the iliopsoas flexes the trunk on the thigh. For example, the iliopsoas does most of the work when a person does sit-ups.

The posterolateral hip muscles consist of the gluteal muscles and the **tensor fasciae latae** (fash'ē-ē lā'tē). The **gluteus** (gloo-tē'ūs) **maximus** (see figure 10.32) contributes most of the mass that can be seen as the buttocks (see figure 10.32c); the **gluteus medius**, a common site for injections, creates a smaller mass just superior and lateral to the gluteus maximus. The gluteus maximus functions at its maximum force in extension of the thigh when the hip is flexed at a 45-degree angle so that the muscle is optimally stretched, which accounts for both the sprinter's stance and the bicycle racing posture.

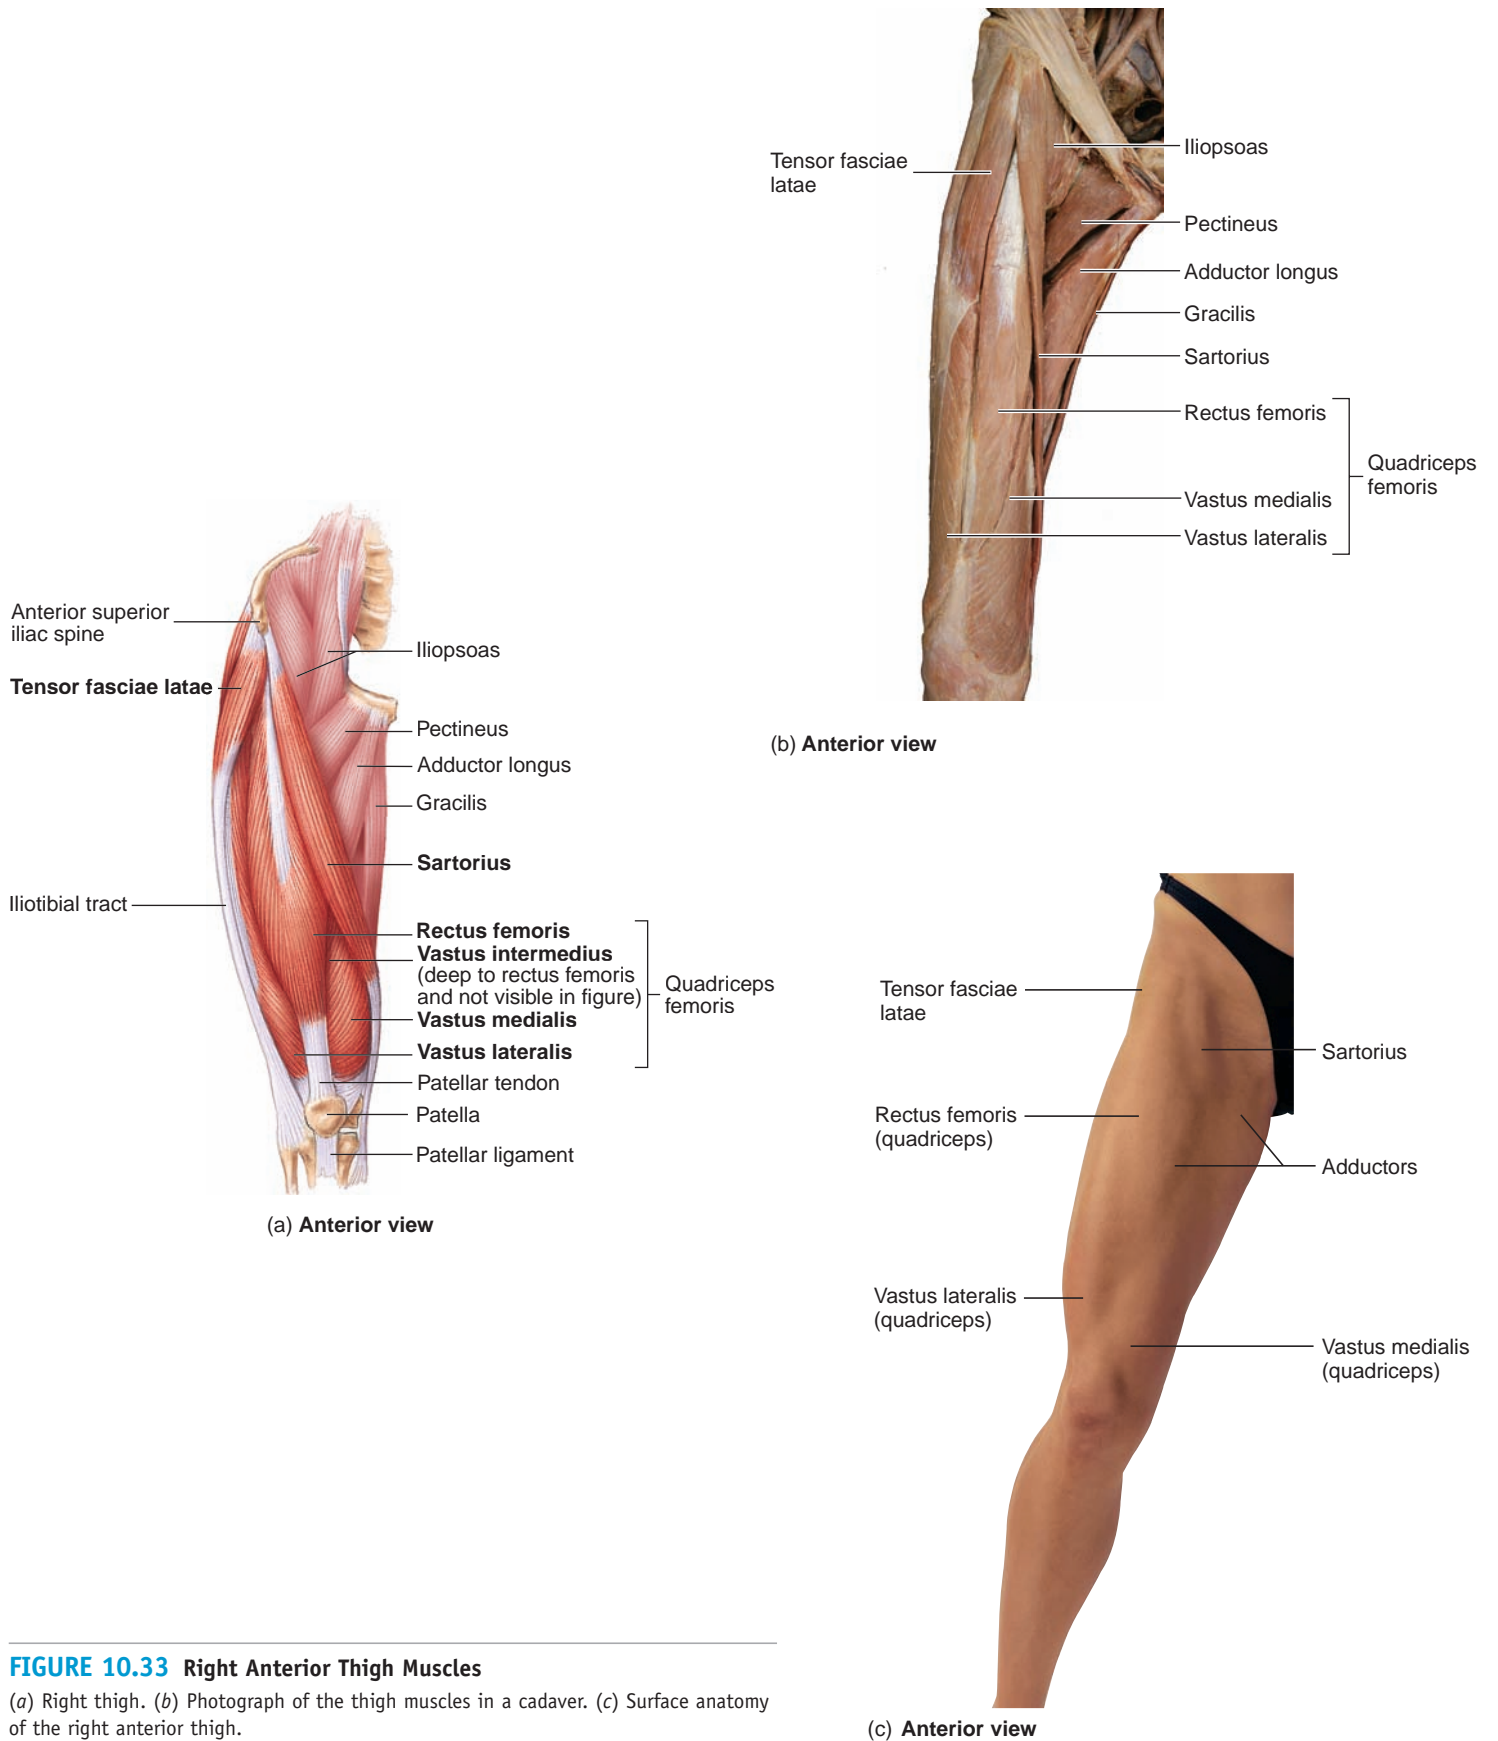

FIGURE 10.33 Right Anterior Thigh Muscles

(a) Right thigh. (b) Photograph of the thigh muscles in a cadaver. (c) Surface anatomy of the right anterior thigh.

FIGURE 10.34 Right Medial Thigh Muscles

The deep hip muscles, as well as the gluteus maximus, function as lateral thigh rotators. The gluteus medius, gluteus minimus, and tensor fasciae latae are medial hip rotators (see table 10.18 and figure 10.32*b*). The gluteus medius and minimus muscles help tilt the pelvis and maintain the trunk in an upright posture during walking, as the foot of the opposite limb is raised from the ground. Without the action of these muscles, the pelvis tends to sag downward on the unsupported side.

In addition to the hip muscles, some of the muscles located in the thigh originate on the coxal bone and can cause movement of the thigh (tables 10.19 and 10.20). Three groups of thigh muscles have been identified based on their location in the thigh: the anterior, which flex the hip and/or extend the knee (see figure 10.33*a*); the medial, which adduct the thigh (see figure 10.34); and the posterior, which extend the hip and flex the knee (see figure 10.35).

26 Name the anterior hip muscle that flexes the hip. What muscles act as synergists to this muscle?

27 Describe the movements produced by the gluteus muscles.

Leg Movements

The anterior thigh muscles are the **quadriceps femoris** (fem'ō-ris) and the **sartorius** (sar-tōr'ē-ūs; see table 10.20 and figure 10.33*a*). The quadriceps femoris is actually four muscles: the **rectus femoris**, the **vastus lateralis**, the **vastus medialis**, and the **vastus intermedius**.

FIGURE 10.35 Right Posterior Thigh Muscles

Hip muscles are removed.

The quadriceps group extends the knee. The rectus femoris also flexes the hip because it crosses both the hip and knee joints.

The quadriceps femoris makes up the large mass on the anterior thigh (see figure 10.33*c*). The vastus lateralis sometimes is used as an injection site, especially in infants who may not have well-developed deltoid or gluteal muscles. The muscles of the quadriceps femoris have a common insertion, the patellar tendon, on and around the patella. The patellar ligament is an extension of the patellar tendon onto the tibial tuberosity. The patellar ligament is the point that is tapped with a rubber hammer when testing the knee-jerk reflex in a physical examination.

The sartorius is the longest muscle of the body, crossing from the lateral side of the hip to the medial side of the knee. As the muscle contracts, it flexes the hip and knee and laterally rotates the thigh. This movement is the action required for crossing the legs.

Sartorius—the Tailor's Muscle

The term *sartorius* means tailor. The sartorius muscle is so-named because its action is to cross the legs, a common position traditionally preferred by tailors because they can hold their sewing in their lap as they sit and sew by hand.

TABLE 10.19 Summary of Muscle Actions on the Hip and Thigh

Flexion	Extension	Abduction	Adduction	Medial Rotation	Lateral Rotation
Iliopsoas	Gluteus maximus	Gluteus maximus	Adductor magnus	Tensor fasciae latae	Gluteus maximus
Tensor fasciae latae	Semitendinosus	Gluteus medius	Adductor longus	Gluteus medius	Obturator internus
Rectus femoris	Semimembranosus	Gluteus minimus	Adductor brevis	Gluteus minimus	Obturator externus
Sartorius	Biceps femoris	Tensor fasciae latae	Pectineus		Superior gemellus
Adductor longus	Adductor magnus	Obturator internus	Gracilis		Inferior gemellus
Adductor brevis		Gemellus superior and inferior			Quadratus femoris
Pectineus		Piriformis			Piriformis
					Adductor magnus
					Adductor longus
					Adductor brevis

TABLE 10.20 Muscles of the Thigh (See Figures 10.33 and 10.35)

Muscle	Origin	Insertion	Nerve	Action
Anterior Compartment				
Quadriceps femoris (kwah'dri-seps fem'ō-ris)	Rectus femoris— anterior inferior iliac spine Vastus lateralis— greater trochanter and linea aspera of femur Vastus intermedius— body of femur Vastus medialis— linea aspera of femur	Patella and onto tibial tuberosity through patellar ligament	Femoral	Extends knee; rectus femoris also flexes hip
Sartorius (sar-tōr'ē-ūs)	Anterior superior iliac spine	Medial side of tibial tuberosity	Femoral	Flexes hip and knee; rotates thigh laterally and leg medially
Medial Compartment				
Adductor brevis (a-dūk'ter, a-dūk'tōr brev'is)	Pubis	Pectineal line and linea aspera of femur	Obturator	Adducts, laterally rotates thigh; flexes hip
Adductor longus (a-dūk'ter, a-dūk'tōr lon'gūs)	Pubis	Linea aspera of femur	Obturator	Adducts, laterally rotates thigh; flexes hip
Adductor magnus (a-dūk'ter, a-dūk'tōr mag'nūs)	Adductor part: pubis and ischium Hamstring part: ischial tuberosity	Adductor part: linea aspera of femur Hamstring part: adductor tubercle of femur	Adductor part: obturator Hamstring part: tibial	Adductor part: adducts thigh and flexes hip Hamstring part: extends hip and adducts thigh
Gracilis (gras'i-lis)	Pubis near symphysis	Tibia	Obturator	Adducts thigh; flexes knee
Pectineus (pek'ti-nē'ūs)	Pubic crest	Pectineal line of femur	Femoral and obturator	Adducts thigh; flexes hip
Posterior Compartment				
Biceps femoris (bi'seps fem'ō-ris)	Long head—ischial tuberosity Short head—femur	Head of fibula	Long head—tibial Short head—common fibular	Flexes knee; laterally rotates leg; extends hip
Semimembranosus (sem'ē-mem-brā-nō'sūs)	Ischial tuberosity	Medial condyle of tibia and collateral ligament	Tibial	Flexes knee; medially rotates leg; tenses capsule of knee joint; extends hip
Semitendinosus (sem'ē-ten-dī-nō'sūs)	Ischial tuberosity	Tibia	Tibial	Flexes knee; medially rotates leg; extends hip

FIGURE 10.36 Surface Anatomy of the Posterior Lower Limb

The medial thigh muscles (see figure 10.34) are involved primarily in adduction of the thigh. Some of these muscles also laterally rotate the thigh and/or flex or extend the hip. The gracilis also flexes the knee.

The posterior thigh muscles (see figure 10.35), collectively called the hamstring muscles, consist of the **biceps femoris**, **semimembranosus** (sem'ē-mem-brā-nō'sūs), and **semitendinosus** (sem'ē-ten-di-nō'sūs; see table 10.20). Their tendons are easily seen or felt on the medial and lateral posterior aspect of a slightly bent knee (figure 10.36).

Hamstrings

The **hamstrings** are so-named because in pigs these tendons can be used to suspend hams during curing. Some animals, such as wolves, often bring down their prey by biting through the hamstrings; therefore, “to hamstring” someone is to render the person helpless. A “pulled hamstring” results from tearing one or more of these muscles or their tendons, usually near the origin of the muscle.

28 Name the muscle compartments of the thigh and the movements produced by the muscles of each compartment. List the muscles of each compartment and the individual action of each muscle.

29 How is it possible for thigh muscles to move both the thigh and the leg? Name six muscles that can do this.

Ankle, Foot, and Toe Movements

The muscles of the leg that move the ankle and the foot are listed in table 10.21 and are illustrated in figures 10.37–10.39. These **extrinsic foot muscles** are divided into three groups, each located within a separate compartment of the leg: anterior, posterior, and lateral (see figure 10.37). The anterior leg muscles (see figure 10.38a) are extensor muscles involved in dorsiflexion and eversion or inversion of the foot and extension of the toes.

Shinsplints

Shinsplints is a catchall term involving any one of the following four conditions associated with pain in the anterior portion of the leg:

1. Excessive stress on the tibialis anterior, resulting in pain along the origin of the muscle
2. Tibial periostitis, an inflammation of the tibial periosteum
3. Anterior compartment syndrome. During hard exercise, the anterior compartment muscles may swell with blood. The overlying fascia is very tough and does not expand; thus, the nerves and vessels are compressed, causing pain.
4. Stress fracture of the tibia 2–5 cm distal to the knee

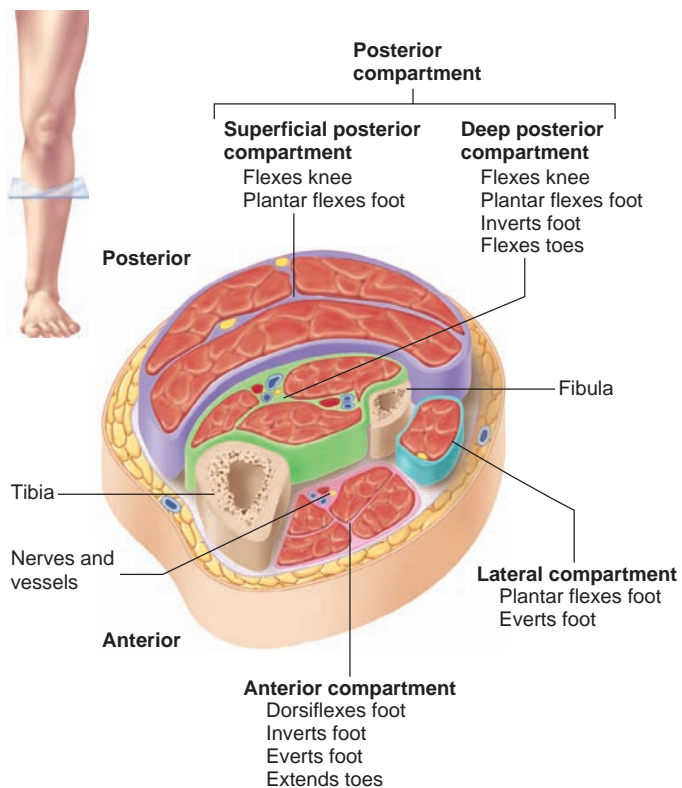

FIGURE 10.37 Cross Section Through the Left Leg

Drawing of the muscular compartments.

TABLE 10.21 Muscles of the Leg Acting on the Leg, Ankle, and Foot (See Figures 10.37–10.39)

Muscle	Origin	Insertion	Nerve	Action
Anterior Compartment				
Extensor digitorum longus (dĭj'ĭ-tōr'ŭm lon'gŭs)	Lateral condyle of tibia and fibula	Four tendons to phalanges of four lateral toes	Deep fibular*	Extends four lateral toes; dorsiflexes and everts foot
Extensor hallucis longus (hal'i-sis lon'gŭs)	Middle fibula and interosseous membrane	Distal phalanx of great toe	Deep fibular*	Extends great toe; dorsiflexes and inverts foot
Tibialis anterior (tib-ē-a'lis)	Proximal, lateral tibia and interosseous membrane	Medial cuneiform and first metatarsal	Deep fibular*	Dorsiflexes and inverts foot
Fibularis tertius (peroneus tertius) (per'ō-nē'ŭs ter'shē-ŭs)	Fibula and interosseous membrane	Fifth metatarsal	Deep fibular*	Dorsiflexes and everts foot
Lateral Compartment				
Fibularis brevis (peroneus brevis) (fib-ŭ-lā'ris brev'is)	Inferior two-thirds of lateral fibula	Fifth metatarsal	Superficial fibular*	Everts and plantar flexes foot
Fibularis longus (peroneus longus) (fib-ŭ-lā'ris lon'gŭs)	Superior two-thirds of lateral fibula	First metatarsal and medial cuneiform	Superficial fibular*	Everts and plantar flexes foot
Posterior Compartment				
Superficial				
Gastrocnemius (gas-trok-nē'mē-ŭs)	Medial and lateral condyles of femur	Through calcaneal (Achilles) tendon to calcaneus	Tibial	Plantar flexes foot; flexes knee
Plantaris (plan-tār'is)	Femur	Through calcaneal tendon to calcaneus	Tibial	Plantar flexes foot; flexes knee
Soleus (sō-lē'ŭs)	Fibula and tibia	Through calcaneal tendon to calcaneus	Tibial	Plantar flexes foot
Deep				
Flexor digitorum longus (dĭj'ĭ-tōr'ŭm lon'gŭs)	Tibia	Four tendons to distal phalanges of four lateral toes	Tibial	Flexes four lateral toes; plantar flexes and inverts foot
Flexor hallucis longus (hal'i-sis lon'gŭs)	Fibula	Distal phalanx of great toe	Tibial	Flexes great toe; plantar flexes and inverts foot
Popliteus (pop-li-tē'ŭs)	Lateral femoral condyle	Posterior tibia	Tibial	Flexes knee; medially rotates leg
Tibialis posterior (tib-ē-a'lis)	Tibia, interosseous membrane, and fibula	Navicular, cuneiforms, cuboid, and second through fourth metatarsals	Tibial	Plantar flexes and inverts foot

*Also referred to as the peroneal nerve.

The lateral muscles (see figure 10.38*b*) are primarily everters of the foot, but they also aid plantar flexion. The **fibularis brevis** inserts onto the fifth metatarsal and everts and plantar flexes the foot. The **fibularis longus** crosses under the lateral four metatarsals to insert onto the first metatarsal and medial cuneiform. The fibular muscle was formerly referred to as *peroneal*, which means relating to the fibula; the term has now been simplified by using the term *fibular*. The tendons of the fibularis muscles can be seen on the lateral side of the ankle (see figure 10.38*d*).

The superficial muscles of the posterior compartment, the **gastrocnemius** (gas-trok-nē'mē-ŭs) and **soleus**, form the bulge of the calf (posterior leg; see figures 10.39*a*, *b*, and *d*). They join with the small **plantaris** muscle to form the common **calcaneal** (kal-kā'nē-al), or Achilles, **tendon**. These muscles are

involved in plantar flexion of the foot. The deep muscles of the posterior compartment plantar flex and invert the foot and flex the toes.

Achilles Tendon

The **Achilles tendon** derives its name from a hero of Greek mythology. When Achilles was a baby, his mother dipped him into magic water, which made him invulnerable to harm everywhere the water touched his skin. His mother, however, held him by the heel and failed to submerge this part of his body under the water. Consequently, his heel was vulnerable and proved to be his undoing; he was shot in the heel with an arrow at the battle of Troy and died. Thus, saying that someone has an “Achilles heel” means that the person has a weak spot that can be attacked.

TABLE 10.22 Intrinsic Muscles of the Foot (See Figure 10.40)

Muscle	Origin	Insertion	Nerve	Action
Abductor digiti minimi (ab-dük'ter, ab-dük'tör dij'i-ti min'i-mi)	Calcaneus	Proximal phalanx of fifth toe	Lateral plantar	Abducts and flexes little toe
Abductor hallucis (ab-dük'ter, ab-dük'tör hal'i-sis)	Calcaneus	Base of proximal phalanx of great toe	Medial plantar	Abducts great toe
Adductor hallucis (a-dük'ter, a-dük'tör hal'i-sis) (not illustrated)	Lateral four metatarsals	Proximal phalanx of great toe	Lateral plantar	Adducts great toe
Extensor digitorum brevis (dij'i-tör'üm brev'is) (not illustrated)	Calcaneus	Four tendons fused with tendons of extensor digitorum longus	Deep fibular*	Extends toes
Flexor digiti minimi brevis (dij'i-ti min'i-mi brev'is)	Fifth metatarsal	Proximal phalanx of fifth digit	Lateral plantar	Flexes little toe (proximal phalanx)
Flexor digitorum brevis (dij'i-tör'üm brev'is)	Calcaneus and plantar fascia	Four tendons to middle phalanges of four lateral toes	Medial plantar	Flexes lateral four toes
Flexor hallucis brevis (hal'i-sis brev'is)	Cuboid; medial and lateral cuneiforms	Two tendons to proximal phalanx of great toe	Medial and lateral plantar	Flexes great toe
Dorsal interossei (in'ter-os'e-i) (not illustrated)	Metatarsal bones	Proximal phalanges of second, third, and fourth digits	Lateral plantar	Abduct second, third, and fourth toes
Plantar interossei (plan'tär in'ter-os'e-i)	Third, fourth, and fifth metatarsals	Proximal phalanges of third, fourth, and fifth digits	Lateral plantar	Adduct third, fourth, and fifth toes
Lumbricales (lum'bri-kā-lēz)	Tendons of flexor digitorum longus	Extensor expansion of second through fifth digits	Lateral and medial plantar	Flex proximal and extend middle and distal phalanges
Quadratus plantae (kwah'drā'tūs plan'tē)	Calcaneus	Tendons of flexor digitorum longus	Lateral plantar	Assists flexor digitorum longus in flexing lateral four toes

*Also referred to as the peroneal nerve.

Intrinsic foot muscles, located within the foot itself (table 10.22 and figure 10.40), flex, extend, abduct, and adduct the toes. They are arranged in a manner similar to that of the intrinsic muscles of the hand.

Plantar Fasciitis

The muscles in the plantar region of the foot are covered with thick fascia and the plantar aponeurosis. Running on a hard surface wearing poorly fitting or worn-out shoes can result in inflammation of the plantar aponeurosis. The pain resulting from **plantar fasciitis** occurs in the fascia over the heel and along the medial-inferior side of the foot.

FIGURE 10.40 Right Foot Muscles

(a) Superficial muscles of the right foot. Plantar aponeurosis is cut. (b) Deep muscles of the right foot. Flexor digitorum brevis and flexor hallucis longus are cut.

- 30** What movements are produced by the three muscle compartments of the leg? Name the muscles of each compartment, and describe the movements for which each muscle is responsible.
- 31** What movement do the fibularis (peroneus) muscles have in common? The tibialis muscles?
- 32** Name the leg muscles that flex the knee. Which of them can also plantar flex the foot?
- 33** List the general actions performed by the intrinsic foot muscles.

CLINICAL FOCUS

Bodybuilding

Bodybuilding is a popular sport worldwide. Participants in this sport combine diet and specific weight training to develop maximum muscle mass and minimum body fat, with their major goal being a well-balanced, complete physique. An uninformed, untrained muscle builder can build some muscles and ignore others; the result is a disproportioned body. Skill, training, and concentration are required to build a well-proportioned, muscular body and to know which exercises build a large number of muscles and which are specialized to build certain parts of the body. Is the old adage “no pain, no gain” correct? Not really. Overexercising can cause small tears in muscles and soreness. Torn muscles are weaker, and it may take up to 3 weeks to repair the damage, even though the soreness may last only 5–10 days.

Bodybuilders concentrate on increasing skeletal muscle mass. Endurance tests conducted years ago demonstrated that the cardiovascular and respiratory abilities of bodybuilders were similar to the abilities of normal, healthy persons untrained in a sport. More recent studies, however, indicate that the cardiorespiratory fitness of bodybuilders is similar to that of other well-trained athletes. The difference between the results of the new studies and those of the older ones is attrib-

FIGURE A Bodybuilders

uted to modern bodybuilding techniques that include aerobic exercise and running, as well as “pumping iron.”

Bodybuilding has its own language. Bodybuilders refer to the “lats,” “traps,” and “delts” rather than the latissimus dorsi, trapezius, and deltoids. The exercises also have special

names, such as “lat pulldowns,” “preacher curls,” and “triceps extensions.”

Photographs of bodybuilders are very useful in the study of anatomy because they enable the easy identification of the surface anatomy of muscles that cannot usually be seen in untrained people (figure A).

SUMMARY

Body movements result from the contraction of skeletal muscles.

General Principles (p. 321)

1. The less movable end of a muscle attachment is the origin; the more movable end is the insertion.
2. An agonist causes a certain movement and an antagonist acts in opposition to the agonist.
3. Synergists are muscles that function together to produce movement.
4. Prime movers are mainly responsible for a movement. Fixators stabilize the action of prime movers.

Muscle Shapes

Muscle shape is determined primarily by the arrangement of muscle fasciculi.

Nomenclature

Muscles are named according to their location, size, shape, orientation of fasciculi, origin and insertion, number of heads, and function.

Movements Accomplished by Muscles

Contracting muscles generate a force that acts on bones (levers) across joints (fulcrums) to create movement. Three classes of levers have been identified.

Muscle Anatomy

Muscles of the head, neck, trunk and limbs are presented.

Head Muscles (p. 327)

Head and Neck Muscles

Origins of these muscles are mainly on the cervical vertebrae (except for the sternocleidomastoid); insertions are on the occipital bone or mastoid process. They cause flexion, extension, rotation, abduction, and adduction of the head.

Facial Expression

Origins of facial muscles are on skull bones or fascia; insertions are into the skin, causing movement of the facial skin, lips, and eyelids.

Mastication

Three pairs of muscles close the jaw; gravity opens the jaw. Forced opening is caused by the lateral pterygoids and the hyoid muscles.

Tongue Movements

Intrinsic tongue muscles change the shape of the tongue; extrinsic tongue muscles move the tongue.

Swallowing and the Larynx

1. Hyoid muscles can depress the jaw and assist in swallowing.
2. Muscles open and close the openings to the nasal cavity, pharyngo-tympanic tubes, and larynx.

Movements of the Eyeball

Six muscles with their origins on the orbital bones insert on the eyeball and cause it to move within the orbit.

Trunk Muscles (p. 340)

Muscles Moving the Vertebral Column

1. These muscles extend, abduct, rotate, or flex the vertebral column.
2. A deep group of muscles connects adjacent vertebrae.
3. A more superficial group of muscles runs from the pelvis to the skull, extending from the vertebrae to the ribs.

Thoracic Muscles

1. Most respiratory movement is caused by the diaphragm.
2. Muscles attached to the ribs aid in respiration.

Abdominal Wall

Abdominal wall muscles hold and protect abdominal organs and cause flexion, rotation, and lateral flexion of the vertebral column.

Pelvic Floor and Perineum

These muscles support the abdominal organs inferiorly.

Upper Limb Muscles (p. 346)

Scapular Movements

Six muscles attach the scapula to the trunk and enable the scapula to function as an anchor point for the muscles and bones of the arm.

Arm Movements

Seven muscles attach the humerus to the scapula. Two additional muscles attach the humerus to the trunk. These muscles cause flexion and extension of the shoulder and abduction, adduction, rotation, and circumduction of the arm.

Forearm Movements

1. Flexion and extension of the elbow are accomplished by three muscles located in the arm and two in the forearm.
2. Supination and pronation are accomplished primarily by forearm muscles.

Wrist, Hand, and Finger Movements

1. Forearm muscles that originate on the medial epicondyle are responsible for flexion of the wrist and fingers. Muscles extending the wrist and fingers originate on the lateral epicondyle.
2. Extrinsic hand muscles are in the forearm. Intrinsic hand muscles are in the hand.

Lower Limb Muscles (p. 359)

Thigh Movements

1. Anterior pelvic muscles cause flexion of the hip.
2. Muscles of the buttocks are responsible for extension of the hip and abduction and rotation of the thigh.
3. The thigh can be divided into three compartments.
 - The anterior compartment muscles flex the hip and extend the knee.
 - The medial compartment muscles adduct the thigh.
 - The posterior compartment muscles extend the hip and flex the knee.

Leg Movements

Some muscles of the thigh also act on the leg. The anterior thigh muscles extend the leg, and the posterior thigh muscles flex the leg.

Ankle, Foot, and Toe Movements

1. The leg is divided into three compartments.
 - Muscles in the anterior compartment cause dorsiflexion, inversion, or eversion of the foot and extension of the toes.
 - Muscles of the lateral compartment plantar flex and evert the foot.
 - Muscles of the posterior compartment flex the leg, plantar flex and invert the foot, and flex the toes.
2. Intrinsic foot muscles flex or extend and abduct or adduct the toes.

REVIEW AND COMPREHENSION

1. Muscles that oppose one another are

a. synergists.	c. hateful.	e. fixators.
b. levers.	d. antagonists.	
2. The most movable attachment of a muscle is its

a. origin.	c. fascia.	e. belly.
b. insertion.	d. fulcrum.	
3. Which of these muscles is correctly matched with its type of fascicle orientation?

a. pectoralis major—pennate	d. biceps femoris—straight
b. transversus abdominis—circular	e. orbicularis oris—straight
c. temporalis—convergent	

4. The muscle whose name means it is larger and round is the
 a. gluteus maximus. d. latissimus dorsi.
 b. vastus lateralis. e. adductor magnus.
 c. teres major.
5. In a class III lever system, the
 a. fulcrum is located between the pull and the weight.
 b. weight is located between the fulcrum and the pull.
 c. pull is located between the fulcrum and the weight.
6. A prominent lateral muscle of the neck that can cause flexion of the neck or rotate the head is the
 a. digastric. c. sternocleidomastoid. e. platysma.
 b. mylohyoid. d. buccinator.
7. Harry Wolf has just picked up his date for the evening. She is wearing a stunning new outfit. Harry shows his appreciation by moving his eyebrows up and down, winking, smiling, and finally kissing her. Given the muscles listed:
 1. zygomaticus
 2. levator labii superioris
 3. occipitofrontalis
 4. orbicularis oris
 5. orbicularis oculi
 In which order did Harry use these muscles?
 a. 2,3,4,1 c. 2,5,4,3 e. 3,5,2,4
 b. 2,5,3,1 d. 3,5,1,4
8. An aerial circus performer who supports herself only by her teeth while spinning around should have strong
 a. temporalis muscles. d. both a and b.
 b. masseter muscles. e. all of the above.
 c. buccinator muscles.
9. The tongue curls and folds *primarily* because of the action of the
 a. extrinsic tongue muscles.
 b. intrinsic tongue muscles.
10. The infrahyoid muscles
 a. elevate the mandible.
 b. move the mandible from side to side.
 c. fix (prevent movement of) the hyoid.
 d. both a and b.
 e. all of the above.
11. The soft palate muscles
 a. prevent food from entering the nasal cavity.
 b. close the pharyngotympanic tube.
 c. force food into the esophagus.
 d. prevent food from entering the larynx.
 e. elevate the mandible.
12. Which of these movements is *not* caused by contraction of the erector spinae muscles?
 a. flexion of the vertebral column
 b. lateral flexion of the vertebral column
 c. extension of the vertebral column
 d. rotation of the vertebral column
13. Which of these muscles is (are) responsible for flexion of the vertebral column (below the neck)?
 a. deep back muscles
 b. superficial back muscles (erector spinae)
 c. rectus abdominis
 d. both a and b
 e. all of the above
14. Which of these muscles is *not* involved with the inspiration of air?
 a. diaphragm c. scalene
 b. external intercostals d. transversus thoracis
15. Given these muscles:
 1. external abdominal oblique
 2. internal abdominal oblique
 3. transversus abdominis
 Choose the arrangement that lists the muscles from most superficial to deepest.
 a. 1,2,3 c. 2,1,3 e. 3,1,2
 b. 1,3,2 d. 2,3,1
16. Tendinous intersections
 a. attach the rectus abdominis muscles to the xiphoid process.
 b. divide the rectus abdominis muscles into segments.
 c. separate the abdominal wall from the thigh.
 d. are the site of exit of blood vessels from the abdomen into the thigh.
 e. are the central point of attachment for all the abdominal muscles.
17. Which of these muscles can both elevate and depress the scapula?
 a. rhomboideus major and minor d. trapezius
 b. levator scapulae e. pectoralis minor
 c. serratus anterior
18. Which of these muscles does *not* adduct the arm (humerus)?
 a. latissimus dorsi c. teres major e. coracobrachialis
 b. deltoid d. pectoralis major
19. Which of these muscles is most directly involved in abduction of the arm (humerus)?
 a. supraspinatus c. teres minor e. subscapularis
 b. infraspinatus d. teres major
20. Which of these muscles would you expect to be especially well developed in a boxer known for his powerful jab (punching straight ahead)?
 a. biceps brachii c. trapezius e. supinator
 b. brachialis d. triceps brachii
21. Which of these muscles is an antagonist of the triceps brachii?
 a. biceps brachii c. latissimus dorsi e. supinator
 b. anconeus d. brachioradialis
22. The posterior group of forearm muscles is responsible for
 a. flexion of the wrist. d. both a and b.
 b. flexion of the fingers. e. all of the above.
 c. extension of the fingers.
23. Which of these muscles is an intrinsic hand muscle that moves the thumb?
 a. flexor pollicis brevis d. extensor pollicis longus
 b. flexor digiti minimi brevis e. all of the above
 c. flexor pollicis longus
24. Which of these muscles can extend the hip?
 a. gluteus maximus c. gluteus minimus e. sartorius
 b. gluteus medius d. tensor fasciae latae
25. Given these muscles:
 1. iliopsoas
 2. rectus femoris
 3. sartorius
 Which of the muscles flex the hip?
 a. 1 c. 1,3 e. 1,2,3
 b. 1,2 d. 2,3
26. Which of these muscles is found in the medial compartment of the thigh?
 a. rectus femoris c. gracilis e. semitendinosus
 b. sartorius d. vastus medialis
27. Which of these is *not* a muscle that can flex the knee?
 a. biceps femoris c. gastrocnemius e. sartorius
 b. vastus medialis d. gracilis

28. The _____ muscles evert the foot, whereas the _____ muscles invert the foot.
- fibularis (longus and brevis), gastrocnemius and soleus
 - fibularis (longus and brevis), tibialis anterior and extensor hallucis longus
 - tibialis anterior and extensor hallucis longus, fibularis longus and brevis
 - tibialis anterior and extensor hallucis longus, flexor digitorum longus and flexor hallucis longus
 - flexor digitorum longus and flexor hallucis longus, gastrocnemius and soleus
29. Which of these muscles causes plantar flexion of the foot?
- tibialis anterior
 - extensor digitorum longus
 - fibularis (peroneus) tertius
 - soleus
 - sartorius

Answers in Appendix E

CRITICAL THINKING

- For each of the following muscles, (1) describe the movement that the muscle produces and (2) name the muscles that act as synergists and antagonists for them: longus capitis, erector spinae, coracobrachialis.
- Propose an exercise that would benefit each of the following muscles specifically: biceps brachii, triceps brachii, deltoid, rectus abdominis, quadriceps femoris, and gastrocnemius.
- Consider only the effect of the brachioradialis muscle for this question. If a weight is held in the hand and the forearm is flexed, what type of lever system is in action? If the weight is placed on the forearm? Which system can lift more weight, and how far?
- A patient was involved in an automobile accident in which the car was “rear-ended,” resulting in whiplash injury of the head (hyperextension). What neck muscles might be injured in this type of accident? What is the easiest way to prevent such injury in an automobile accident?
- During surgery, a branch of a patient’s facial nerve was accidentally cut on one side of the face. As a result, after the operation, the lower eyelid and the corner of the patient’s mouth drooped on that side of the face. What muscles were apparently affected?
- When a person becomes unconscious, the tongue muscles relax and the tongue tends to retract or fall back and obstruct the airway. Which tongue muscle is responsible? How can this be prevented or reversed?
- The mechanical support of the head of the humerus in the glenoid fossa is weakest in the inferior direction. What muscles help prevent dislocation of the shoulder when a heavy weight, such as a suitcase, is carried?
- How would paralysis of the quadriceps femoris of the left leg affect a person’s ability to walk?
- Speedy Sprinter started a 200 m dash and fell to the ground in pain. Examination of her right leg revealed the following symptoms: inability to plantar flex the foot against resistance, normal ability to evert the foot, dorsiflexion of the foot more than normal, and abnormal bulging of the calf muscles. Explain the nature of her injury.
- What muscles are required to turn this page?

Answers in Appendix F

11

Functional Organization of Nervous Tissue

A hungry man prepares to drink a cup of hot soup. He smells the aroma and anticipates the taste of the soup. Feeling the warmth of the cup in his hands, he quickly raises the cup to his lips and takes a sip. The soup is so hot that it burns his lips and tongue. He jerks the cup away from his lips and gasps in pain. None of these sensations, thoughts, emotions, and movements would be possible without the nervous system, which is responsible for sensations, mental activities, and control of muscles and many glands. The nervous system is made up of the brain, spinal cord, nerves and sensory receptors.

This chapter explains the *functions of the nervous system* (p. 375), the *divisions of the nervous system* (p. 375), the *cells of the nervous system* (p. 377), the *organization of nervous tissue* (p. 382), *electric signals* (p. 382), the *synapse* (p. 394), and *neuronal pathways and circuits* (p. 404).

Light photomicrograph of pyramid-shaped neurons (*green*) growing on a fibrous network (*yellow*) in the central nervous system.

FUNCTIONS OF THE NERVOUS SYSTEM

The nervous system is involved in most body functions. Some of the major functions of the nervous system are

1. **Sensory input.** Sensory receptors monitor numerous external and internal stimuli. Some stimuli result in sensations we are aware of, such as sight, vision, hearing, taste, smell, touch, pain, body position, and temperature. Other stimuli, such as blood pH, blood gases, or blood pressure, are processed at an unconscious level.
2. **Integration.** The brain and spinal cord are the major organs for processing sensory input and initiating responses. The input may produce an immediate response, may be stored as memory, or may be ignored.
3. **Control of muscles and glands.** Skeletal muscles normally contract only when stimulated by the nervous system, and the nervous system controls the major movements of the body through the control of skeletal muscle. Some smooth muscle, such as in the walls of blood vessels, contracts only when stimulated by the nervous system or hormones (see chapter 18). Cardiac muscle and some smooth muscle, such as in the wall of the stomach, contract autorhythmically—that is, no external stimulation is necessary for contraction to occur. Although the nervous system does not initiate contraction in these muscles, it can cause the contractions to occur more rapidly or slowly. Finally, the nervous system controls the secretions from many glands, such as sweat glands, salivary glands, and the glands of the digestive system.
4. **Homeostasis.** The regulatory and coordinating activities of the nervous system are necessary for maintaining homeostasis. The trillions of cells in the human body do not function independently of each other but must work together to maintain homeostasis. For example, heart cells must contract at a rate that ensures adequate delivery of blood, skeletal muscles of respiration must contract at a rate that ensures oxygenation of blood, and kidney cells must regulate blood volume and remove waste products. The nervous system can stimulate or inhibit the activities of these and other structures to help maintain homeostasis.
5. **Mental activity.** The brain is the center of mental activities, including consciousness, thinking, memory, and emotions.

1 List and give examples of the general functions of the nervous system.

DIVISIONS OF THE NERVOUS SYSTEM

Humans have only one nervous system, even though some of its subdivisions are referred to as separate systems (figure 11.1). Thus, the central nervous system and the peripheral nervous system are subdivisions of the nervous system, instead of separate organ systems, as their names suggest. The **central nervous system (CNS)** consists of the brain and the spinal cord. The brain is located within the skull, and the spinal cord is located within the vertebral canal, formed by the vertebrae (see chapter 7). The brain and spinal cord are continuous with each other at the foramen magnum.

FIGURE 11.1 Nervous System

The central nervous system (CNS) consists of the brain and spinal cord. The peripheral nervous system (PNS) consists of cranial nerves, which arise from the brain, and spinal nerves, which arise from the spinal cord. The nerves, which are shown cut in the illustration, actually extend throughout the body.

The **peripheral nervous system (PNS)** is external to the CNS. It consists of sensory receptors, nerves, ganglia, and plexuses. **Sensory receptors** are the endings of nerve cells or separate, specialized cells that detect temperature, pain, touch, pressure, light, sound, odors, and other stimuli. Sensory receptors are located in the skin, muscles, joints, internal organs, and specialized sensory organs, such as the eyes and ears. A **nerve** is a bundle of axons and their sheaths; it connects the CNS to sensory receptors, muscles, and glands. Twelve pairs of **cranial nerves** originate from the brain, and 31 pairs of **spinal nerves** originate from the spinal cord (see figure 11.1). A **ganglion** (gang'glē-on; pl. *ganglia*, gang'glē-ă; knot) is a collection of neuron cell bodies located outside the CNS. A **plexus** (plek'sus; braid) is an extensive network of axons and, in some cases, neuron cell bodies, located outside the CNS.

The PNS can be divided into two subcategories. The **sensory, or afferent, division** transmits electric signals, called **action potentials**, from the sensory receptors to the CNS. The cell bodies of sensory neurons are located in dorsal root ganglia near the spinal

cord (figure 11.2a) or in ganglia near the origin of certain cranial nerves. The **motor**, or **effluent, division** transmits action potentials from the CNS to effector organs, such as muscles and glands.

The motor division is divided into the **somatic nervous system** and the **autonomic nervous system (ANS)**. The somatic nervous system transmits action potentials from the CNS to skeletal muscles (figure 11.2b). Skeletal muscles are voluntarily controlled through the somatic nervous system. The cell bodies of somatic motor neurons are located within the CNS, and their axons extend through nerves to form synapses with skeletal muscle cells. A **synapse** is the junction of a nerve cell with another cell. The neuromuscular junction, the synapse between a neuron and a skeletal muscle cell, is discussed in detail in chapter 9. Nerve cells can also form synapses with other nerve cells, smooth muscle cells, cardiac muscle cells, and gland cells.

The ANS transmits action potentials from the CNS to smooth muscle, cardiac muscle, and certain glands. Subconscious, or involuntary, control of smooth muscle, cardiac muscle, and glands occurs through the ANS. The ANS has two sets of neurons in a series between the CNS and the effector organs (figure 11.2c). Cell bodies of the first neurons are within the CNS and send their axons to autonomic ganglia, where neuron cell bodies of the second neurons are located. Synapses exist between the first and second neurons within the autonomic ganglia, and the axons of the second neurons extend from the autonomic ganglia to the effector organs.

The ANS is subdivided into the sympathetic and the parasympathetic divisions and the enteric nervous system. In general, the **sympathetic division** is most active during physical activity, whereas the **parasympathetic division** regulates resting or vegetative functions, such as digesting food or emptying the urinary bladder. The **enteric nervous system** consists of plexuses within the wall of the digestive tract (see figure 24.4). Although the enteric nervous system is capable of controlling the digestive tract independently of the CNS, it is considered part of the ANS because of the parasympathetic and sympathetic neurons that contribute to the plexuses. See chapters 16 and 24 for details on the enteric nervous system.

The sensory division of the PNS detects stimuli and transmits information in the form of action potentials to the CNS (figure 11.3). The CNS is the major site for processing information, initiating responses, and integrating mental processes. It is much like a computer, with the ability to receive input, process and store information, and generate responses. The motor division of the PNS conducts action potentials from the CNS to muscles and glands.

(a) Sensory division

(b) Somatic nervous system

(c) Autonomic nervous system

FIGURE 11.2 Divisions of the Peripheral Nervous System

(a) Sensory division. A neuron with its cell body in a dorsal root ganglion.
 (b) Somatic nervous system. The neuron extends from the CNS to skeletal muscle.
 (c) Autonomic nervous system. Two neurons are in series between the CNS and the effector cells (smooth muscle or glands). The first neuron has its cell body in the CNS, and the second neuron has its cell body in an autonomic ganglion.

2 Define CNS and PNS.

3 What is a sensory receptor, nerve, ganglion, and plexus?

4 Based on the direction they transmit action potentials, what are the two subcategories of the PNS?

5 Based on the structures they supply, what are the two subcategories of the motor division?

6 Where are the cell bodies of sensory, somatic motor, and autonomic neurons located? What is a synapse?

7 What are the subcategories of the ANS?

8 Compare the general functions of the CNS and the PNS.

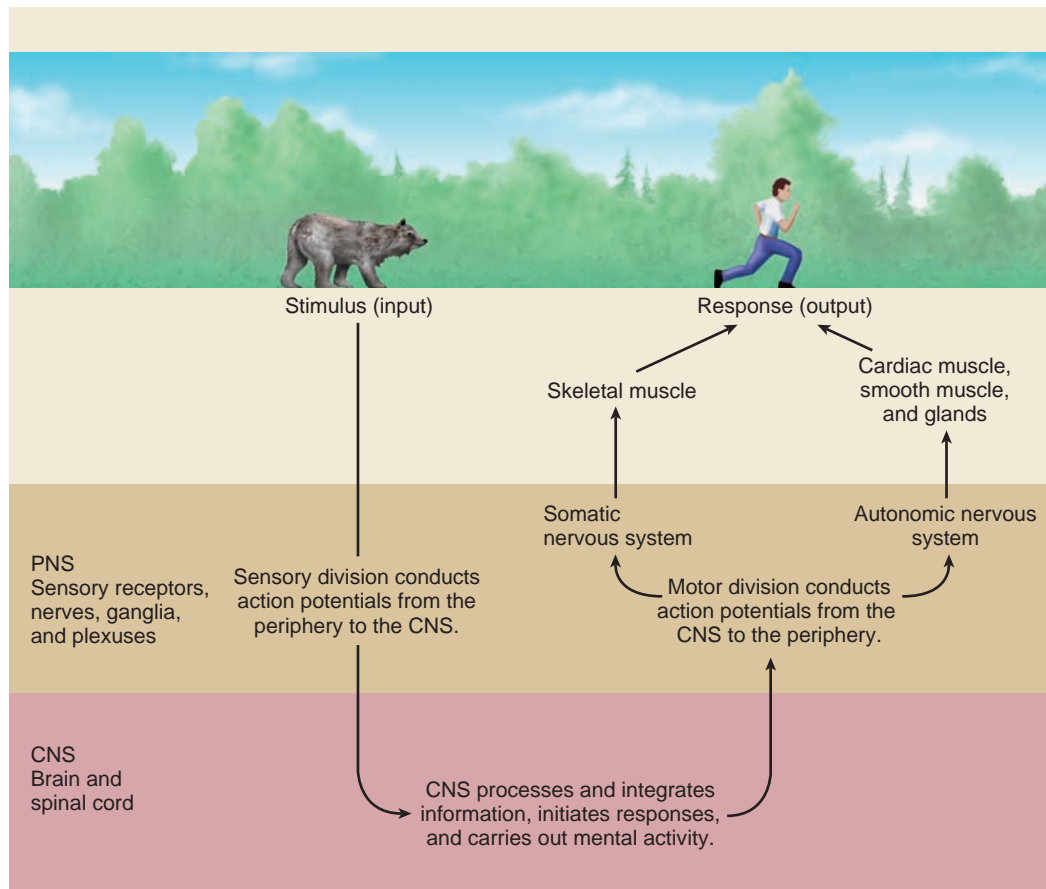

FIGURE 11.3 Organization of the Nervous System

The sensory division of the peripheral nervous system (PNS) detects stimuli and conducts action potentials to the central nervous system (CNS). The CNS interprets incoming action potentials and initiates action potentials that are conducted through the motor division to produce a response. The motor division is divided into the somatic nervous system and the autonomic nervous system.

CELLS OF THE NERVOUS SYSTEM

The nervous system is made up of neurons and nonneural cells. Neurons receive stimuli and conduct action potentials. Nonneural cells are called **glial** (glī'äl, glē'äl) **cells**, or **neuroglia** (noo-rog'lē-ä; nerve glue), and they support and protect neurons and perform other functions. Glial cells account for over half of the brain's weight, and there can be 10 to 50 times more glial cells than neurons in various parts of the brain.

Neurons

Neurons, or **nerve cells**, receive stimuli and transmit action potentials to other neurons or to effector organs. They are organized to form complex networks that perform the functions of the nervous system. Each neuron consists of a cell body and two types of processes. The cell body is called the **neuron cell body**, or **soma** (sō'mä; body), and the processes are called **dendrites** (den'drītz) and **axons** (ak'sonz; figure 11.4). *Dendrite* means tree and refers to the branching organization of dendrites. *Axon* means axis and refers to the straight alignment and uniform diameter of most axons. Axons are also referred to as **nerve fibers**.

Neuron Cell Body

Each neuron cell body contains a single relatively large and centrally located nucleus with a prominent nucleolus. Extensive rough endoplasmic reticulum and Golgi apparatuses surround the nucleus, and a moderate number of mitochondria and other organelles are present. Randomly arranged lipid droplets and melanin pigments accumulate in the cytoplasm of some neuron cell bodies. The lipid droplets and melanin pigments increase as humans age, but their functional significance is unknown. Large numbers of intermediate filaments (neurofilaments) and microtubules form bundles that course through the cytoplasm in all directions. The neurofilaments separate abundant rough endoplasmic reticulum (ER), called **Nissl substance**, which is located in the cell body and dendrites but not the axon. Nissl substance is the primary site of protein synthesis in neurons.

PREDICT 1

Predict the effect on the part of a severed axon that is no longer connected to its neuron cell body. Explain your prediction.

FIGURE 11.4 Neuron

The structural features of a neuron include a cell body and two types of cell processes: dendrites and an axon.

Dendrites

Dendrites are short, often highly branched cytoplasmic extensions that are tapered from their bases at the neuron cell body to their tips (see figure 11.4). Many dendrite surfaces have small extensions

called **dendritic spines**, where axons of other neurons form synapses with the dendrites. Dendrites are the input part of the neuron. When stimulated, they generate small electric currents, which are conducted to the neuron cell body.

Axons

In most neurons, a single axon arises from a cone-shaped area of the neuron cell body called the **axon hillock**. The beginning of the axon is called the **initial segment**. An axon can remain as a single structure or can branch to form collateral axons, or side branches (see figure 11.4). Each axon has a constant diameter, but it can vary in length from a few millimeters to more than 1 meter. The cytoplasm of an axon is sometimes called **axoplasm**, and its plasma membrane is called the **axolemma** (*lemma* is Greek, meaning husk or sheath). Axons terminate by branching to form small extensions with enlarged ends called **presynaptic terminals**. Numerous small vesicles containing neurotransmitters are present in the presynaptic terminals. The presynaptic terminals release the **neurotransmitters** which are chemicals that cross the synapse to stimulate or inhibit the postsynaptic cell. Functionally, action potentials are generated at the **trigger zone**, which consists of the axon hillock and the part of the axon nearest the cell body. Action potentials are conducted along the axon to the presynaptic terminal, where they stimulate the release of neurotransmitters.

Axon transport mechanisms can move cytoskeletal proteins (see chapter 3), organelles (such as mitochondria), and vesicles containing neurohormones to be secreted (see chapter 17) down the axon to the presynaptic terminals. In addition, damaged organelles, recycled plasma membrane, and substances taken in by endocytosis can be transported up the axon to the neuron cell body. The movement of materials within the axon is necessary for its normal function, but it also provides a way for infectious agents and harmful substances to be transported from the periphery to the CNS. For example, rabies and herpes viruses can enter damaged axons in the skin and be transported within the axons to the CNS.

- 9 Compare the functions of glial cells and neurons.
- 10 Describe and give the function of a neuron cell body, a dendrite, and an axon.
- 11 Define trigger zone, presynaptic terminal, and neurotransmitter.

Types of Neurons

Neurons are classified according to their function or structure. The functional classification is based on the direction in which action potentials are conducted. **Sensory**, or **afferent, neurons** conduct action potentials toward the CNS; **motor**, or **efferent, neurons** conduct action potentials away from the CNS toward muscles or glands. **Interneurons**, or **association neurons**, conduct action potentials from one neuron to another within the CNS.

The structural classification scheme is based on the number of processes that extend from the neuron cell body. The three major categories of neurons are multipolar, bipolar, and unipolar.

Multipolar neurons have many dendrites and a single axon. The dendrites vary in number and in their degree of branching

FIGURE 11.5 Types of Neurons

Neurons are classified structurally by the number of cell processes extending from their cell bodies. Dendrites and sensory receptors are specialized to receive stimuli and axons are specialized to conduct action potentials.

(figure 11.5a). Most of the neurons within the CNS and motor neurons are multipolar.

Bipolar neurons have two processes: one dendrite and one axon (figure 11.5b). The dendrite often is specialized to receive the stimulus, and the axon conducts action potentials to the CNS. Bipolar neurons are located in some sensory organs, such as in the retina of the eye and in the nasal cavity.

Unipolar neurons have a single process extending from the cell body (figure 11.5c). This process divides into two branches a short distance from the cell body. One branch extends to the CNS, and the other branch extends to the periphery and has dendritelike sensory receptors. The two branches function as a single axon. The sensory receptors respond to stimuli, resulting in the production of action potentials that are transmitted to the CNS. Most sensory neurons are unipolar neurons. According to a functional definition of a dendrite, the branch of a unipolar neuron that extends from the periphery to the neuron cell body can be classified as a dendrite because it conducts action potentials toward the neuron cell body. This branch is usually referred to as an axon, however, for two reasons: It cannot be distinguished from an axon on the basis of its structure, and it conducts action potentials in the same fashion as an axon.

12 Describe the three types of neurons based on their function.

13 Describe the three types of neurons based on their structure, and give an example of where each type is found.

Glial Cells of the CNS

Glial cells are the major supporting cells in the CNS; they participate in the formation of a permeability barrier between the blood and the neurons, phagocytize foreign substances, produce

cerebrospinal fluid, and form myelin sheaths around axons. There are four types of CNS glial cells, each with unique structural and functional characteristics.

Astrocytes

Astrocytes (as'trō-sītz, *aster* is Greek, meaning star) are glial cells that are star-shaped because of cytoplasmic processes that extend from the cell body. These extensions widen and spread out to form foot processes, which cover the surfaces of blood vessels (figure 11.6), neurons, and the pia mater. (The pia mater is a membrane covering the outside of the brain and spinal cord.) Astrocytes have an extensive cytoskeleton of microfilaments (see chapter 3), which enables them to form a supporting framework for blood vessels and neurons.

Astrocytes play a role in regulating the extracellular composition of brain fluid. They release chemicals that promote the formation of tight junctions (see chapter 4) between the endothelial cells of capillaries. The endothelial cells with their tight junctions form the **blood–brain barrier**, which determines what substances can pass from the blood into the nervous tissue of the brain and spinal cord. The blood–brain barrier protects neurons from toxic substances in the blood, allows the exchange of nutrients and waste products between neurons and the blood, and prevents fluctuations in the composition of the blood from affecting the functions of the brain.

Astrocytes contribute to beneficial and detrimental responses to tissue damage in the CNS. Almost all injuries to CNS tissue induce **reactive astrocytosis**, in which astrocytes participate in walling off the injury site and limiting the spread of inflammation to the surrounding healthy tissue. Reactive scar-forming astrocytes also limit the regeneration of the axons of injured neurons.

Other astrocyte functions include the release of chemicals that promote the development of synapses and assistance in the

FIGURE 11.6 Astrocytes

Astrocyte processes form foot processes, which cover the surfaces of neurons, blood vessels, and the pia mater. The astrocytes provide structural support and play a role in regulating what substances from the blood reach the neurons.

regulation of synaptic activity through the synthesis, absorption, and recycling of neurotransmitters.

Ependymal Cells

Ependymal (ep-en'di-mäl) cells line the ventricles (cavities) of the brain and the central canal of the spinal cord (figure 11.7a). Specialized ependymal cells and blood vessels form the **choroid plexuses** (ko'royd plek'süs-ez; figure 11.7b), which are located within certain regions of the ventricles. The choroid plexuses secrete the cerebrospinal fluid that circulates through the ventricles of the brain (see chapter 13). The free surface of the ependymal cells frequently has patches of cilia that help move cerebrospinal fluid through the cavities of the brain. Ependymal cells also have long processes at their basal surfaces that extend deep into the brain and the spinal cord and seem, in some cases, to have astrocyte-like functions.

Microglia

Microglia (mī-krog'lē-ă) are glial cells in the CNS that become mobile and phagocytic in response to inflammation. They phagocytize necrotic tissue, microorganisms, and other foreign substances that invade the CNS (figure 11.8).

Microglia and Brain Damage

Numerous microglia migrate to areas damaged by infection, trauma, or stroke and perform phagocytosis. A pathologist can identify these damaged areas in the CNS during an autopsy because large numbers of microglia are found in them.

FIGURE 11.7 Ependymal Cells

(a) Ciliated ependymal cells lining the ventricles of the brain and the central canal of the spinal cord help move cerebrospinal fluid. (b) Ependymal cells on the surface of the choroid plexus secrete cerebrospinal fluid.

FIGURE 11.8 Microglia

Microglia are phagocytic cells within the CNS.

Oligodendrocytes

Oligodendrocytes (ol'i-gō-den'drō-sītz) have cytoplasmic extensions that can surround axons. If the cytoplasmic extensions wrap many times around the axons, they form **myelin** (mī'ě-lin) **sheaths**. A single oligodendrocyte can form myelin sheaths around portions of several axons (figure 11.9).

FIGURE 11.9 Oligodendrocytes

Extensions from oligodendrocytes form part of the myelin sheaths of several axons within the CNS.

Glial Cells of the PNS

Schwann cells, or **neurolemmocytes** (noor-ō-lem'mō-sītz), are glial cells in the PNS that wrap around axons. If a Schwann cell wraps many times around an axon, it forms a myelin sheath. Unlike oligodendrocytes, however, each Schwann cell forms a myelin sheath around a portion of only one axon (figure 11.10).

Satellite cells surround neuron cell bodies in sensory ganglia (see figure 11.10). They provide support and nutrition to the neuron cell bodies, and they protect neurons from heavy metal poisons, such as lead and mercury, by absorbing them and reducing their access to the neuron cell bodies.

- 14** Which type of glial cell supports neurons and blood vessels and promotes the formation of the blood–brain barrier? What is the blood–brain barrier, and what is its function?

FIGURE 11.10 Glial Cells of the PNS

Neuron cell bodies within ganglia are surrounded by satellite cells. Schwann cells form the myelin sheath of an axon within the PNS.

- 15** Name the different kinds of glial cells responsible for the following functions: production of cerebrospinal fluid, phagocytosis, production of myelin sheaths in the CNS, production of myelin sheaths in the PNS, support of neuron cell bodies in the PNS.

Myelinated and Unmyelinated Axons

Cytoplasmic extensions of the Schwann cells in the PNS and of the oligodendrocytes in the CNS surround axons to form either myelinated or unmyelinated axons. Myelin protects and electrically insulates axons from one another. In addition, action potentials travel along myelinated axons more rapidly than along unmyelinated axons (see “Propagation of Action Potentials,” p. 391).

In **myelinated axons**, the extensions from Schwann cells or oligodendrocytes repeatedly wrap around a segment of an axon to form a series of tightly wrapped membranes rich in phospholipids with little cytoplasm sandwiched between the membrane layers (figure 11.11a). The tightly wrapped membranes constitute the myelin sheath and give myelinated axons a white appearance because of the high lipid concentration. The myelin sheath is not continuous but is interrupted every 0.3–1.5 mm. At these locations, there are slight constrictions where the myelin sheaths of adjacent cells dip toward the axon but do not cover it, leaving a bare area 2–3 μm in length. These interruptions in the myelin sheath are the **nodes of Ranvier** (ron've-ā). Although the axon at a node of Ranvier is not covered with myelin, Schwann cells or oligodendrocytes extend across the node and connect to each other.

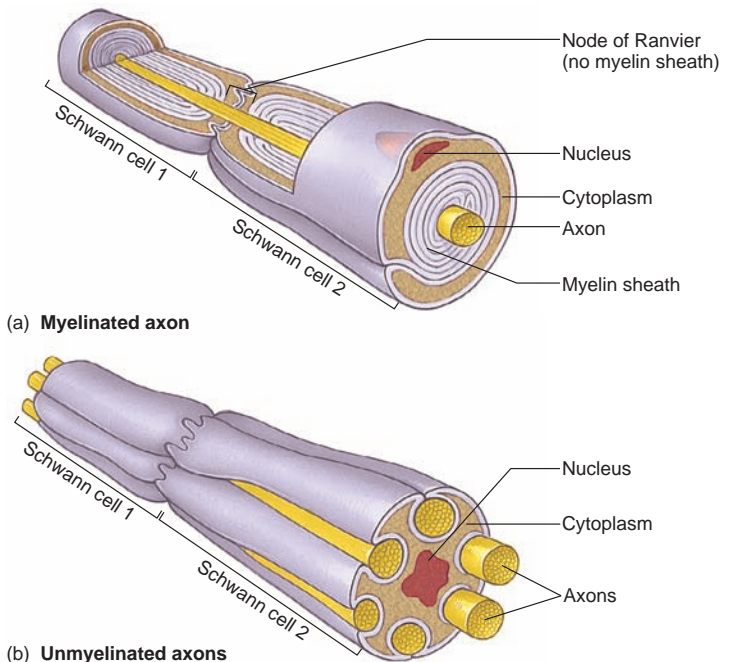

FIGURE 11.11 Comparison of Myelinated and Unmyelinated Axons

(a) Myelinated axon with two Schwann cells forming part of the myelin sheath around a single axon. Each Schwann cell surrounds part of one axon. (b) Unmyelinated axons with two Schwann cells surrounding several axons in parallel formation. Each Schwann cell surrounds part of several axons.

Unmyelinated axons rest in invaginations of the Schwann cells or oligodendrocytes (figure 11.11*b*). The cell's plasma membrane surrounds each axon but does not wrap around it many times. Thus, each axon is surrounded by a series of cells, and each cell can simultaneously surround more than one unmyelinated axon.

16 Define myelin sheath and node of Ranvier.

17 How are myelinated and unmyelinated axons different from each other?

ORGANIZATION OF NERVOUS TISSUE

Nervous tissue is organized so that axons form bundles, and neuron cell bodies and their relatively short dendrites are grouped together. Bundles of parallel axons with their associated myelin sheaths are whitish in color, which accounts for their name, **white matter**. Collections of neuron cell bodies and unmyelinated axons are grayer in color and are called **gray matter**.

The axons that make up the white matter of the CNS form **nerve tracts**, which propagate action potentials from one area in the CNS to another. The gray matter of the CNS performs integrative functions or acts as relay areas in which axons synapse with the cell bodies of other neurons. The central area of the spinal cord is gray matter, and the outer surface of much of the brain consists of gray matter called **cortex**. Within the brain are other collections of gray matter called **nuclei**.

In the PNS, bundles of axons form nerves, which conduct action potentials to and from the CNS. Most nerves contain myelinated axons, but some consist of unmyelinated axons. Collections of neuron cell bodies in the PNS are called ganglia.

18 What is white and gray matter?

19 Define and state the location of nerve tracts, nerves, brain cortex, nuclei, and ganglia.

ELECTRIC SIGNALS

Like computers, humans depend on electric signals to communicate and process information. The electric signals produced by cells are called **action potentials**. They are an important means by which cells transfer information from one part of the body to another. For example, stimuli, such as light, sound, and pressure, act on specialized sensory cells in the eye, ear, and skin to produce action potentials, which are conducted from these cells to the spinal cord and brain. Action potentials originating within the brain and spinal cord are conducted to muscles and certain glands to regulate their activities.

The ability to perceive our environment, perform complex mental activities, and act depends on action potentials. For example, interpreting the action potentials received from sensory cells results in the sensations of sight, hearing, and touch. Complex mental activities, such as conscious thought, memory, and emotions, result from action potentials. The contraction of muscles and the secretion of certain glands occur in response to action potentials generated in them.

A basic knowledge of the electrical properties of cells is necessary for understanding many of the normal functions and pathologies of the body. These properties result from the ionic

concentration differences across the plasma membrane and from the permeability characteristics of the plasma membrane.

Concentration Differences Across the Plasma Membrane

Table 11.1 lists the concentration differences for positively charged ions (cations) and negatively charged ions (anions) between the intracellular and extracellular fluids. The concentration of sodium ions (Na^+) and chloride ions (Cl^-) is much greater outside the cell than inside. The concentration of potassium ions (K^+) and negatively charged molecules, such as proteins and other molecules containing phosphate, is much greater inside the cell than outside. Note that a steep concentration gradient (see chapter 3) exists for Na^+ from outside the cell to the inside. Also, a steep concentration gradient exists for K^+ from the inside to the outside of the cell.

Differences in intracellular and extracellular concentrations of ions result primarily from (1) the Na^+-K^+ pump and (2) the permeability characteristics of the plasma membrane.

The Na^+-K^+ Pump

The differences in K^+ and Na^+ concentrations across the plasma membrane are maintained primarily by the action of the **Na^+-K^+ pump** (see figure 3.21). Through active transport, the Na^+-K^+ pump moves K^+ and Na^+ through the plasma membrane against their concentration gradients. Potassium ions are transported into the cell, increasing the concentration of K^+ inside the cell, and Na^+ are transported out of the cell, increasing the concentration of Na^+ outside the cell. Approximately three Na^+ are transported out of the cell and two K^+ are transported into the cell for each ATP molecule used.

TABLE 11.1 Representative Concentrations of the Principal Cations and Anions in Extracellular and Intracellular Fluids of Vertebrates

Ions	Intracellular Fluid (mEq/L)*	Extracellular Fluid (mEq/L)
Cations (Positive)		
Potassium (K^+)	148	5
Sodium (Na^+)	10	142
Calcium (Ca^{2+})	<1	5
Others	41	3
TOTAL	200	155
Anions (Negative)		
Proteins	56	16
Chloride (Cl^-)	4	103
Others	140	36
TOTAL	200	155

*See Appendix C for an explanation of milliequivalents (mEq).

Permeability Characteristics of the Plasma Membrane

As noted in chapter 3, the plasma membrane is selectively permeable, thus allowing some, but not all, substances to pass through it. Negatively charged proteins are synthesized inside the cell, and because of their large size and their solubility characteristics they cannot readily diffuse across the plasma membrane (figure 11.12). Negatively charged Cl^- are repelled by the negatively charged proteins and other negatively charged ions inside the cell. Chloride ions diffuse through the plasma membrane and accumulate outside it, resulting in a higher concentration of Cl^- outside the cell than inside.

Ions pass through the plasma membrane through ion channels. The two major types of ion channels are leak channels and gated ion channels.

Leak Channels

Leak channels, or **nongated ion channels**, are always open and are responsible for the permeability of the plasma membrane to ions when the plasma membrane is unstimulated, or at rest (see figure 11.12). Each ion channel is specific for one type of ion, although the specificity is not absolute. The number of each type of leak channels in the plasma membrane determines the permeability characteristics of the resting plasma membrane to different types of ions. The plasma membrane is more permeable to K^+ and Cl^- and much less permeable to Na^+ because there are many more K^+ and Cl^- leak channels than Na^+ leak channels in the plasma membrane.

Gated Ion Channels

Gated ion channels open and close in response to stimuli. By opening and closing, these channels can change the permeability characteristics of the plasma membrane. The major types of gated ion channels are

1. **Ligand-gated ion channels.** A **ligand** is a molecule that binds to a receptor. A **receptor** is a protein or glycoprotein that has a **receptor site** to which a ligand can bind. Most receptors are located in the plasma membrane. **Ligand-gated ion channels** are receptors that have an extracellular receptor site and a membrane-spanning part that forms an ion channel. When a ligand binds to the receptor site, the ion channel opens or closes. For example, the neurotransmitter acetylcholine released from the presynaptic terminal of a neuron is a chemical signal that can bind to a ligand-gated Na^+ channel in the membrane of a muscle cell. As a result, the Na^+ channel opens, allowing Na^+ to enter the cell (see figure 3.10). Ligand-gated ion channels exist for Na^+ , K^+ , Ca^{2+} , and Cl^- , and these channels are common in tissues such as nervous and muscle tissues, as well as glands.
2. **Voltage-gated ion channels.** These channels open and close in response to small voltage changes across the plasma membrane. In an unstimulated cell, the inside of the plasma membrane is negatively charged relative to the outside. This charge difference can be measured in units called **millivolts** (mV; $1 \text{ mV} = 1/1000 \text{ V}$). When a cell is stimulated, the permeability of the plasma membrane changes because gated ion channels open or close. The movement of ions into or out of the cell changes the charge difference across the plasma

FIGURE 11.12 Membrane Permeability and Ion Channels

The permeability of the membrane to K^+ and Cl^- is greater than its permeability to Na^+ because some K^+ and Cl^- leak channels are open, whereas most gated Na^+ channels are closed. The membrane is not permeable to the negatively charged proteins inside the cell because they are too large to pass through membrane channels.

membrane, which causes voltage-gated ion channels to open or close. Voltage-gated channels specific for Na^+ and K^+ are most numerous in electrically excitable tissues, but voltage-gated Ca^{2+} channels are also important, especially in smooth muscle and cardiac muscle cells (see chapters 9 and 20).

3. **Other gated ion channels.** Gated ion channels that respond to stimuli other than ligands or voltage changes are present in specialized electrically excitable tissues. Examples include touch receptors, which respond to mechanical stimulation of the skin, and temperature receptors, which respond to temperature changes in the skin.

20 Describe the concentration differences for Na^+ and K^+ that exist across the plasma membrane.

21 In what direction, into or out of cells, does the Na^+-K^+ pump move Na^+ and K^+ ?

22 Define leak channels and gated ion channels. How are they responsible for the permeability characteristics of a resting versus a stimulated plasma membrane?

23 Define ligand, receptor, and receptor site.

24 What kinds of stimuli cause gated ion channels to open or close?

Establishing the Resting Membrane Potential

Intracellular fluid is electrically neutral because the number of positively charged cations is equal to the number of negatively charged anions (see table 11.1). Similarly, extracellular fluid is electrically neutral. There is, however, a difference in charge across the plasma membrane. The immediate inside of the membrane is negative, compared with the immediate outside of

FIGURE 11.13 Measuring Resting Membrane Potential

The recording electrode is inside the cell; the reference electrode is outside. A potential difference of about -70 mV is recorded, with the inside of the plasma membrane negative with respect to the outside of the membrane.

the membrane (figure 11.13). The plasma membrane, therefore, is said to be **polarized** because there are opposite charges, or poles, across the membrane.

The electric charge difference across the plasma membrane is called a **potential difference**. In an unstimulated, or resting, cell, the potential difference is called the **resting membrane potential**. It can be measured using a voltmeter or an oscilloscope connected to microelectrodes positioned just inside and outside the plasma membrane (see figure 11.13). The resting membrane potential of nerve cells is approximately -70 mV and of skeletal muscle cells is

approximately -85 mV (see chapter 9). The potential difference is reported as a negative number because the inside of the plasma membrane is negative, compared with the outside. The greater the charge difference across the plasma membrane, the greater the potential difference. A resting membrane potential of -85 mV has a greater charge difference than a resting membrane potential of -70 mV.

The resting membrane potential results from the permeability characteristics of the resting plasma membrane and the difference in concentration of ions between the intracellular and the extracellular fluids. The plasma membrane is somewhat permeable to K^+ because of K^+ leak channels. Positively charged K^+ can therefore diffuse down their concentration gradient from inside to just outside the cell (figure 11.14). Negatively charged proteins and other molecules cannot diffuse through the plasma membrane with the K^+ . As K^+ diffuse out of the cell, the loss of positive charges makes the inside of the plasma membrane more negative. Because opposite charges attract, the K^+ are attracted back toward the cell. The accumulation of K^+ just outside of the plasma membrane makes the outside of the plasma membrane positive relative to the inside. The resting membrane potential is an equilibrium that is established when the tendency for K^+ to diffuse out of the cell, because of the K^+ concentration gradient, is equal to the tendency for K^+ to move into the cell because of the attraction of the positively charged K^+ to negatively charged proteins and other molecules.

PREDICT 2

Given that tissue A has significantly more K^+ leak channels than tissue B, which tissue has the larger resting membrane potential?

Other ions, such as Na^+ , Cl^- , and Ca^{2+} , have a minor influence on the resting membrane potential, but the major influence

FIGURE 11.14 Potassium Ions and the Resting Membrane Potential

is from K^+ . Because the resting plasma membrane is 50–100 times less permeable to Na^+ than to K^+ , very few Na^+ can diffuse from the outside to the inside of the resting cell. The resting plasma membrane is not very permeable to Ca^{2+} , either. The plasma membrane is relatively permeable to Cl^- , but these negatively charged ions are repelled by the negative charge inside the cell.

The resting membrane potential is proportional to the tendency for K^+ to diffuse out of the cell, not to the actual rate of flow for K^+ . At equilibrium, very few of these ions pass through the plasma membrane because their movement out of the cell is opposed by the negative charge inside the cell. Still, some Na^+ and K^+ diffuse continuously across the plasma membrane, although at a low rate. The large concentration gradients for Na^+ and K^+ would eventually disappear without the continuous activity of the Na^+-K^+ pump.

As already noted, the function of the Na^+-K^+ pump is to maintain the normal concentration gradients for Na^+ and K^+ across the plasma membrane. The pump is also responsible for a small portion of the resting membrane potential, usually less than 15 mV, because it transports approximately three Na^+ out of the cell and two K^+ into the cell for each ATP molecule used (see figure 3.21). The outside of the plasma membrane becomes more positively charged than the inside because more positively charged ions are pumped out of the cell than are pumped into it.

The characteristics responsible for a resting membrane potential are summarized in table 11.2.

25 Define resting membrane potential. Is the outside of the plasma membrane positively or negatively charged relative to the inside?

26 Explain the role of K^+ and the Na^+-K^+ pump in establishing the resting membrane potential.

Changing the Resting Membrane Potential

The resting membrane potential can decrease or increase (figure 11.15). **Depolarization** (dē-pō'lār-i-zā'shūn) is a decrease in the membrane potential in which the charge difference, or polarity, across the plasma membrane decreases. **Hyperpolarization** (hī'per-pō'lār-i-zā'shūn) is an increase in the membrane potential caused by an increase in the charge difference across the plasma

TABLE 11.2 Characteristics Responsible for the Resting Membrane Potential

1.	The number of charged molecules and ions inside and outside the cell is nearly equal.
2.	The concentration of K^+ is higher inside than outside the cell, and the concentration of Na^+ is higher outside than inside the cell.
3.	The plasma membrane is 50–100 times more permeable to K^+ than to other positively charged ions, such as Na^+ .
4.	The plasma membrane is impermeable to large, intracellular, negatively charged molecules, such as proteins.
5.	Potassium ions tend to diffuse across the plasma membrane from the inside to the outside of the cell.
6.	Because negatively charged molecules cannot follow the positively charged K^+ , a small negative charge develops just inside the plasma membrane.
7.	The negative charge inside the cell attracts positively charged K^+ . When the negative charge inside the cell is great enough to prevent additional K^+ from diffusing out of the cell through the plasma membrane, an equilibrium is established.
8.	The charge difference across the plasma membrane at equilibrium is reflected as a difference in potential, which is measured in millivolts (mV).
9.	The resting membrane potential is proportional to the potential for K^+ to diffuse out of the cell but not to the actual rate of flow for K^+ .
10.	At equilibrium, there is very little movement of K^+ or other ions across the plasma membrane.

membrane. The charge difference can be changed by decreasing or increasing the movement of ions across the plasma membrane. Ion movement can be changed by altering ion concentration gradients or ion permeability.

Potassium Ions

Changes in the K^+ concentration gradient and K^+ permeability can change the resting membrane potential. An increase in the extracellular concentration of K^+ decreases the K^+ concentration gradient because the concentration of K^+ is lower outside than inside a cell. As a consequence, the tendency for K^+ to diffuse out

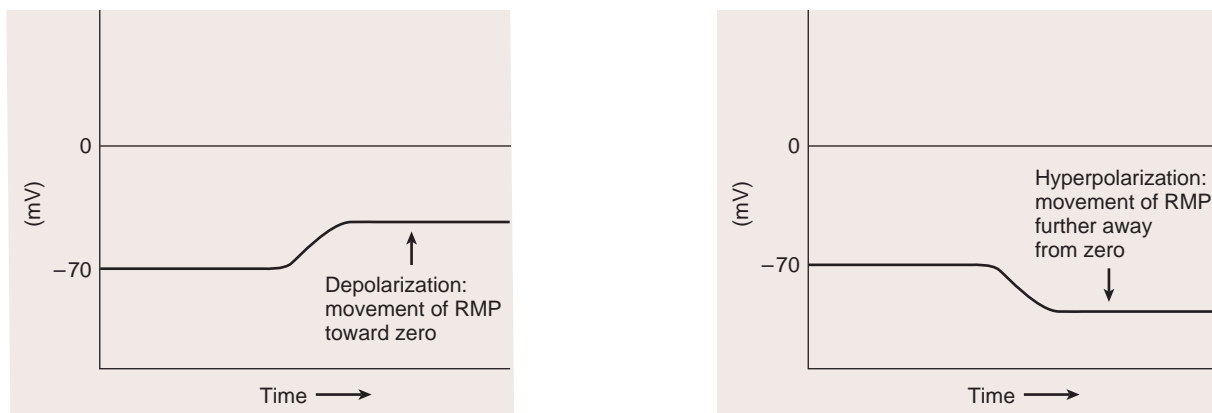

FIGURE 11.15 Depolarization and Hyperpolarization of the Resting Membrane Potential

(a) In depolarization, membrane potential decreases, becoming less negative. (b) In hyperpolarization, membrane potential increases, becoming more negative.

of the cell decreases, and a smaller negative charge inside the cell is required to oppose the diffusion of K^+ out of the cell. At this new equilibrium, the smaller charge difference across the plasma membrane is a depolarization. On the other hand, a decrease in the extracellular concentration of K^+ increase the K^+ concentration gradient. As a result, the tendency for K^+ to diffuse out of the cell increases, and a larger negative charge inside the cell is required to resist that diffusion. At this new equilibrium, the larger charge difference across the plasma membrane is a hyperpolarization.

Although K^+ leak channels allow some K^+ to diffuse across the plasma membrane, the resting membrane is not freely permeable to K^+ . There are gated K^+ channels in the plasma membrane, however; if they open, membrane permeability to K^+ increases, and more K^+ diffuse out of the cell. The increased tendency for K^+ to diffuse out of the cell is opposed by the greater negative charge that develops inside the plasma membrane, resulting in hyperpolarization.

PREDICT 3

Does the resting membrane potential increase or decrease when the intracellular concentration of K^+ is increased by the injection of a potassium succinate solution into a cell? Explain.

Sodium Ions

In an unstimulated cell, the membrane is not very permeable to Na^+ because there are few Na^+ leak channels. Changes in the concentration of Na^+ on either side of the plasma membrane do not influence the resting membrane potential very much because of this low permeability. There are gated Na^+ channels in the plasma membrane, however; if they open, membrane permeability to Na^+ increases (see figure 3.10). Sodium ions then diffuse into the cell because the concentration gradient for Na^+ is from the outside to the inside of the cell. As Na^+ diffuse into the cell, the inside of the membrane becomes more positive, resulting in depolarization.

Calcium Ions

Calcium ions alter membrane potentials in two ways: (1) by affecting voltage-gated Na^+ channels and (2) by entering cells through gated Ca^{2+} channels. Voltage-gated Na^+ channels are sensitive to changes in the extracellular concentration of Ca^{2+} . Positively charged Ca^{2+} in the extracellular fluid are attracted to the negatively charged groups of proteins in voltage-gated Na^+ channels. If the extracellular concentration of Ca^{2+} decreases, these ions diffuse away from the voltage-gated Na^+ channels, causing the channels to open. If the extracellular concentration of Ca^{2+} increases, they bind to voltage-gated Na^+ channels, causing them to close. At the Ca^{2+} concentrations normally found in the extracellular fluid, only a small percentage of the voltage-gated Na^+ channels are open at any moment in an unstimulated cell.

PREDICT 4

Predict the effect of a decrease in the extracellular concentration of Ca^{2+} on the resting membrane potential.

Changes in the permeability of Ca^{2+} can change the resting membrane potential. If the plasma membrane becomes permeable to Ca^{2+} by the opening of gated Ca^{2+} channels, Ca^{2+} diffuse into

the cell and the inside of the membrane becomes more positive, resulting in depolarization.

Chloride Ions

Changes in the permeability of Cl^- can change the resting membrane potential. If the permeability of the plasma membrane to Cl^- increases by the opening of gated Cl^- channels, then Cl^- diffuse into the cell and the inside of the membrane becomes more negative, resulting in hyperpolarization.

27 Define depolarization and hyperpolarization. How do alterations in the K^+ concentration gradient, changes in membrane permeability to K^+ , Na^+ , Ca^{2+} , or Cl^- and changes in extracellular Ca^{2+} concentration affect depolarization and hyperpolarization?

Graded Potentials

A stimulus applied at one location on the plasma membrane of a cell normally causes a change in the resting membrane potential called a **graded potential**. Graded potentials are so-called because the potential change can vary from small to large. Graded potentials are also called **local potentials** because they are confined to a small region of the plasma membrane. Graded potentials can result from (1) chemical signals binding to their receptors, (2) changes in the voltage across the plasma membrane, (3) mechanical stimulation, (4) temperature changes, or (5) spontaneous changes in membrane permeability.

A graded potential can be either a depolarization or a hyperpolarization (see figure 11.5). A change in membrane permeability to Na^+ , K^+ , or other ions can produce a graded potential. For example, if a stimulus causes gated Na^+ channels to open, the diffusion of a few Na^+ into cells results in depolarization. If a stimulus causes gated K^+ channels to open, the diffusion of a few K^+ out of the cell results in hyperpolarization.

The magnitude of graded potentials can vary from small to large, depending on the stimulus strength or on summation. For example, a weak stimulus can cause a few gated Na^+ channels to open. A few Na^+ diffuse into the cell and cause a small depolarization. A stronger stimulus can cause a greater number of gated Na^+ channels to open. A greater number of Na^+ diffusing into the cell causes a larger depolarization (figure 11.16a).

Local potentials can **summate** (sŭm-āt'), or add onto each other (figure 11.16b). **Summation** of graded potentials occurs when the effects produced by one graded potential are added onto the effects produced by another graded potential (see figure 11.16b). For example, if a second stimulus is applied before the graded potential produced by the first stimulus has returned to the resting membrane potential, a larger depolarization results than would result from a single stimulus. The first stimulus causes gated Na^+ channels to open, and the second stimulus causes additional Na^+ channels to open. As a result, more Na^+ diffuse into the cell, producing a larger graded potential. Summation is discussed in greater detail in this chapter (see "Spatial and Temporal Summation," p. 404).

Graded potentials spread, or are conducted, over the plasma membrane in a decremental fashion. That is, they rapidly decrease in magnitude as they spread over the surface of the plasma membrane,

(a)

(b)

FIGURE 11.16 Graded Potentials

(a) Graded potentials are proportional to the stimulus strength. A weak stimulus applied briefly causes a small depolarization, which quickly returns to the resting membrane potential (1). Progressively stronger stimuli result in larger depolarizations (2 to 4). (b) A stimulus applied to a cell causes a small depolarization. When a second stimulus is applied before the depolarization disappears, the depolarization caused by the second stimulus is added to the depolarization caused by the first to result in a larger depolarization.

much as a teacher talks to a large class. At the front of the class, the teacher's voice can be easily heard, but, the farther away a student sits, the more difficult it is to hear. Normally, a graded potential cannot be detected more than a few millimeters from the site of stimulation. As a consequence, a graded potential cannot transfer information over long distances from one part of the body to another.

Graded potentials are important because of their effect on the generation of action potentials. The characteristics of graded potentials are summarized in table 11.3.

28 Define a graded potential. What does it mean to say a graded potential can summate and spreads in a decremental fashion?

PREDICT 5

Given two cells that are identical in all ways except that the extracellular concentration of Na^+ is less for cell A than for cell B, how would the magnitude of the graded potential in cell A differ from that in cell B if stimuli of identical strength were applied to each?

TABLE 11.3 Characteristics of Graded Potentials

1. A stimulus causes ion channels to open, resulting in increased permeability of the membrane to Na^+ , K^+ , or Cl^- .
2. Increased permeability of the membrane to Na^+ results in depolarization. Increased permeability of the membrane to K^+ or Cl^- results in hyperpolarization.
3. The size of the graded potential is proportional to the strength of the stimulus. Graded potentials can also summate. Thus, a graded potential produced in response to several stimuli is larger than one produced in response to a single stimulus.
4. Graded potentials are conducted in a decremental fashion, meaning that their magnitude decreases as they spread over the plasma membrane. Graded potentials cannot be measured a few millimeters from the point of stimulation.
5. A depolarizing graded potential can cause an action potential.

Action Potentials

When a graded potential causes depolarization of the plasma membrane to a level called **threshold**, a series of permeability changes occur that results in an action potential (figure 11.17). The action potential has a **depolarization phase**, in which the membrane potential moves away from the resting membrane potential and becomes more positive, and a **repolarization phase**, in which the membrane potential returns toward the resting membrane state and becomes more negative. After the repolarization phase, the plasma membrane may be slightly hyperpolarized for a short period called the **afterpotential**. An action potential is a large change in the membrane potential that propagates, without changing its magnitude, over long distances along the plasma membrane. Thus, action potentials can transfer information from one part of the body to another.

FIGURE 11.17 Action Potential

The action potential consists of a depolarization phase and a repolarization phase, often followed by a short period of hyperpolarization, called the afterpotential.

TABLE 11.4 Characteristics of Action Potentials

- | |
|---|
| 1. Action potentials are produced when a graded potential reaches threshold. |
| 2. Action potentials are all-or-none. |
| 3. Depolarization is a result of increased membrane permeability to Na ⁺ and movement of Na ⁺ into the cell. Activation gates of the voltage-gated Na ⁺ channels open. |
| 4. Repolarization is a result of decreased membrane permeability to Na ⁺ and increased membrane permeability to K ⁺ , which stops Na ⁺ movement into the cell and increases K ⁺ movement out of the cell. The inactivation gates of the voltage-gated Na ⁺ channels close, and the voltage-gated K ⁺ channels open. |
| 5. No action potential is produced by a stimulus, no matter how strong, during the absolute refractory period. During the relative refractory period, a stronger-than-threshold stimulus can produce an action potential. |
| 6. Action potentials are propagated, and for a given axon or muscle fiber the magnitude of the action potential is constant. |
| 7. Stimulus strength determines the frequency of action potentials. |

It generally takes 1–2 milliseconds (ms; 1 ms = 0.001 s) for an action potential to occur. The characteristics of action potentials are summarized in table 11.4.

All-or-None Principle

The generation of action potentials is dependent on graded potentials. Depolarizing graded potentials that reach threshold produce an action potential. Hyperpolarizing graded potentials can never reach threshold and do not produce action potentials. Thus, depolarizing graded potentials can potentially activate a cell by causing the production of an action potential, whereas hyperpolarizing graded potentials can prevent the production of an action potential.

The magnitude of a depolarizing graded potential affects the likelihood of generating an action potential. For example, a weak stimulus can produce a small depolarizing graded potential that does not reach threshold and therefore does not cause the production of an action potential. A stronger stimulus, however, can produce a larger depolarizing graded potential that reaches threshold, resulting in the production of an action potential.

Action potentials occur according to the **all-or-none principle**. If a stimulus produces a depolarizing graded potential that is large enough to reach threshold, all the permeability changes responsible for an action potential proceed without stopping and are constant in magnitude (the “all” part). If a stimulus is so weak that the depolarizing graded potential does not reach threshold, few of the permeability changes occur. The membrane potential returns to its resting level after a brief period without producing an action potential (the “none” part). An action potential can be compared to the flash system of a camera. When the shutter is triggered (reaches threshold), the

camera flashes (an action potential is produced), and each flash is the same brightness (magnitude; the “all” part) as previous flashes. If the shutter is depressed, but not triggered, no flash results (the “none” part).

Depolarization Phase

The change in charge across the plasma membrane caused by a graded potential causes increasing numbers of voltage-gated Na⁺ channels to open for a brief time. As soon as a threshold depolarization is reached, many voltage-gated Na⁺ channels begin to open. Sodium ions diffuse into the cell, and the resulting depolarization causes additional voltage-gated Na⁺ channels to open. As a consequence, more Na⁺ diffuse into the cell, causing a greater depolarization of the membrane, which in turn causes still more voltage-gated Na⁺ channels to open. This is an example of a positive-feedback cycle, and it continues until most of the voltage-gated Na⁺ channels in the plasma membrane are open.

Each voltage-gated Na⁺ channel has two voltage-sensitive gates, called **activation** and **inactivation gates**. When the plasma membrane is at rest, the activation gates of the voltage-gated Na⁺ channel are closed, and the inactivation gates are open (figure 11.18, step 1). Because the activation gates are closed, Na⁺ cannot diffuse through the channels. When the graded potential reaches threshold, the change in the membrane potential causes many of the activation gates to open, and Na⁺ can diffuse through the Na⁺ channels into the cell.

When the plasma membrane is at rest, voltage-gated K⁺ channels, which have one gate, are closed (see figure 11.18, step 1). When the graded potential reaches threshold, the voltage-gated K⁺ channels begin to open at the same time as the voltage-gated Na⁺ channels, but they open more slowly (figure 11.18, step 2). Only a small number of voltage-gated K⁺ channels are open, compared with the number of voltage-gated Na⁺ channels because the voltage-gated K⁺ channels open slowly. Depolarization occurs because more Na⁺ diffuse into the cell than K⁺ diffuse out of it.

PREDICT 6

Predict the effect of a reduced extracellular concentration of Na⁺ on the magnitude of the action potential in an electrically excitable cell.

Repolarization Phase

As the membrane potential approaches its maximum depolarization, the change in the potential difference across the plasma membrane causes the inactivation gates in the voltage-gated Na⁺ channels to begin closing, and the permeability of the plasma membrane to Na⁺ decreases. During the repolarization phase, the voltage-gated K⁺ channels, which started to open along with the voltage-gated Na⁺ channels, continue to open (figure 11.18, step 3). Consequently, the permeability of the plasma membrane to Na⁺ decreases, and the permeability to K⁺ increases. The decreased diffusion of Na⁺ into the cell and the increased diffusion of K⁺ out of the cell causes repolarization.

1. Resting membrane potential.

Voltage-gated Na^+ channels (pink) are closed (the activation gates are closed and the inactivation gates are open). Voltage-gated K^+ channels (purple) are closed.

2. Depolarization. Voltage-gated Na^+ channels open because the activation gates open. Voltage-gated K^+ channels start to open. Depolarization results because the inward diffusion of Na^+ is much greater than the outward diffusion of K^+ .

3. Repolarization. Voltage-gated Na^+ channels are closed because the inactivation gates close. Voltage-gated K^+ channels are now open. Sodium ions diffusion into the cell stops and K^+ diffuse out of the cell, causing repolarization.

4. End of repolarization and afterpotential. Voltage-gated Na^+ channels are closed. Closure of the activation gates and opening of the inactivation gates reestablish the resting condition for Na^+ channels (see step 1). Diffusion of K^+ through voltage-gated channels produces the afterpotential.

**5. Resting membrane potential.**

The resting membrane potential is reestablished after the voltage-gated K^+ channels close.

**PROCESS FIGURE 11.18 Voltage-Gated Ion Channels and the Action Potential**

Step 1 illustrates the status of voltage-gated Na^+ and K^+ channels in a resting cell. Steps 2–5 show how the channels open and close to produce an action potential. Next to each step, a graph shows in red the membrane potential resulting from the condition of the ion channels.

At the end of repolarization, the decrease in membrane potential causes the activation gates in the voltage-gated Na^+ channels to close and the inactivation gates to open. Although this change does not affect the diffusion of Na^+ , it does return the voltage-gated Na^+ channels to their resting state (figure 11.18, step 4).

Afterpotential

In many cells, a period of hyperpolarization, or afterpotential, exists following each action potential. The afterpotential exists because the voltage-gated K^+ channels remain open for a short time (see figure 11.18, step 4). The increased K^+ permeability that develops during the repolarization phase of the action potential lasts slightly longer than the time required to bring the membrane potential back to its resting level. As the voltage-gated K^+ channels close, the original resting membrane potential is reestablished (figure 11.18, step 5).

During an action potential, a small number of Na^+ diffuse into the cell and a small number of K^+ diffuse out of the cell. The Na^+-K^+ pump restores normal resting ion concentrations by transporting these ions in the opposite direction of their movement during the action potential. That is, Na^+ are pumped out of the cell and K^+ are pumped into the cell. The Na^+-K^+ pump is too slow to have an effect on either the depolarization or the repolarization phase of individual action potentials. As long as the Na^+ and K^+ concentrations remain unchanged across the plasma membrane, all the action potentials produced by a cell are identical. They all take the same amount of time, and they all exhibit the same magnitude.

- 29** Define action potential. How do depolarizing and hyperpolarizing graded potentials affect the likelihood of generating an action potential?
- 30** Explain the “all” and the “none” parts of the all-or-none principle of action potentials.
- 31** What are the depolarization and repolarization phases of an action potential? Explain how changes in membrane permeability and the movement of Na^+ and K^+ cause each phase. What happens when the activation gates in the voltage-gated Na^+ channels open and the inactivation gates close?
- 32** Describe the afterpotential and its cause.

Refractory Period

Once an action potential is produced at a given point on the plasma membrane, the sensitivity of that area to further stimulation decreases for a time called the **refractory** (rē-frak'tōr-ē) **period**. The first part of the refractory period, during which complete insensitivity exists to another stimulus, is called the **absolute refractory period**. In many cells, it occurs from the beginning of the action potential until near the end of repolarization (figure 11.19). At the beginning of the action potential, depolarization occurs when the activation gates in the voltage-gated Na^+ channel open. At this time, the inactivation gates in the voltage-gated Na^+ channels are already open (see figure 11.18, step 2). Depolarization ends as the inactivation gates close (see figure 11.18, step 3). As long as the inactivation gates are closed, further depolarization cannot occur. When the inactivation gates open and the activation gates close near the end

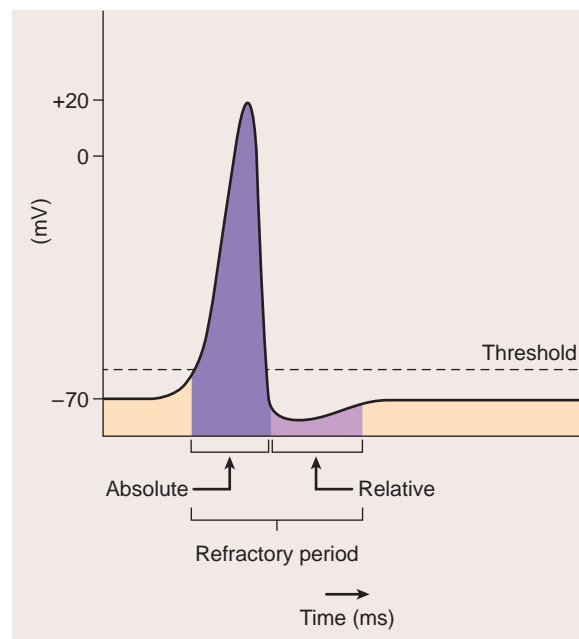

FIGURE 11.19 Refractory Period

The absolute and relative refractory periods of an action potential. In some cells, the absolute refractory period ends during the repolarization phase of the action potential.

of repolarization (see figure 11.18, step 4), once again it is possible to stimulate the production of another action potential.

The existence of the absolute refractory period guarantees that, once an action potential is begun, both the depolarization and the repolarization phases will be completed, or nearly completed, before another action potential can begin and that a strong stimulus cannot lead to prolonged depolarization of the plasma membrane. The absolute refractory period has important consequences for the rate at which action potentials can be generated and for the propagation of action potentials.

The second part of the refractory period, called the **relative refractory period**, follows the absolute refractory period. A stronger-than-threshold stimulus can initiate another action potential during the relative refractory period. Thus, after the absolute refractory period, but before the relative refractory period is completed, a sufficiently strong stimulus can produce another action potential. During the relative refractory period, the membrane is more permeable to K^+ because many voltage-gated K^+ channels are open (see figure 11.18, step 4). The relative refractory period ends when the voltage-gated K^+ channels close (see figure 11.18, step 5).

- 33** What are the absolute and relative refractory periods? Relate them to the depolarization and repolarization phases of the action potential.

PREDICT 7

Does a prolonged threshold stimulus or a prolonged stronger-than-threshold stimulus of the same duration produce the most action potentials? Explain.

Action Potential Frequency

The **action potential frequency** is the number of action potentials produced per unit of time in response to a stimulus. Action potential frequency is directly proportional to stimulus strength and to the size of the graded potential. A **subthreshold stimulus** is any stimulus not strong enough to produce a graded potential that reaches threshold. Therefore, no action potential is produced (figure 11.20). A **threshold stimulus** produces a graded potential that is just strong enough to reach threshold and cause the production of a single action potential. A **maximal stimulus** is just strong enough to produce a maximum frequency of action potentials. A **submaximal stimulus** includes all stimuli between threshold and the maximal stimulus strength. For submaximal stimuli, the action potential frequency increases in proportion to the strength of the stimulus because the size of the graded potential increases with stimulus strength. A **supramaximal stimulus** is any stimulus stronger than a maximal stimulus. These stimuli cannot produce a greater frequency of action potentials than a maximal stimulus.

The duration of the absolute refractory period determines the maximum frequency of action potentials generated in an excitable cell. During the absolute refractory period, a second stimulus, no matter how strong, cannot stimulate an additional action potential. As soon as the absolute refractory period ends, however, it is possible for a second stimulus to cause the production of an action potential.

PREDICT 8

If the duration of the absolute refractory period of a nerve cell is 1 millisecond (ms), how many action potentials are generated by a maximal stimulus in 1 second?

The frequency of action potentials provides information about the strength of a stimulus. For example, a weak pain stimulus generates a low frequency of action potentials, whereas a stronger pain stimulus generates a higher frequency of action potentials. The ability to interpret a stimulus as mildly painful versus very painful depends, in part, on the frequency of action potentials generated by individual pain receptors. Communication regarding the strength of stimuli cannot depend on the magnitudes of action potentials because, according to the all-or-none principle, the magnitudes are always the same. The magnitudes of action potentials produced by weak and strong pain stimuli are the same.

The ability to stimulate muscle or gland cells also depends on action potential frequency. A low frequency of action potentials produces a weaker muscle contraction or less secretion than does a higher frequency. For example, a low frequency of action potentials in a muscle results in incomplete tetanus and a high frequency in complete tetanus (see chapter 9).

In addition to the frequency of action potentials, how long the action potentials are produced provides important information.

For example, a pain stimulus of 1 second is interpreted differently than the same stimulus applied for 30 seconds.

34 Define action potential frequency. What two factors determine action potential frequency?

35 Define subthreshold, threshold, maximal, submaximal, and supramaximal stimuli. What determines the maximum frequency of action potential generation?

Propagation of Action Potentials

An action potential occurs in a very small area of the plasma membrane and does not affect the entire membrane at one time. Action

FIGURE 11.20 Stimulus Strength and Action Potential Frequency

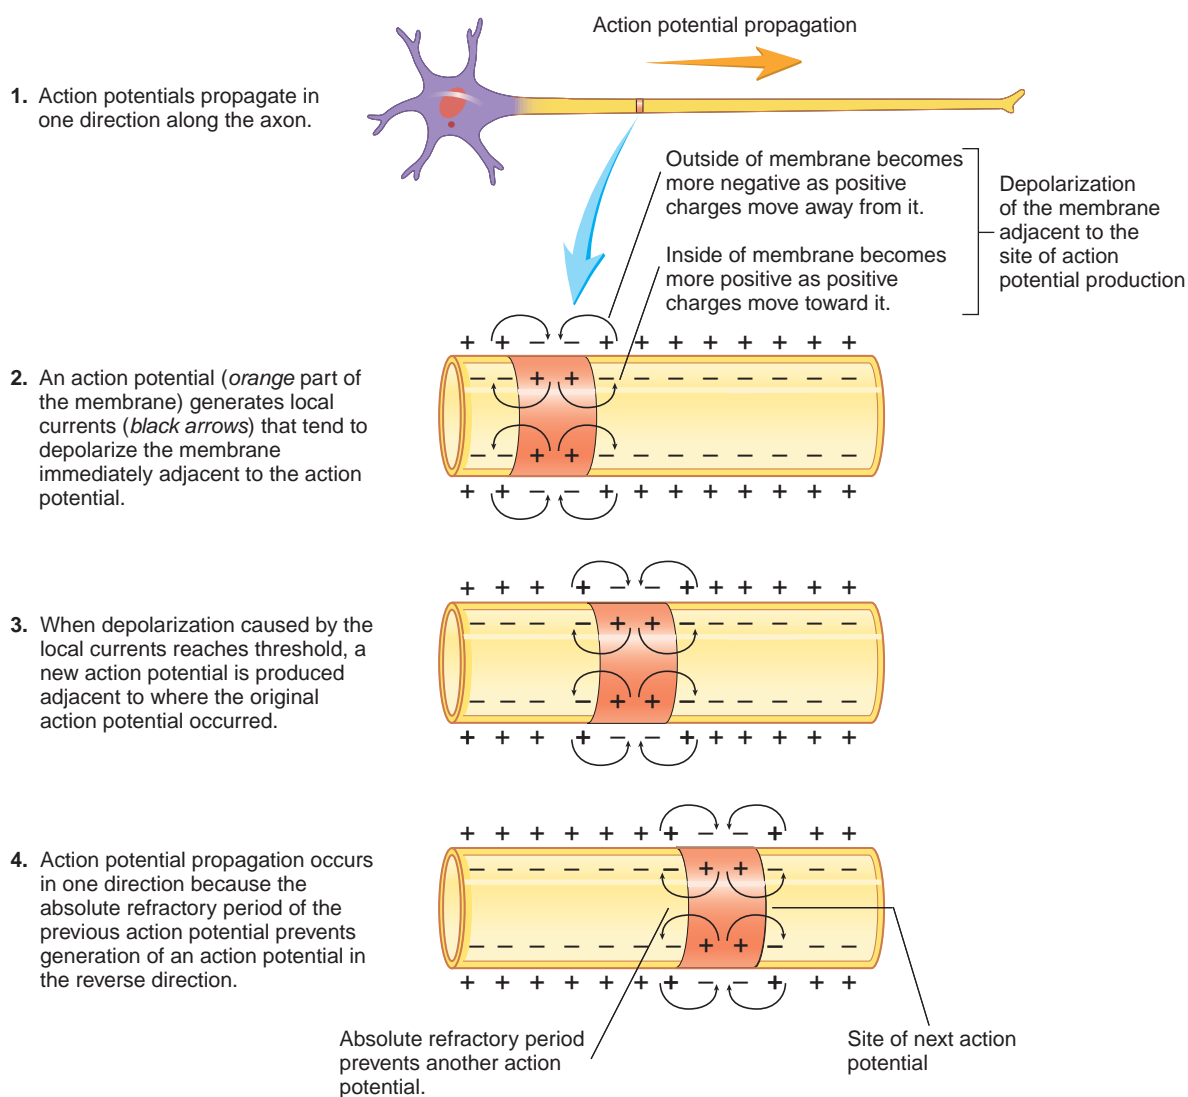

From left to right, each stimulus in the figure is stronger than the previous one. As stimulus strength increases, the frequency of action potentials increases until a maximal rate is produced. Thereafter, increasing stimulus strength does not increase action potential frequency.

potentials can, however, **propagate**, or spread, across the plasma membrane because an action potential produced at one location in the plasma membrane can stimulate the production of an action potential at an adjacent area of the plasma membrane. Note that an action potential does not actually move along an axon. Rather, an action potential at one location stimulates the production of another action potential at an adjacent location, which in turn stimulates the production of another, and so on, like a long row of toppling dominos in which each domino knocks down the next one. Each domino falls, but no one domino actually travels the length of the row.

In a neuron, action potentials are normally produced at the trigger zone and propagate in one direction along the axon (figure 11.21, step 1). The location at which the next action potential is generated is different for unmyelinated and myelinated axons (see figure 11.11). In an unmyelinated axon, the next action potential is generated immediately adjacent to the previous action potential. When an action potential is produced, the

inside of the membrane becomes more positive than the outside (figure 11.21, step 2). On the outside of the membrane, positively charged ions from the adjacent area are attracted to the negative charges at the site of the action potential. On the inside of the plasma membrane, positively charged ions at the site of the action potential are attracted to the adjacent negatively charged part of the membrane. The movement of positively charged ions is called an **ionic current**, or **local current**. As a result of the ionic current, the part of the membrane immediately adjacent to the action potential depolarizes. That is, the outside of the membrane immediately adjacent to the action potential becomes more negative because of the loss of positive charges and the inside becomes more positive because of the gain of positive charges. When the depolarization reaches threshold, an action potential is produced (figure 11.21, step 3).

If an action potential is initiated at one end of an axon, it is propagated in one direction down the axon. The absolute refractory period ensures one-way propagation of an action

PROCESS FIGURE 11.21 Action Potential Propagation in an Unmyelinated Axon

CLINICAL FOCUS

Examples of Abnormal Membrane Potentials

Several conditions are examples of the physiology of membrane potentials and the consequence of abnormal ones. **Hypokalemia** (hī-pō-ka-lē'mē-ā) is a lower than normal concentration of K^+ in the blood or extracellular fluid. Reduced extracellular K^+ concentrations cause hyperpolarization of the resting membrane potential (see figure 11.15b). Thus, a greater than normal stimulus is required to depolarize the membrane to its threshold level and to initiate action potentials in neurons, skeletal muscle, and cardiac muscle. Symptoms of hypokalemia include

muscular weakness, an abnormal electrocardiogram, and sluggish reflexes. The symptoms result from the reduced sensitivity of the excitable tissues to stimulation. The causes of hypokalemia include potassium depletion during starvation, alkalosis, and certain kidney diseases.

Hypocalcemia (hī-pō-kal-sē'mē-ā) is a lower than normal concentration of Ca^{2+} in blood or extracellular fluid. Symptoms of hypocalcemia include nervousness and uncontrolled contraction of skeletal muscles, called **tetany** (tet'ā-nē). The symptoms are

due to an increased membrane permeability to Na^+ that results because low blood levels of Ca^{2+} cause voltage-gated Na^+ channels in the membrane to open. Sodium ions diffuse into the cell, causing depolarization of the plasma membrane to threshold and initiating action potentials. The tendency for action potentials to occur spontaneously in nervous tissue and muscles accounts for the symptoms. A lack of dietary calcium, a lack of vitamin D, and a reduced secretion rate of a parathyroid gland hormone are conditions that cause hypocalcemia.

potential because it prevents the ionic current from stimulating the production of an action potential in the reverse direction (figure 11.21, step 4).

In a myelinated axon, an action potential is conducted from one node of Ranvier to another in a process called **saltatory conduction** (*saltare* is Latin, meaning to leap). An action potential at

one node of Ranvier generates ionic currents that flow toward the next node of Ranvier (figure 11.22, step 1). The lipids within the membranes of the myelin sheath act as a layer of insulation, forcing the ionic currents to flow from one node of Ranvier to the next. In addition, voltage-gated Na^+ channels are highly concentrated at the nodes of Ranvier. Therefore, the ionic current quickly flows

PROCESS FIGURE 11.22 Saltatory Conduction: Action Potential Propagation in a Myelinated Axon

The gaps between the Schwann cells are exaggerated for clarity.

to a node and stimulates the voltage-gated Na^+ channels to open, resulting in the production of an action potential (figure 11.22, step 2).

The speed of action potential conduction along an axon depends on the myelination of the axon. Action potentials are conducted more rapidly in myelinated than unmyelinated axons because they are formed quickly at each successive node of Ranvier (figure 11.22, step 3), instead of being propagated more slowly through every part of the axon's membrane, as in unmyelinated axons (see figure 11.21). Action potential conduction in a myelinated fiber is like a grasshopper jumping; in an unmyelinated axon, it is like a grasshopper walking. The grasshopper (action potential) moves more rapidly by jumping. The generation of action potentials at nodes of Ranvier occurs so rapidly that as many as 30 successive nodes of Ranvier are simultaneously in some phase of an action potential.

The speed of action potential conduction is also affected by the thickness of the myelin sheath, which is determined by how many times oligodendrocytes or Schwann cells wrap around the axon. Heavily myelinated axons have a thicker myelin sheath and conduct action potentials more rapidly than lightly myelinated axons.

In addition to myelination, the diameter of axons affects the speed of action potential conduction. Large-diameter axons conduct action potentials more rapidly than small-diameter axons because large-diameter axons have a greater surface area. Consequently, at a given site on an axon, more voltage-gated Na^+ channels open during depolarization, resulting in a greater ionic current flow, which more rapidly stimulates adjacent membrane areas.

Nerve fibers (axons) are classified according to their size and myelination. It is not surprising that the structure of nerve fibers reflects their functions. Type A fibers are large-diameter, myelinated axons that conduct action potentials at 15–120 m/s. Motor neurons supplying skeletal muscles and most sensory neurons have type A fibers. Rapid response to the external environment is possible because of the rapid input of sensory information to the CNS and rapid output of action potentials to skeletal muscles.

Type B fibers are medium-diameter, lightly myelinated axons that conduct action potentials at 3–15 m/s, and type C fibers are small-diameter, unmyelinated axons that conduct action potentials at 2 m/s or less. Type B and C fibers are primarily part of the ANS, which stimulates internal organs, such as the stomach, intestines, and heart. The responses necessary to maintain internal homeostasis, such as digestion, need not be as rapid as responses to the external environment.

Importance of Myelin Sheaths

Myelin sheaths begin to form late in fetal development. The process continues rapidly until the end of the first year after birth and continues more slowly thereafter. The development of myelin sheaths is associated with the infant's continuing development of more rapid and better coordinated responses.

The importance of myelinated fibers is dramatically illustrated in diseases in which the myelin sheath is gradually destroyed. Action potential transmission is slowed, resulting in impaired control of skeletal and smooth muscles. In severe cases, complete blockage of action potential transmission can occur. Multiple sclerosis and some cases of diabetes mellitus result in myelin sheath destruction.

THE SYNAPSE

Just as the fire from one lit torch can light another torch, action potentials in one cell can stimulate action potentials in another cell, thereby allowing communication between the cells. For example, if your finger touches a hot pan, the heat is a stimulus that produces action potentials in sensory nerve fibers. The action potentials are propagated along the sensory fibers from the finger toward the CNS. For the CNS to get this information, the action potentials of the sensory neurons must produce action potentials in CNS neurons. After the CNS has received the information, it produces a response. One response is the contraction of the appropriate skeletal muscles, causing the finger to move away from the hot pan. CNS action potentials cause motor neurons to produce action potentials that are then transmitted by the motor neurons toward skeletal muscles. The action potentials of the motor neuron produce skeletal muscle action potentials, which are the stimuli that cause muscle fibers to contract (see chapter 9).

The **synapse** (sin'aps), which is the junction between two cells, is where two cells communicate with each other. The cell that transmits a signal toward a synapse is called the **presynaptic cell**, and the cell that receives the signal is called the **postsynaptic cell**.

The average presynaptic neuron synapses with about 1000 other neurons, but the average postsynaptic neuron has up to 10,000 synapses. Some postsynaptic neurons in the part of the brain called the cerebellum have up to 100,000 synapses. There are two types of synapses: electrical and chemical.

Electrical Synapses

Electrical synapses are gap junctions (see chapter 4) that allow an ionic current to flow between adjacent cells (figure 11.23). At these gap junctions, the membranes of adjacent cells are separated by a 2 nm gap spanned by tubular proteins called **connexons**. The movement of ions through the connexons can generate an ionic current. Thus, an action potential in one cell produces an ionic current that generates an action potential in the adjacent cell almost as if the two cells had the same membrane. As a result, action potentials are conducted rapidly between cells, allowing the cells' activity to be synchronized. Electrical synapses are not common in the nervous system of vertebrates, but there are some in humans.

CLINICAL FOCUS

Nervous Tissue Response to Injury

When a nerve is cut, either healing or permanent interruption of the neural pathways occurs. The final outcome depends on the severity of the injury and on its treatment.

Several degenerative changes result when a nerve is cut (figure A). Within about 3–5 days, the axons in the part of the nerve distal to the cut break into irregular segments and degenerate. This occurs because the neuron cell body produces the substances essential to maintain the axon, and these substances have no way of reaching parts of the axon distal to the point of damage. Eventually, the distal part of the axon completely degenerates. As the axons degenerate, the myelin part of the Schwann cells around them also degenerates, and macrophages invade the area to phagocytize the myelin. The Schwann cells then enlarge, undergo mitosis, and finally form a column of cells along the regions once

occupied by the axons. The columns of Schwann cells are essential for the growth of new axons. If the ends of the regenerating axons encounter a Schwann cell column, their rate of growth increases, and reinnervation of peripheral structures is likely. If the ends of the axons do not encounter the columns, they fail to reinnervate the peripheral structures.

The end of each regenerating axon forms several axonal sprouts. It normally takes about 2 weeks for the axonal sprouts to enter the Schwann cell columns. Only one of the sprouts from each severed neuron forms an axon, however. The other branches degenerate. After the axons grow through the Schwann cell columns, new myelin sheaths are formed, and the neurons reinnervate the structures they previously supplied.

Treatment strategies that increase the probability of reinnervation include bringing the ends of the severed nerve close together

surgically. In some cases in which sections of nerves are destroyed as a result of trauma, nerve transplants are performed to replace damaged segments. The transplanted nerve eventually degenerates, but it does provide Schwann cell columns through which axons can grow.

The regeneration of damaged nerve tracts within the CNS is very limited and is poor in comparison with the regeneration of nerves in the PNS. In part, the difference may result from the oligodendrocytes, which exist only in the CNS. Each oligodendrocyte has several processes, each of which forms part of a myelin sheath. The cell bodies of the oligodendrocytes are a short distance from the axons they ensheath, and fewer oligodendrocytes than Schwann cells are present. Consequently, when the myelin degenerates following damage, no column of cells remains in the CNS to act as a guide for the growing axons.

FIGURE A Changes That Occur in an Injured Nerve Fiber

(a) When the two ends of an injured nerve fiber are aligned in close proximity, healing and regeneration of the axon are likely to occur. Without stimulation from the nerve, the muscle is paralyzed and atrophies (shrinks in size). After reinnervation, the muscle can become functional and hypertrophy (increase in size). (b) When the two ends of an injured nerve fiber are not aligned in close proximity, regeneration is unlikely to occur. Without innervation from the nerve, muscle function is completely lost, and the muscle remains atrophied.

1. Electrical synapses connect cardiac muscle cells.
2. An electrical synapse has gap junctions in which the membranes of two cells are separated by a gap but are connected by proteins called connexons.
3. An action potential (*orange arrow*) in the plasma membrane generates ionic currents (*black arrows*) that flow to adjacent parts of the plasma membrane and through the gap junction.
4. An ionic current stimulates the production of another action potential. Thus, the action potential propagates along the plasma membrane.
5. An ionic current flows through a gap junction and stimulates the production of an action potential in the adjacent cardiac muscle cell. Thus, the action potential propagates to the adjacent cell.

PROCESS FIGURE 11.23 Electrical Synapse

Electrical synapses are important, however, in cardiac muscle and in many types of smooth muscle. Coordinated contractions of these muscle cells occur when action potentials in one cell propagate to adjacent cells because of electrical synapses (see chapters 9 and 20).

41 *What is an electrical synapse? Describe its operation. In what kinds of tissue are electrical synapses found?*

Chemical Synapses

The essential components of a **chemical synapse** are the presynaptic terminal, the synaptic cleft, and the postsynaptic membrane (figure 11.24). The **presynaptic terminal** is formed from the end of an axon, and the space separating the axon ending and the cell with which it synapses is the **synaptic cleft**. The membrane of the postsynaptic cell opposed to the presynaptic terminal is the **postsynaptic membrane**. Postsynaptic cells are typically other neurons, muscle cells, or gland cells.

Neurotransmitter Release

In chemical synapses, action potentials do not pass directly from the presynaptic terminal to the postsynaptic membrane. Instead,

the action potentials in the presynaptic terminal cause the release of neurotransmitters from the terminal.

Presynaptic terminals are specialized to produce and release neurotransmitters. The major cytoplasmic organelles within presynaptic terminals are mitochondria and numerous membrane-bound **synaptic vesicles**, which contain neurotransmitters, such as acetylcholine (see figure 11.24). Each action potential arriving at the presynaptic terminal initiates a series of specific events, which result in the release of neurotransmitters. In response to an action potential, voltage-gated Ca^{2+} channels open, and Ca^{2+} diffuse into the presynaptic terminal. These ions cause synaptic vesicles to fuse with the presynaptic membrane and release their neurotransmitters by exocytosis into the synaptic cleft.

Once neurotransmitters are released from the presynaptic terminal, they diffuse rapidly across the synaptic cleft, which is about 20 nm wide, and bind in a reversible fashion to specific receptors in the postsynaptic membrane (see figure 11.24). Depending on the receptor type, this binding produces a depolarizing or hyperpolarizing graded potential in the postsynaptic membrane. For example, the binding of acetylcholine to ligand-gated Na^+ channels causes them to open, allowing the diffusion of Na^+ into the postsynaptic cell. If the resulting depolarizing graded potential reaches threshold, an action

1. Action potentials arriving at the presynaptic terminal cause voltage-gated Ca²⁺ channels to open.
2. Calcium ions diffuse into the cell and cause synaptic vesicles to release neurotransmitters.
3. Neurotransmitters diffuse from the presynaptic terminal across the synaptic cleft.
4. Neurotransmitters combine with their receptor sites and cause ligand-gated ion channels to open. Ions diffuse into the cell (shown in illustration) or out of the cell (not shown) and cause a change in membrane potential.

PROCESS FIGURE 11.24 Chemical Synapse

A chemical synapse consists of the end of a neuron (presynaptic terminal), a small space (synaptic cleft), and the postsynaptic membrane of another neuron or an effector cell, such as a muscle or gland cell.

potential is produced. On the other hand, the opening of K⁺ or Cl⁻ channels results in a hyperpolarizing graded potential.

42 What are the three parts of a chemical synapse?

43 Describe the release of a neurotransmitter in a chemical synapse.

PREDICT 9

Is an action potential transmitted fastest between cells connected by electrical or chemical synapses? Explain.

Neurotransmitter Removal

The interaction between a neurotransmitter and a receptor represents an equilibrium.

When the neurotransmitter concentration in the synaptic cleft is high, many of the receptor molecules have neurotransmitter molecules bound to them; when the neurotransmitter concentration declines, the neurotransmitter molecules diffuse away from the receptor molecules.

Neurotransmitters have short-term effects on postsynaptic membranes because the neurotransmitter is rapidly destroyed or removed from the synaptic cleft. For example, in the neuromuscular junction (see chapter 9), the neurotransmitter acetylcholine is broken down by the enzyme **acetylcholinesterase** (as'e-til-kō-lin-es'ter-ās) to acetic acid and choline (figure 11.25a). Choline is then transported back into the presynaptic terminal and reacts with acetyl-CoA to form acetylcholine. Acetyl-CoA is synthesized by mitochondria as foods are metabolized to produce ATP (see chapter 25). Acetic acid can be absorbed from the synaptic cleft into the presynaptic terminal, or it can diffuse out of the synaptic cleft and be taken up by a variety of cells. Acetic acid can be used to synthesize acetyl-CoA.

When the neurotransmitter norepinephrine is released into the synaptic cleft, most of it is transported back into the presynaptic terminal, where most of it is repackaged into synaptic vesicles for reuse (figure 11.25b). The enzyme **monoamine oxidase (MAO; mon-ō-am'in ok'si-dās)** inactivates some of the norepinephrine.

Diffusion of neurotransmitter molecules away from the synapse and into the extracellular fluid also limits the length of time the neurotransmitter molecules remain bound to their receptors. Norepinephrine in the circulation is taken up primarily by liver and kidney cells, where the enzymes monoamine oxidase and **catechol-O-methyltransferase** (kat'ē-kol-ō-meth-il-trans'fer-ās) convert it into inactive metabolites.

44 Name three ways to stop the effect of a neurotransmitter on the postsynaptic membrane. Give an example of each way.

Receptor Molecules in Synapses

Receptor molecules in synapses are membrane-bound, ligand-activated receptors with highly specific receptor sites. Consequently, only neurotransmitter molecules or very closely related substances normally bind to their receptors. For example, acetylcholine binds to acetylcholine receptors, but not to norepinephrine receptors, whereas norepinephrine binds to norepinephrine receptors, but not to acetylcholine receptors. Any given cell does not have all possible receptors. Therefore, a neurotransmitter affects only the cells with receptors for that neurotransmitter.

A neurotransmitter can stimulate some cells but inhibit others. More than one type of receptor molecule exists for some neurotransmitters. Different cells respond differently to a neurotransmitter when

1. Acetylcholine molecules bind to their receptors.
2. Acetylcholine molecules unbind from their receptors.
3. Acetylcholinesterase splits acetylcholine into choline and acetic acid, which prevents acetylcholine from again binding to its receptors. Choline is taken up by the presynaptic terminal.
4. Choline is used to make new acetylcholine molecules that are packaged into synaptic vesicles.

(a)

1. Norepinephrine binds to its receptor.
2. Norepinephrine unbinds from its receptor.
3. Norepinephrine is taken up by the presynaptic terminal, which prevents norepinephrine from again binding to its receptor.
4. Norepinephrine is repackaged into synaptic vesicles or is broken down by monoamine oxidase (MAO).

(b)

PROCESS FIGURE 11.25 Removal of Neurotransmitter from the Synaptic Cleft

(a) In some synapses, neurotransmitters are broken down by enzymes and recycled into the presynaptic terminal. (b) In some synapses, neurotransmitters are taken up whole into the presynaptic terminal.

these cells have different receptors. For example, norepinephrine can bind to one type of norepinephrine receptor to cause depolarization in one synapse and to another type of norepinephrine receptor to cause hyperpolarization in another synapse. Thus, norepinephrine is either stimulatory or inhibitory, depending on the type of norepinephrine receptor to which it binds and on the effect that receptor has on the permeability of the postsynaptic membrane.

Although neurotransmitter receptors are in greater concentrations on postsynaptic membranes, some receptors exist on presynaptic membranes. For example, norepinephrine released from the presynaptic membrane binds to receptors on both the presynaptic and postsynaptic membranes. Its binding to the receptors of the presynaptic membrane decreases the release of additional synaptic vesicles. Norepinephrine can therefore modify its own release by binding to presynaptic receptors. A high frequency of presynaptic action potentials results in the release of fewer synaptic vesicles in response to later action potentials.

Neurotransmitters and Neuromodulators

Several substances have been identified as neurotransmitters, and others are suspected neurotransmitters. It was once thought that each neuron contains only one type of neurotransmitter; however, it is now known that some neurons can secrete more than one type. If a neuron does produce more than one neurotransmitter, it secretes all of them from each of its presynaptic terminals. The physiologic significance of presynaptic terminals that secrete more than one type of neurotransmitter has not been clearly established.

Neuromodulators are substances released from neurons that can presynaptically or postsynaptically influence the likelihood that an action potential in the presynaptic terminal will result in the production of an action potential in the postsynaptic cell. For example, a neuromodulator that decreases the release of an excitatory neurotransmitter from a presynaptic terminal decreases the likelihood of action potential production in the postsynaptic cell. A list of neurotransmitters and neuromodulators is presented in table 11.5.

TABLE 11.5 Clinical Examples of Synaptic Function

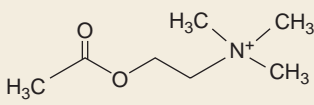

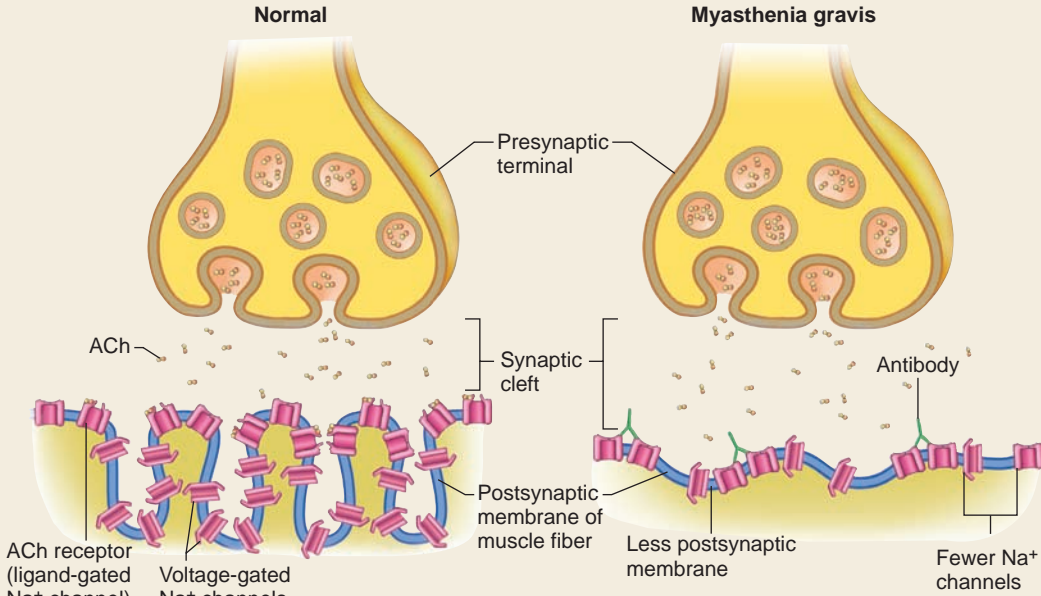

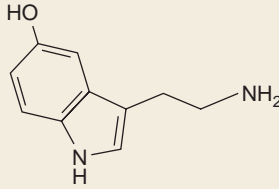

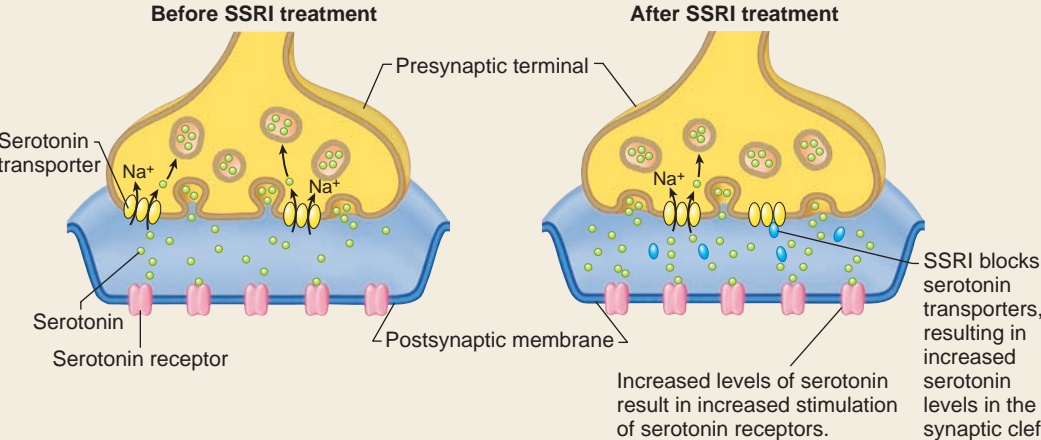

Neurotransmitter/Neuromodulator	Clinical Examples
<p>Acetylcholine Structure:</p>  <p>Site of release: CNS synapses, ANS synapses, and neuromuscular junctions</p> <p>Effect: excitatory in the CNS and neuromuscular junctions; inhibitory or excitatory in ANS synapses</p>	<p>Myasthenia Gravis</p> <p>Myasthenia gravis is a disease in which the ability of skeletal muscle to respond to nervous system stimulation decreases, resulting in muscle weakness and even paralysis. Antibodies are proteins produced by the immune system that can attach to foreign substances, such as bacteria (see chapter 22). In myasthenia gravis, antibodies inappropriately attach to acetylcholine receptors. The antibodies link the receptors together, which cause them to be removed from the plasma membrane faster than normal, decreasing the number of receptors. The antibodies also stimulate immune responses that lead to destruction of the postsynaptic membrane, which decreases the number of Na⁺ channels in the synapse. Thus, the ability of ACh to stimulate action potential production decreases because there are fewer ligand-gated ACh receptors, and the ability to generate an action potential is reduced because there are fewer voltage-gated Na⁺ channels.</p> 
<p>Biogenic Amines <i>Serotonin</i> Structure:</p>  <p>Site of release: CNS synapses</p> <p>Effect: generally inhibitory</p>	<p>Antidepressant Therapy</p> <p>Selective serotonin reuptake inhibitors (SSRIs), such as Prozac and Zoloft, are drugs commonly used to treat depression. They temporarily block serotonin transporters (symporters), which decreases serotonin transport back into presynaptic terminals, resulting in increased serotonin levels in synaptic clefts. In some people, the increased stimulation of the postsynaptic neuron by serotonin relieves depression.</p> 

TABLE 11.5 Clinical Examples of Synaptic Function—Continued

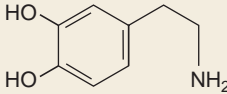

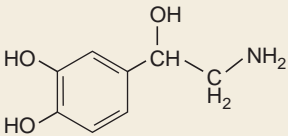

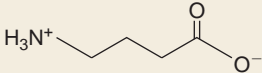

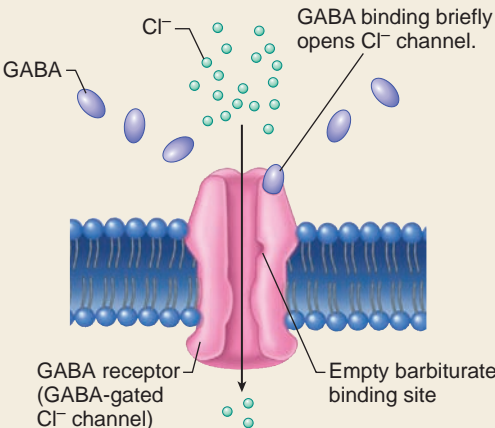

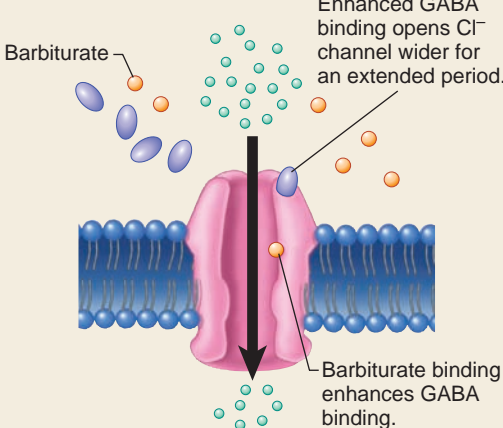

Neurotransmitter/Neuromodulator	Clinical Examples
<p><i>Serotonin (continued)</i></p> <p><i>Dopamine</i> Structure:</p>  <p>Site of release: selected CNS synapses; also found in some ANS synapses</p> <p>Effect: excitatory or inhibitory</p>	<p>Anxiety Disorders SSRIs are also used to treat panic disorders, such as obsessive-compulsive disorder (OCD), a fact that makes researchers believe that OCD might be linked to abnormalities in serotonin function.</p> <p>Hallucinogens The hallucinogenic drug D-lysergic acid diethylamide (LSD) blocks serotonin transporters in specific areas of the brain and produces hallucinogenic effects. Other drugs, such as ecstasy, are also hallucinogens that block serotonin transporters.</p> <p>Drug Addiction Cocaine blocks dopamine transporters (symporters), which increases dopamine levels in synaptic clefts, resulting in overstimulation of postsynaptic neurons. Although moderate levels of dopamine can cause euphoria, high levels of dopamine can produce psychotic effects.</p> <p>Parkinson Disease Parkinson disease results from the destruction of dopamine-producing neurons, and it is characterized by tremors and decreased voluntary motor control. Parkinson disease is treated with the drug L-Dopa, which increases the production of dopamine in the presynaptic terminals of remaining neurons. Another treatment option is drugs that mimic the action of dopamine.</p>
<p><i>Norepinephrine</i> Structure:</p>  <p>Site of release: selected CNS synapses and some ANS synapses</p> <p>Effect: excitatory</p>	<p>Attention-Deficit Hyperactivity Disorder (ADHD) ADHD is often treated with drugs that increase the level of excitatory neurotransmitters, such as norepinephrine, in the synaptic clefts. This is achieved by using selective norepinephrine reuptake inhibitors (SNRIs) that block norepinephrine transporters (symporters) and increase the levels of norepinephrine in the synaptic clefts.</p> <p>Amphetamines Amphetamines are drugs with excitatory effects on the CNS. They increase the levels of norepinephrine and dopamine in synaptic clefts by either blocking the reuptake of these neurotransmitters or promoting their release from synaptic vesicles. The CNS effects of amphetamines include decreased appetite, increased alertness, and increased ability to concentrate and perform physical tasks. Amphetamines are used to treat ADHD, clinical depression, narcolepsy, and chronic fatigue syndrome. An overdose of amphetamines can cause insomnia, tremors, anxiety, and panic.</p>
<p>Amino Acids <i>Gamma-Amino Butyric Acid (GABA)</i> Structure:</p>  <p>Site of release: CNS synapses</p> <p>Effect: inhibitory effect on postsynaptic neurons; some presynaptic inhibition occurs in the spinal cord</p>	<p>Barbiturates Certain GABA receptors are ligand-gated channels that permit the inflow of Cl⁻ when stimulated. GABA produces an inhibitory (or a hyperpolarizing) effect by binding to these receptors and promoting Cl⁻ inflow. Barbiturates enhance the binding of GABA to their receptors, resulting in the prolonged inhibition of postsynaptic neurons. These drugs are used as sedatives and anesthetics and as a treatment for epilepsy, which is characterized by excessive neuronal discharge.</p> <div style="display: flex; justify-content: space-around;"> <div data-bbox="512 1365 1006 1911"> <p>Without barbiturates</p>  <p>GABA binding briefly opens Cl⁻ channel.</p> <p>The inflow of Cl⁻ causes inhibition of the postsynaptic neuron.</p> </div> <div data-bbox="1050 1365 1553 1911"> <p>With barbiturates</p>  <p>Enhanced GABA binding opens Cl⁻ channel wider for an extended period.</p> <p>Barbiturate binding enhances GABA binding.</p> <p>Greater inflow of Cl⁻ causes prolonged inhibition of the postsynaptic neuron.</p> </div> </div>

TABLE 11.5 Clinical Examples of Synaptic Function—Continued

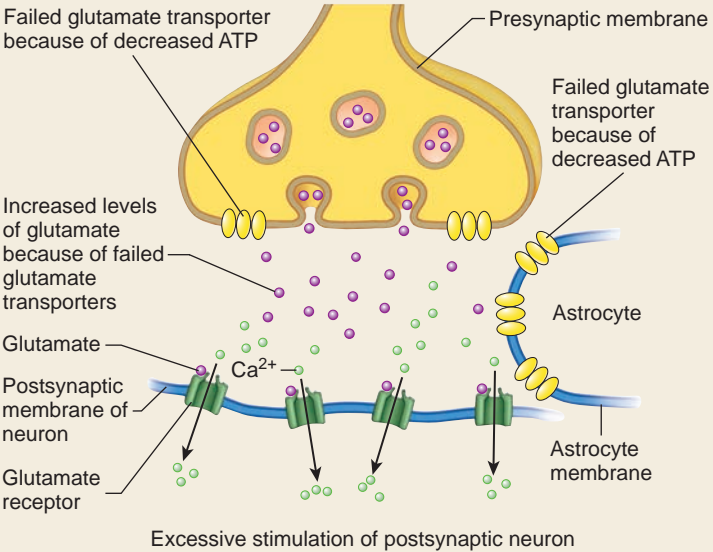

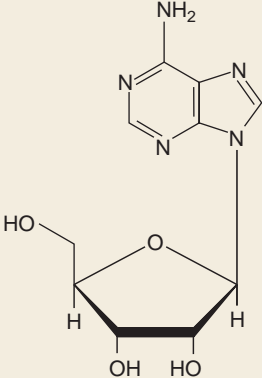

Neurotransmitter/Neuromodulator	Clinical Examples
<p><i>GABA (continued)</i></p> <p><i>Glycine</i> Structure:</p> <chem>NC(=O)O</chem> <p>Site of release: CNS synapses Effect: inhibitory</p> <p><i>Glutamate</i> Structure:</p> <chem>NC(=O)CC(=O)O</chem> <p>Site of release: CNS synapses; in areas of the brain that are involved in learning and memory Effect: excitatory</p>	<p>Benzodiazepines Benzodiazepines that are used in anti-anxiety drugs also have binding sites on certain GABA receptors. Their action is similar to that of barbiturates in that they enhance the binding of GABA to its receptor, producing an inhibitory effect.</p> <p>Alcohol Dependence Alcohol acts in ways similar to barbiturates to enhance the effect of GABA. As a result, the ligand-gated Cl^- channel becomes more permeable to Cl^-, producing an inhibitory effect. Chronic consumption of alcohol renders the GABA receptor less sensitive to both alcohol and GABA, resulting in increased alcohol dependence and alcohol withdrawal symptoms, such as anxiety, tremors, and insomnia. Alcohol withdrawal symptoms are often treated with benzodiazepines.</p> <p>Strychnine Poisoning Glycine receptors are similar to GABA receptors in that they act as ligand-gated channels permitting the inflow of Cl^-. The poison strychnine blocks glycine receptors, which increases the excitability of certain neurons by preventing their inhibition. Strychnine poisoning results in powerful muscle contractions and convulsions. Tetanus of respiratory muscles can cause death.</p> <p>Stroke and Excitotoxicity Glutamate is the major excitatory neurotransmitter of the CNS. Glutamate receptors are ligand-gated Ca^{2+} channels. When stimulated, Ca^{2+} channels open, causing depolarization of postsynaptic membranes. Some glutamate is removed from the synapse by transporters in presynaptic terminals, whereas the bulk of it is removed by transporters (symporters) in neighboring astrocytes. When a person suffers a stroke, brain tissue is deprived of oxygen and ATP levels decrease. This causes the secondary active transport of glutamate by the glutamate transporters to fail temporarily. As a result, glutamate accumulates in the synaptic clefts and causes excessive stimulation of postsynaptic neurons. Excessive movement of Ca^{2+} into neurons activates a variety of destructive processes, which can cause cell death.</p>  <p>Cognition Glutamate is implicated in learning and memory. Drugs that target specific glutamate receptors are often used in the treatment of Alzheimer disease.</p>

TABLE 11.5 Clinical Examples of Synaptic Function—Continued

Neurotransmitter/Neuromodulator	Clinical Examples
<p>Purines <i>Adenosine</i> Structure:</p>  <p>Site of release: CNS synapses; in the areas of the brain that are involved in learning and memory Effect: inhibitory</p> <p>Neuropeptides <i>Substance P</i> Structure: polypeptide (10 amino acids) Site of release: descending pain pathways Effect: excitatory</p> <p><i>Endorphins</i> Structure: Polypeptide (30 amino acids) Site of release: descending pain pathways Effect: inhibitory</p> <p>Gases <i>Nitric Oxide (NO)</i> Structure: N=O Site of release: CNS, nerves supplying the adrenal gland, penis Effect: excitatory</p>	<p>Neuroprotective Agent Adenosine acts both as a neurotransmitter and a neuromodulator. Adenosine receptors are linked to G-proteins (see figure 3.11). As a neurotransmitter, adenosine stimulates the opening of Cl^- and K^+ channels on postsynaptic membranes, thereby producing a hyperpolarizing effect. Acting as a neuromodulator, adenosine stimulates the closing of Ca^{2+} channels on presynaptic neurons, causing the inhibition of neurotransmitter release. Adenosine production greatly increase during a stroke. It prevents the release of glutamate from presynaptic vesicles, which reduces the level of glutamate in synaptic clefts. It also hyperpolarizes the postsynaptic membranes of glutamate synapses, thereby countering the excitatory effects of glutamate. As a result, the damaging effects of glutamate during a stroke are diminished. The possibility of using adenosine as an antistroke agent is being investigated.</p> <p>Caffeine Adenosine produces drowsiness, which is countered by caffeine, which blocks adenosine receptors and promotes alertness. Caffeine also promotes cognition by blocking adenosine's inhibitory effect on glutamate function.</p> <p>Pain Therapy Substance P acts as a neurotransmitter and neuromodulator. The receptor for substance P is called a neurokinin receptor, which is linked to a G-protein complex (see figure 3.11). Drugs such as morphine reduce pain by blocking the release of substance P.</p> <p>Opiates Endorphins bind to endorphin receptors on presynaptic neurons and reduce pain by blocking the release of substance P. Endorphins also produce feelings of euphoria. Opiates such as morphine and heroin also bind to endorphin receptors, resulting in similar effects.</p> <p>Stroke Damage During a stroke, rising glutamate levels act on postsynaptic neurons and cause the release of NO, which in high concentrations can be toxic to cells. Nitric oxide also diffuses out of postsynaptic neurons, enters neighboring cells, and damages them.</p> <p>Treatment of Erectile Dysfunction During sexual arousal, NO is released from nerves, causing the vasodilation of the blood vessels supplying the penis. Viagra, which is used to treat erectile dysfunction, acts by prolonging the effect of NO on these blood vessels (see chapter 28).</p>

- 45** Why does a given type of neurotransmitter affect only certain types of cells? How can a neurotransmitter stimulate one type of cell but inhibit another type?

- 46** What is a neuromodulator?

Excitatory and Inhibitory Postsynaptic Potentials

The combination of neurotransmitters with their specific receptors causes either depolarization or hyperpolarization of

the postsynaptic membrane. When depolarization occurs, the response is stimulatory, and the graded potential is called an **excitatory postsynaptic potential (EPSP)**; figure 11.26a). EPSPs are important because the depolarization might reach threshold, thereby producing an action potential and a response from the cell. Neurons releasing neurotransmitter substances that cause EPSPs are **excitatory neurons**. In general, an EPSP occurs because of an increase in the membrane's permeability to Na^+ . For example, glutamate in the brain and acetylcholine in skeletal muscle can

(a)

(b)

FIGURE 11.26 Postsynaptic Potentials

(a) Excitatory postsynaptic potential (EPSP) is closer to threshold. (b) Inhibitory postsynaptic potential (IPSP) is farther from threshold.

bind to their receptors, causing Na^+ channels to open. Because the concentration gradient is large for Na^+ and because the negative charge inside the cell attracts the positively charged Na^+ , they diffuse into the cell and cause depolarization. If EPSPs cause a depolarizing graded potential that reaches threshold, an action potential is produced.

How Local Anesthetics Work

Awareness of pain can occur only if action potentials generated by sensory neurons stimulate the production of action potentials in CNS neurons. Local anesthetics, such as procaine (Novocain), act at their site of application to prevent pain sensations. They do so by blocking voltage-gated Na^+ channels, which prevents the propagation of action potentials along sensory neurons. Consequently, neurotransmitters are not released from the presynaptic terminals of the sensory neurons and EPSPs are not produced in CNS neurons.

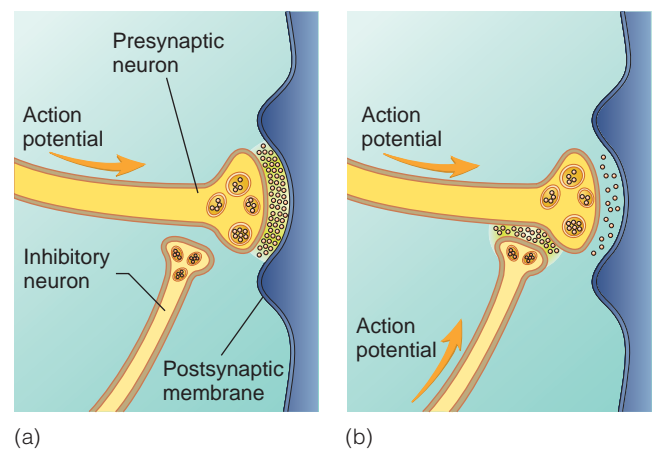

When the combination of a neurotransmitter with its receptor results in hyperpolarization of the postsynaptic membrane,

the response is inhibitory, and the local hyperpolarization is called an **inhibitory postsynaptic potential (IPSP; figure 11.26b)**. IPSPs are important because they decrease the likelihood of producing action potentials by moving the membrane potential farther from threshold. Neurons releasing neurotransmitter substances that cause IPSPs are called **inhibitory neurons**. The IPSP is the result of an increase in the permeability of the plasma membrane to Cl^- or K^+ . For example, in the spinal cord, glycine binds to its receptors, directly causing Cl^- channels to open. Because Cl^- are more concentrated outside the cell than inside, when the membrane's permeability to Cl^- increases, they diffuse into the cell, causing the inside of the cell to become more negative, resulting in hyperpolarization. Acetylcholine can bind to its receptors in the heart, causing G protein-mediated opening of K^+ channels (see chapter 3). The concentration of K^+ is greater inside the cell than outside, and increased permeability of the membrane to K^+ results in diffusion of K^+ out of the cell. Consequently, the outside of the cell becomes more positive than the inside, resulting in hyperpolarization.

Presynaptic Inhibition and Facilitation

Many of the synapses of the CNS are **axoaxonic synapses**, meaning that the axon of one neuron synapses with the presynaptic terminal (axon) of another (figure 11.27). Through axoaxonic synapses, one neuron can release a neuromodulator that influences the release of a neurotransmitter from the presynaptic terminal of another neuron.

In **presynaptic inhibition**, there is a reduction in the amount of neurotransmitter released from the presynaptic terminal. For example, sensory neurons for pain can release neurotransmitters from their presynaptic terminals and stimulate the postsynaptic membranes of neurons in the brain or spinal cord. Awareness of pain occurs only if action potentials are produced in the postsynaptic membranes of the CNS neurons. Enkephalins and endorphins released from inhibitory neurons of axoaxonic

(a)

(b)

FIGURE 11.27 Presynaptic Inhibition at an Axoaxonic Synapse

(a) The inhibitory neuron of the axoaxonic synapse is inactive and has no effect on the release of neurotransmitter from the presynaptic terminal. (b) The release of a neuromodulator from the inhibitory neuron of the axoaxonic synapse reduces the amount of neurotransmitter released from the presynaptic terminal.

synapses can reduce or eliminate pain sensations by inhibiting the release of neurotransmitter from the presynaptic terminals of sensory neurons (see figure 11.27). Enkephalins and endorphins can block voltage-gated Ca^{2+} channels. Consequently, when action potentials reach the presynaptic terminal, the influx of Ca^{2+} that normally stimulates neurotransmitter release is blocked.

In **presynaptic facilitation**, there is an increase in the amount of neurotransmitter released from the presynaptic terminal. For example, serotonin, released in certain axoaxonic synapses, functions as a neuromodulator that increases the release of neurotransmitter from the presynaptic terminal by causing voltage-gated Ca^{2+} channels to open.

47 Define and explain the production of EPSPs and IPSPs. Why are they important?

48 What is presynaptic inhibition and facilitation?

Spatial and Temporal Summation

Depolarizations produced in postsynaptic membranes are graded potentials. Within the CNS and in many PNS synapses, a single presynaptic action potential does not cause a graded potential in the postsynaptic membrane sufficient to reach threshold and produce an action potential. Instead, many presynaptic action potentials cause many graded potentials in the postsynaptic neuron. The graded potentials combine in summation at the trigger zone of the postsynaptic neuron, which is the normal site of action potential generation for most neurons. If summation results in a graded potential that exceeds threshold at the trigger zone, an action potential is produced. Action potentials are readily produced at the trigger zone because the concentration of voltage-gated Na^+ channels is approximately seven times greater there than at the rest of the cell body.

Two types of summation, called spatial summation and temporal summation, are possible. The simplest type of **spatial summation** occurs when two action potentials arrive simultaneously at two different presynaptic terminals that synapse with the same postsynaptic neuron. In the postsynaptic neuron, each action potential causes a depolarizing graded potential that undergoes summation at the trigger zone. If the summated depolarization reaches threshold, an action potential is produced (figure 11.28a).

Temporal summation results when two or more action potentials arrive in very close succession at a single presynaptic terminal. The first action potential causes a depolarizing graded potential in the postsynaptic membrane that remains for a few milliseconds before it disappears, although its magnitude decreases through time. Temporal summation results when another action potential initiates another graded depolarization before the depolarization caused by the previous action potential returns to its resting value (see figure 11.16b). Subsequent action potentials cause depolarizations that summate with previous depolarizations. If the summated depolarizing graded potentials reach threshold at the trigger zone, an action potential is produced in the postsynaptic neuron (figure 11.28b).

PREDICT 10

Excitatory neurons A and B both synapse with neuron C. Neuron A releases a neurotransmitter, and neuron B releases the same type and amount of neurotransmitter plus a neuromodulator that produces EPSPs in neuron C. Action potentials produced in neuron A alone can result in action potential production in neuron C. Action potentials produced in neuron B alone also can cause action potential production in neuron C. Which results in more action potentials in neuron C, stimulation by only neuron A or stimulation by only neuron B? Explain.

Excitatory and inhibitory neurons can synapse with the same postsynaptic neuron. Spatial summation of EPSPs and IPSPs occurs in the postsynaptic neuron, and whether a postsynaptic action potential is initiated or not depends on which type of graded potential has the greatest influence on the postsynaptic membrane potential (figure 11.28c). If the EPSPs (local depolarizations) cancel the IPSPs (local hyperpolarizations) and summate to threshold, an action potential is produced. If the IPSPs prevent the EPSPs from summing to threshold, no action potential is produced.

The synapse is an essential structure for the process of integration carried out by the CNS. For example, action potentials propagated along axons from sensory organs to the CNS can produce a sensation, or they can be ignored. To produce a sensation, action potentials must be transmitted across synapses as they travel through the CNS to the cerebral cortex, where information is interpreted. Stimuli that do not result in action potential transmission across synapses are ignored because information never reaches the cerebral cortex. The brain can ignore large amounts of sensory information as a result of complex integration.

49 Define spatial and temporal summation. In what part of the neuron does summation take place?

50 How do EPSPs and IPSPs affect the likelihood that summation will result in an action potential?

NEURONAL PATHWAYS AND CIRCUITS

The organization of neurons within the CNS varies from relatively simple to extremely complex patterns. The axon of a neuron can branch repeatedly to form synapses with many other neurons, and hundreds or even thousands of axons can synapse with the cell body and dendrites of a single neuron. Although their complexity varies, three basic patterns can be recognized: convergent pathways, divergent pathways, and oscillating circuits.

In **convergent pathways**, many neurons converge and synapse with a smaller number of neurons (figure 11.29a). Convergence makes it possible for different parts of the nervous system to activate or inhibit the activity of neurons. For example, one part of the nervous system can stimulate the neurons responsible for making a muscle contract, whereas another part can inhibit those neurons. Through summation, action potentials resulting in muscle contraction can be produced if the converging neurons stimulate the production of more EPSPs than IPSPs. Conversely, muscle contraction is inhibited if the converging neurons stimulate the production of more IPSPs than EPSPs.

- (a) **Spatial summation.** Action potentials 1 and 2 cause the production of graded potentials at two different dendrites. These graded potentials summate at the trigger zone to produce a graded potential that exceeds threshold, resulting in an action potential.

- (b) **Temporal summation.** Two action potentials arrive in close succession at the presynaptic membrane. The first action potential causes the production of a graded potential that does not reach threshold at the trigger zone. The second action potential results in the production of a second graded potential that summates with the first to reach threshold, resulting in the production of an action potential.

- (c) **Combined spatial and temporal summation with both excitatory postsynaptic potentials (EPSPs) and inhibitory postsynaptic potentials (IPSPs).** An action potential is produced at the trigger zone when the graded potentials produced as a result of the EPSPs and IPSPs summate to reach threshold.

FIGURE 11.28 Summation

In **divergent pathways**, a smaller number of presynaptic neurons synapse with a larger number of postsynaptic neurons to allow information transmitted in one neuronal pathway to diverge into two or more pathways (figure 11.29*b*). Diverging pathways allow one part of the nervous system to affect more than one other part of the nervous system. For example, sensory input to the central nervous system can go to both the spinal cord and the brain.

Oscillating circuits have neurons arranged in a circular fashion, which allows action potentials entering the circuit to cause a

neuron farther along in the circuit to produce an action potential more than once (figure 11.29*c*). This response is called **after-discharge**, and its effect is to prolong the response to a stimulus. Oscillating circuits are similar to positive-feedback systems. Once an oscillating circuit is stimulated, it continues to discharge until the synapses involved become fatigued or until they are inhibited by other neurons. Oscillating circuits play a role in neuronal circuits that are periodically active. Respiration may be controlled by an oscillating circuit that controls inspiration and another that controls expiration.

FIGURE 11.29 Neuronal Pathways and Circuits

The direction of action potential propagation is represented by the *gold arrows*. (a) General model of a convergent pathway; many neurons converge and synapse with a smaller number of neurons. (b) General model of a divergent pathway; a few neurons synapse with a larger number of neurons. (c) Simple model of an oscillating circuit; input action potentials result in the production of a larger number of output action potentials because neurons within the circuit are repeatedly stimulated to produce action potentials.

Neurons that spontaneously produce action potentials are common in the CNS and may activate oscillating circuits, which remain active awhile. The cycle of wakefulness and sleep may involve circuits of this type. Spontaneously active neurons can also influence the activity of other circuit types. The complex functions carried out by the CNS are affected by the numerous

circuits operating together and influencing the activity of one another.

51 *Diagram a convergent pathway, a divergent pathway, and an oscillating circuit, and describe what is accomplished in each.*

SUMMARY

Functions of the Nervous System (p. 375)

The nervous system detects external and internal stimuli (sensory input), processes and responds to sensory input (integration), controls body movements through skeletal muscles, maintains homeostasis by regulating other systems, and is the center for mental activities.

Divisions of the Nervous System (p. 375)

- The nervous system has two anatomical divisions.
 - The central nervous system (CNS) consists of the brain and spinal cord and is encased in bone.
 - The peripheral nervous system (PNS), the nervous tissue outside of the CNS, consists of sensory receptors, nerves, ganglia, and plexuses.
- The PNS has two divisions.
 - The sensory division transmits action potentials to the CNS and usually consists of single neurons that have their cell bodies in ganglia.
 - The motor division carries action potentials away from the CNS in cranial or spinal nerves.
- The motor division has two subdivisions.
 - The somatic nervous system innervates skeletal muscle and is mostly under voluntary control. It consists of single neurons that have their cell bodies located within the CNS.
 - The autonomic nervous system (ANS) innervates cardiac muscle, smooth muscle, and glands. It has two sets of neurons between the CNS and effector organs. The first set has its cell bodies within

the CNS, and the second set has its cell bodies within autonomic ganglia.

- The ANS is subdivided into the sympathetic division, which is most active during physical activity; the parasympathetic division, which regulates resting functions; and the enteric nervous system, which controls the digestive system.
- The anatomical divisions perform different functions.
 - The PNS detects stimuli and transmits information to and receives information from the CNS.
 - The CNS processes, integrates, stores, and responds to information from the PNS.

Cells of the Nervous System (p. 377)

Neurons

- Neurons receive stimuli and transmit action potentials.
- Neurons have three components.
 - The cell body is the primary site of protein synthesis.
 - Dendrites are short, branched cytoplasmic extensions of the cell body that usually conduct electric signals toward the cell body.
 - An axon is a cytoplasmic extension of the cell body that transmits action potentials to other cells.

Types of Neurons

- Multipolar neurons have several dendrites and a single axon. Interneurons and motor neurons are multipolar.

2. Bipolar neurons have a single axon and dendrite and are found as components of sensory organs.
3. Unipolar neurons have a single axon. Most sensory neurons are unipolar.

Glial Cells of the CNS

1. Glial cells are nonneural cells that support and aid the neurons of the CNS and PNS.
2. Astrocytes provide structural support for neurons and blood vessels. Astrocytes influence the functioning of the blood–brain barrier and process substances that pass through it. Astrocytes isolate damaged tissue and limit the spread of inflammation. Astrocytes also help maintain synaptic function.
3. Ependymal cells line the ventricles and the central canal of the spinal cord. Some are specialized to produce cerebrospinal fluid.
4. Microglia phagocytize microorganisms, foreign substances, and necrotic tissue.
5. An oligodendrocyte forms myelin sheaths around the axons of several CNS neurons.

Glial Cells of the PNS

1. A Schwann cell forms a myelin sheath around part of the axon of a PNS neuron.
2. Satellite cells support and nourish neuron cell bodies within ganglia.

Myelinated and Unmyelinated Axons

1. Myelinated axons are wrapped by several layers of plasma membrane from Schwann cells (PNS) or oligodendrocytes (CNS). Spaces between the wrappings are the nodes of Ranvier. Myelinated axons conduct action potentials rapidly.
2. Unmyelinated axons rest in invaginations of Schwann cells (PNS) or oligodendrocytes (CNS). They conduct action potentials slowly.

Organization of Nervous Tissue (p. 382)

1. Nervous tissue can be grouped into white and gray matter.
 - White matter consists of myelinated axons; it propagates action potentials.
 - Gray matter consists of collections of neuron cell bodies or unmyelinated axons. Axons synapse with neuron cell bodies, which are functionally the site of integration in the nervous system.
2. White matter forms nerve tracts in the CNS and nerves in the PNS. Gray matter forms cortex and nuclei in the CNS and ganglia in the PNS.

Electric Signals (p. 382)

Electrical properties of cells result from the ionic concentration differences across the plasma membrane and from the permeability characteristics of the plasma membrane.

Concentration Differences Across the Plasma Membrane

1. The Na^+ – K^+ pump moves ions by active transport. Potassium ions are moved into the cell, and Na^+ are moved out of it.
2. The concentration of K^+ and negatively charged proteins and other molecules is higher inside, and the concentrations of Na^+ and Cl^- are higher outside the cell.
3. Negatively charged proteins and other negatively charged ions are synthesized inside the cell and cannot diffuse out of it, and they repel negatively charged Cl^- .

4. The permeability of the plasma membrane to ions is determined by leak channels and gated ion channels.
 - Potassium ion leak channels are more numerous than Na^+ leak channels, thus the plasma membrane is more permeable to K^+ than to Na^+ when at rest.
 - Gated ion channels in the plasma membrane include ligand-gated ion channels, voltage-gated ion channels, and other gated ion channels.

Establishing the Resting Membrane Potential

1. The resting membrane potential is a charge difference across the plasma membrane when the cell is in an unstimulated condition. The inside of the cell is negatively charged, compared with the outside of the cell.
2. The resting membrane potential is due mainly to the tendency of positively charged K^+ to diffuse out of the cell, which is opposed by the negative charge that develops inside the plasma membrane.

Changing the Resting Membrane Potential

1. Depolarization is a decrease in the resting membrane potential and can result from a decrease in the K^+ concentration gradient, a decrease in membrane permeability to K^+ , an increase in membrane permeability to Na^+ , an increase in membrane permeability to Ca^{2+} , or a decrease in extracellular Ca^{2+} concentration.
2. Hyperpolarization is an increase in the resting membrane potential that can result from an increase in the K^+ concentration gradient, an increase in membrane permeability to K^+ , an increase in membrane permeability to Cl^- , a decrease in membrane permeability to Na^+ , or an increase in extracellular Ca^{2+} concentration.

Graded Potentials

1. A graded potential is a small change in the resting membrane potential that is confined to a small area of the plasma membrane.
2. An increase in membrane permeability to Na^+ can cause graded depolarization, and an increase in membrane permeability to K^+ or Cl^- can result in graded hyperpolarization.
3. The term *graded potential* is used because a stronger stimulus produces a greater potential change than a weaker stimulus.
4. Graded potentials can summate, or add together.
5. A graded potential decreases in magnitude as the distance from the stimulation increases.

Action Potentials

1. An action potential is a larger change in the resting membrane potential that spreads over the entire surface of the cell.
2. Threshold is the membrane potential at which a graded potential depolarizes the plasma membrane sufficiently to produce an action potential.
3. Action potentials occur in an all-or-none fashion. If action potentials occur, they are of the same magnitude, no matter how strong the stimulus.
4. Depolarization occurs as the inside of the membrane becomes more positive because Na^+ diffuse into the cell through voltage-gated ion channels.
5. Repolarization is a return of the membrane potential toward the resting membrane potential because voltage-gated Na^+ channels close and Na^+ diffusion into the cell slows to resting levels and because voltage-gated K^+ channels continue to open and K^+ diffuse out of the cell.
6. The afterpotential is a brief period of hyperpolarization following repolarization.

Refractory Period

1. The absolute refractory period is the time during an action potential when a second stimulus, no matter how strong, cannot initiate another action potential.
2. The relative refractory period follows the absolute refractory period and is the time during which a stronger-than-threshold stimulus can evoke another action potential.

Action Potential Frequency

1. The strength of stimuli affects the frequency of action potentials.
 - A subthreshold stimulus produces only a graded potential.
 - A threshold stimulus causes a graded potential that reaches threshold and results in a single action potential.
 - A submaximal stimulus is greater than a threshold stimulus and weaker than a maximal stimulus. The action potential frequency increases as the strength of the submaximal stimulus increases.
 - A maximal or a supramaximal stimulus produces a maximum frequency of action potentials.
2. A low frequency of action potentials represents a weaker stimulus than a high frequency.

Propagation of Action Potentials

1. An action potential generates ionic currents, which stimulate voltage-gated Na^+ channels in adjacent regions of the plasma membrane to open, producing a new action potential.
2. In an unmyelinated axon, action potentials are generated immediately adjacent to previous action potentials.
3. In a myelinated axon, action potentials are generated at successive nodes of Ranvier.
4. Reversal of the direction of action potential propagation is prevented by the absolute refractory period.
5. Action potentials propagate most rapidly in myelinated, large-diameter axons.

The Synapse (p. 394)

Electrical Synapses

1. Electrical synapses are gap junctions in which tubular proteins called connexons allow ionic currents to move between cells.
2. At an electrical synapse, an action potential in one cell generates an ionic current that causes an action potential in an adjacent cell.

Chemical Synapses

1. Anatomically, a chemical synapse has three components.
 - The enlarged ends of the axon are the presynaptic terminals containing synaptic vesicles.

- The postsynaptic membranes contain receptors for the neurotransmitter.
 - The synaptic cleft, a space, separates the presynaptic and postsynaptic membranes.
2. An action potential arriving at the presynaptic terminal causes the release of a neurotransmitter, which diffuses across the synaptic cleft and binds to the receptors of the postsynaptic membrane.
 3. The effect of the neurotransmitter on the postsynaptic membrane is stopped in several ways.
 - The neurotransmitter is broken down by an enzyme.
 - The neurotransmitter is taken up by the presynaptic terminal.
 - The neurotransmitter diffuses out of the synaptic cleft.
 4. Neurotransmitters are specific for their receptors. A neurotransmitter can be stimulatory in one synapse and inhibitory in another, depending on the type of receptor present.
 5. Neuromodulators influence the likelihood that an action potential in a presynaptic terminal will result in an action potential in a postsynaptic cell.
 6. An excitatory postsynaptic potential (EPSP) is a depolarizing graded potential of the postsynaptic membrane. It can be caused by an increase in membrane permeability to Na^+ .
 7. An inhibitory postsynaptic potential (IPSP) is a hyperpolarizing graded potential of the postsynaptic membrane. It can be caused by an increase in membrane permeability to K^+ or Cl^- .
 8. Presynaptic inhibition decreases neurotransmitter release. Presynaptic facilitation increases neurotransmitter release.

Spatial and Temporal Summation

1. Presynaptic action potentials through neurotransmitters produce graded potentials in postsynaptic neurons. The graded potential can summate to produce an action potential at the trigger zone.
2. Spatial summation occurs when two or more presynaptic terminals simultaneously stimulate a postsynaptic neuron.
3. Temporal summation occurs when two or more action potentials arrive in succession at a single presynaptic terminal.
4. Inhibitory and excitatory presynaptic neurons can converge on a postsynaptic neuron. The activity of the postsynaptic neuron is determined by the integration of the EPSPs and IPSPs produced in the postsynaptic neuron.

Neuronal Pathways and Circuits (p. 404)

1. Convergent pathways have many neurons synapsing with a few neurons.
2. Divergent pathways have a few neurons synapsing with many neurons.
3. Oscillating circuits have collateral branches of postsynaptic neurons synapsing with presynaptic neurons.

REVIEW AND COMPREHENSION

1. The peripheral nervous system includes the
 - a. somatic nervous system.
 - b. brain.
 - c. spinal cord.
 - d. nuclei.
 - e. all of the above.
2. The part of the nervous system that controls smooth muscle, cardiac muscle, and glands is the
 - a. somatic nervous system.
 - b. autonomic nervous system.
 - c. skeletal division.
 - d. sensory division.
3. Neurons have cytoplasmic extensions that connect one neuron to another neuron. Given these structures:
 1. axon
 2. dendrite
 3. dendritic spine
 4. presynaptic terminal

Choose the arrangement that lists the structures in the order they are found between two neurons.

 - a. 1,4,2,3
 - b. 1,4,3,2
 - c. 4,1,2,3
 - d. 4,1,3,2
 - e. 4,3,2,1

4. A neuron with many short dendrites and a single long axon is a _____ neuron.
 - a. multipolar
 - b. unipolar
 - c. bipolar
5. Motor neurons and interneurons are _____ neurons.
 - a. unipolar
 - b. bipolar
 - c. multipolar
 - d. afferent
6. Cells found in the choroid plexuses that secrete cerebrospinal fluid are
 - a. astrocytes.
 - b. microglia.
 - c. ependymal cells.
 - d. oligodendrocytes.
 - e. Schwann cells.
7. Glial cells that are phagocytic within the central nervous system are
 - a. oligodendrocytes.
 - b. microglia.
 - c. ependymal cells.
 - d. astrocytes.
 - e. Schwann cells.
8. Unmyelinated axons within nerves may have which of these associated with them?
 - a. Schwann cells
 - b. nodes of Ranvier
 - c. oligodendrocytes
 - d. all of the above
9. Action potentials are conducted more rapidly
 - a. in small-diameter axons than in large-diameter axons.
 - b. in unmyelinated axons than in myelinated axons.
 - c. along axons that have nodes of Ranvier.
 - d. all of the above.
10. Clusters of neuron cell bodies within the peripheral nervous system are
 - a. ganglia.
 - b. fascicles.
 - c. nuclei.
 - d. laminae.
11. Gray matter contains primarily
 - a. myelinated fibers.
 - b. neuron cell bodies.
 - c. Schwann cells.
 - d. oligodendrocytes.
12. Concerning concentration difference across the plasma membrane, there are
 - a. more K^+ and Na^+ outside the cell than inside.
 - b. more K^+ and Na^+ inside the cell than outside.
 - c. more K^+ outside the cell than inside and more Na^+ inside the cell than outside.
 - d. more K^+ inside the cell than outside and more Na^+ outside the cell than inside.
13. Compared with the inside of the resting plasma membrane, the outside surface of the membrane is
 - a. positively charged.
 - b. electrically neutral.
 - c. negatively charged.
 - d. continuously reversing so that it is positive 1 second and negative the next.
 - e. negatively charged whenever the Na^+-K^+ pump is operating.
14. Leak channels
 - a. open in response to small voltage changes.
 - b. open when a chemical signal binds to its receptor.
 - c. are responsible for the ion permeability of the resting plasma membrane.
 - d. allow substances to move into the cell but not out.
 - e. all of the above.
15. The resting membrane potential results when the tendency for _____ to diffuse out of the cell is balanced by their attraction to opposite charges inside the cell.
 - a. Na^+
 - b. K^+
 - c. Cl^-
 - d. negatively charged proteins
16. If the permeability of the plasma membrane to K^+ increases, resting membrane potential _____. This is called _____.
 - a. increases, hyperpolarization
 - b. increases, depolarization
 - c. decreases, hyperpolarization
 - d. decreases, depolarization
17. Decreasing the extracellular concentration of K^+ affects the resting membrane potential by causing
 - a. hyperpolarization.
 - b. depolarization.
 - c. no change.
18. Which of these terms are correctly matched with their definition or description?
 - a. depolarization: membrane potential becomes more negative
 - b. hyperpolarization: membrane potential becomes more negative
 - c. hypopolarization: membrane potential becomes more negative
19. Which of these statements about ion movement through the plasma membrane is true?
 - a. Movement of Na^+ out of the cell requires energy (ATP).
 - b. When Ca^{2+} binds to proteins in ion channels, the diffusion of Na^+ into the cell is inhibited.
 - c. Specific ion channels regulate the diffusion of Na^+ through the plasma membrane.
 - d. All of the above are true.
20. The *major* function of the Na^+-K^+ pump is to
 - a. pump Na^+ into and K^+ out of the cell.
 - b. generate the resting membrane potential.
 - c. maintain the concentration gradients of Na^+ and K^+ across the plasma membrane.
 - d. oppose any tendency of the cell to undergo hyperpolarization.
21. Graded potentials
 - a. spread over the plasma membrane in decremental fashion.
 - b. are not propagated for long distances.
 - c. are confined to a small region of the plasma membrane.
 - d. can summate.
 - e. all of the above.
22. During the depolarization phase of an action potential, the permeability of the membrane
 - a. to K^+ is greatly increased.
 - b. to Na^+ is greatly increased.
 - c. to Ca^{2+} is greatly increased.
 - d. is unchanged.
23. During repolarization of the plasma membrane,
 - a. Na^+ diffuse into the cell.
 - b. Na^+ diffuse out of the cell.
 - c. K^+ diffuse into the cell.
 - d. K^+ diffuse out of the cell.
24. The absolute refractory period
 - a. limits how many action potentials can be produced during a given period of time.
 - b. prevents an action potential from starting another action potential at the same point on the plasma membrane.
 - c. is the period of time when a strong stimulus can initiate a second action potential.
 - d. both a and b.
 - e. all of the above.
25. A subthreshold stimulus
 - a. produces an afterpotential.
 - b. produces a graded potential.
 - c. causes an all-or-none response.
 - d. produces more action potentials than a submaximal stimulus.
26. Neurotransmitter substances are stored in vesicles located in specialized portions of the
 - a. neuron cell body.
 - b. axon.
 - c. dendrite.
 - d. postsynaptic membrane.

27. In a chemical synapse,
- action potentials in the presynaptic terminal cause voltage-gated Ca^{2+} channels to open.
 - neurotransmitters can cause ligand-gated Na^+ channels to open.
 - neurotransmitters can be broken down by enzymes.
 - neurotransmitters can be taken up by the presynaptic terminal.
 - all of the above.
28. An inhibitory presynaptic neuron can affect a postsynaptic neuron by
- producing an IPSP in the postsynaptic neuron.
 - hyperpolarizing the plasma membrane of the postsynaptic neuron.
 - causing K^+ to diffuse out of the postsynaptic neuron.
 - causing Cl^- to diffuse into the postsynaptic neuron.
 - all of the above.
29. Summation
- is caused by combining two or more graded potentials.
 - occurs at the trigger zone of the postsynaptic neuron.
 - results in an action potential if it reaches the threshold potential.
 - can occur when two action potentials arrive in close succession at a single presynaptic terminal.
 - all of the above.
30. In convergent pathways,
- the response of the postsynaptic neuron depends on the summation of EPSPs and IPSPs.
 - a smaller number of presynaptic neurons synapse with a larger number of postsynaptic neurons.
 - information transmitted in one neuronal pathway can go into two or more pathways.
 - all of the above.

Answers in Appendix E

CRITICAL THINKING

- Predict the consequence of a reduced intracellular K^+ concentration on the resting membrane potential.
- A child eats a whole bottle of salt (NaCl) tablets. What effect does this have on action potentials?
- Lithium ions reduce the permeability of plasma membranes to Na^+ . Predict the effect lithium ions in the extracellular fluid would have on the response of a neuron to stimuli.
- Some smooth muscle has the ability to contract spontaneously—that is, it contracts without any external stimulation. Propose an explanation for the ability of smooth muscle to contract spontaneously based on what you know about membrane potentials. Assume that an action potential in a smooth muscle cell causes it to contract.
- Assume that you have two nerve fibers of the same diameter, but one is myelinated and the other is unmyelinated. The conduction of an action potential is most energy-efficient along which type of fiber? (*Hint: ATP.*)
- Explain the consequences when an inhibitory neuromodulator is released from a presynaptic terminal and a stimulatory neurotransmitter is released from another presynaptic terminal, both of which synapse with the same neuron.
- The speed of action potential propagation and synaptic transmission decreases with aging. List possible explanations.
- Students in a veterinary school are given the following hypothetical problem. A dog ingests organophosphate poison, and the students are responsible for saving the animal's life. Organophosphate poisons bind to and inhibit acetylcholinesterase. Several substances they could inject include the following: acetylcholine, curare (which blocks acetylcholine receptors), and potassium chloride. If you were a student in the class, what would you do to save the animal?
- Strychnine blocks receptor sites for inhibitory neurotransmitter substances in the CNS. Explain how strychnine could produce tetanus in skeletal muscles.
- The venom of many cobras contains a potent neurotoxin that binds to ligand-gated Na^+ channels, causing them to open. Unlike ACh, which binds to and then rapidly unbinds from ligand-gated Na^+ channels, the neurotoxin tends to remain bound to ligand-gated Na^+ channels. What effect would this neurotoxin have on the ability of the nervous system to stimulate skeletal muscle contraction? What effect would it have on the ability of skeletal muscle fibers to respond to stimulation?
- Epilepsy is a chronic disorder characterized by seizures resulting from excessive production of action potentials by neurons in the brain. Channelopathies are genetic disorders caused by mutations in ion channel genes, which result in ion channels that do not function normally. What kind of Na^+ or Ca^{2+} channelopathies might contribute to epilepsy?

Spinal Cord and Spinal Nerves

12

The **central nervous system (CNS)** consists of the brain and spinal cord, with the division between these two parts of the CNS placed at the level of the foramen magnum. The **peripheral nervous system (PNS)** consists of nerves and ganglia outside the CNS (see chapter 11). **Nerves** consist of axons, Schwann cells, and connective tissue sheaths. **Ganglia** are accumulations of cell bodies in the PNS. The PNS includes 12 pairs of cranial nerves and 31 pairs of spinal nerves and their ganglia.

The CNS receives sensory information, integrates and evaluates that information, stores some information, and initiates reactions. The PNS collects information from numerous sources both inside and outside the body and relays it through axons of sensory neurons to the CNS. Axons of motor neurons in the PNS relay information from the CNS to various parts of the body, primarily to muscles and glands, thereby regulating activity in those structures.

The spinal cord and spinal nerves are described in this chapter. The brain and cranial nerves are considered in chapter 13. The specific topics of chapter 12 are the *spinal cord* (p. 412), *reflexes* (p. 415), *interactions with spinal cord reflexes* (p. 421), the *structure of peripheral nerves* (p. 421), and *spinal nerves* (p. 422).

Colorized SEM of nerve fascicles containing bundles of axons.

SPINAL CORD

The **spinal cord** is extremely important to the overall function of the nervous system. It is the major communication link between the brain and the PNS inferior to the head; it participates in the integration of incoming information and produces responses through reflex mechanisms.

General Structure

The spinal cord (figure 12.1) extends from the foramen magnum to the level of the second lumbar vertebra. It is considerably shorter than the vertebral column because it does not grow as rapidly as the vertebral column during development. The spinal cord is

Posterior view

FIGURE 12.1 Spinal Cord and Spinal Nerve Roots

composed of cervical, thoracic, lumbar, and sacral segments, named according to the portion of the vertebral column from which their nerves enter and exit. The spinal cord gives rise to 31 pairs of spinal nerves, which exit the vertebral column through intervertebral and sacral foramina (see figure 7.13). The nerves from the lower segments descend some distance in the vertebral canal before they exit because the spinal cord is shorter than the vertebral column.

The spinal cord is not uniform in diameter throughout its length. It is larger in diameter at its superior end, and it gradually decreases in diameter toward its inferior end. Two enlargements occur where nerves supplying the upper and lower limbs enter and leave the spinal cord (see figure 12.1). The **cervical enlargement** in the inferior cervical region corresponds to the location where axons that supply the upper limbs enter and leave the spinal cord. The **lumbo-sacral enlargement** in the inferior thoracic, lumbar, and superior sacral regions is the site where the axons supplying the lower limbs enter or leave the spinal cord.

PREDICT 1

Why is the spinal cord enlarged in the cervical and lumbo-sacral regions?

Immediately inferior to the lumbo-sacral enlargement, the spinal cord tapers to form a conelike region called the **conus medullaris**. Its tip is the inferior end of the spinal cord; it extends to the level of the second lumbar vertebra. The nerves supplying the lower limbs and other inferior structures of the body arise from the lumbar and sacral nerves. They exit the lumbo-sacral enlargement and conus medullaris, course inferiorly through the vertebral canal, and exit through the intervertebral foramina from the second lumbar to the fifth sacral vertebrae. The numerous roots (origins) of spinal nerves extending inferiorly from the lumbo-sacral enlargement and conus medullaris resemble a horse's tail and are therefore called the **cauda** (kaw'dā; tail) **equina** (ē-kwī'nā; horse; see figure 12.1).

1 Describe the cervical and lumbar enlargements of the spinal cord, the conus medullaris, and the cauda equina. How many pairs of spinal nerves exit the spinal cord?

Meninges of the Spinal Cord

The spinal cord and brain are surrounded by connective tissue membranes called **meninges** (mē-nin'jēz; figure 12.2). The most superficial and thickest membrane is the **dura mater** (doo'rā mā'ter; tough mother). The dura mater forms a sac, often called the **thecal** (the'kal) **sac**, that surrounds the spinal cord. The thecal sac attaches to the rim of the foramen magnum and ends at the level of the second sacral vertebra. The spinal dura mater is continuous with the dura mater surrounding the brain and the connective tissue surrounding the spinal nerves. The dura mater around the spinal cord is separated from the periosteum of the vertebral canal by the **epidural space**. This is a true space between the walls of the vertebral canal and the dura mater of the spinal cord that contains spinal nerve roots, blood vessels, areolar connective tissue, and fat. In contrast, the epidural space around the brain is only a potential space. **Epidural anesthesia** of the spinal nerves is induced by injecting anesthetics into this space. Epidural anesthesia is often given to women during childbirth.

FIGURE 12.2 Meningeal Membranes Surrounding the Spinal Cord

PREDICT 2

Epidural anesthesia is usually induced by injection at what level of the vertebral column?

The next deeper meningeal membrane is a very thin, wispy **arachnoid** (ă-rak'noyd; spiderlike—i.e., cobwebs) **mater**. The space between this membrane and the dura mater is the **subdural space**; it contains only a very small amount of serous fluid.

The third, deepest, meningeal layer, the **pia** (pī'ă; affectionate) **mater** is bound very tightly to the surface of the spinal cord. The spinal cord is held in place within the thecal sac by the denticulate ligaments and the filum terminale. The paired **denticulate** (den-tik'ū-lāt) **ligaments** are connective tissue septa extending from the lateral sides of the spinal cord to the dura mater (see figure 12.2b). The term *denticulate* refers to having small teeth, and the denticulate ligaments attach to the dura mater by 21 triangular, or toothlike, processes between the exits of the cervical and thoracic spinal nerves. The denticulate ligaments limit the lateral movement of the spinal cord. The **filum terminale** (fī'lūm ter'mi-nal'ē) is a connective tissue strand that anchors the conus medullaris and the thecal sac to the first coccygeal vertebra, limiting their superior movement.

Between the arachnoid mater and the pia mater is the **subarachnoid space**, which contains weblike strands of the arachnoid mater, blood vessels, and **cerebrospinal** (ser'ĕ-brō-spī-nāl, sĕ-rĕ'brō-spī-nal) **fluid** (CSF), which is described in chapter 13.

Introduction of Needles into the Subarachnoid Space

Several clinical procedures involve the insertion of a needle into the subarachnoid space inferior to the level of the second lumbar vertebra. The needle is introduced into either the L3/L4 or the L4/L5 intervertebral space. The needle does not contact the spinal cord because it extends only approximately to the second lumbar vertebra of the vertebral column, but the subarachnoid space extends to level S2 of the vertebral column. Nor does the needle damage the nerve roots of the cauda equina located in the subarachnoid space because the needle quite easily pushes them aside. In **spinal anesthesia**, or spinal block, drugs that block action potential transmission are introduced into the subarachnoid space to prevent pain sensations in the lower half of the body. A **spinal tap** is the removal of CSF from the subarachnoid space. A spinal tap may be performed to examine the CSF for infectious agents (meningitis), for the presence of blood (hemorrhage), or for the measurement of CSF pressure. A radiopaque substance may also be injected into this area, and a **myelogram** (radiograph of the spinal cord) may be taken to visualize spinal cord defects or damage.

- 2 Name the meninges surrounding the spinal cord. What is found within the epidural, subdural, and subarachnoid spaces?
- 3 How is the spinal cord held within the vertebral canal?

Cross Section of the Spinal Cord

A cross section of the spinal cord reveals that the cord consists of a peripheral white portion and a central gray portion (figure 12.3*a* and *b*). The white matter consists of myelinated axons forming nerve tracts, and the gray matter consists of neuron cell bodies, dendrites, and axons. An **anterior median fissure** and a **posterior median sulcus** are deep clefts partially separating the two halves of the cord. The white matter in each half of the spinal cord is organized into three **columns**, or **funiculi** (fū-nik'ū-lī), called the **ventral** (anterior), **dorsal** (posterior), and **lateral columns**. Each column of the spinal cord is subdivided into **tracts**, or **fasciculi** (fā-sik'ū-lī), also referred to as **pathways**. Individual axons ascending

to the brain or descending from the brain are usually grouped together within the tracts (figure 12.3*c*). Axons within a given tract carry basically the same type of information, although they may overlap to some extent. For example, one ascending tract carries action potentials related to pain and temperature sensations, whereas another carries action potentials related to light touch.

The central gray matter is organized into horns. Each half of the central gray matter of the spinal cord consists of a relatively thin **posterior** (dorsal) **horn** and a larger **anterior** (ventral) **horn**. Small **lateral horns** exist in levels of the cord associated with the autonomic nervous system (see chapter 16). The two halves of the spinal cord are connected by **gray** and **white commissures** (see figure 12.3). The white and gray commissures contain axons

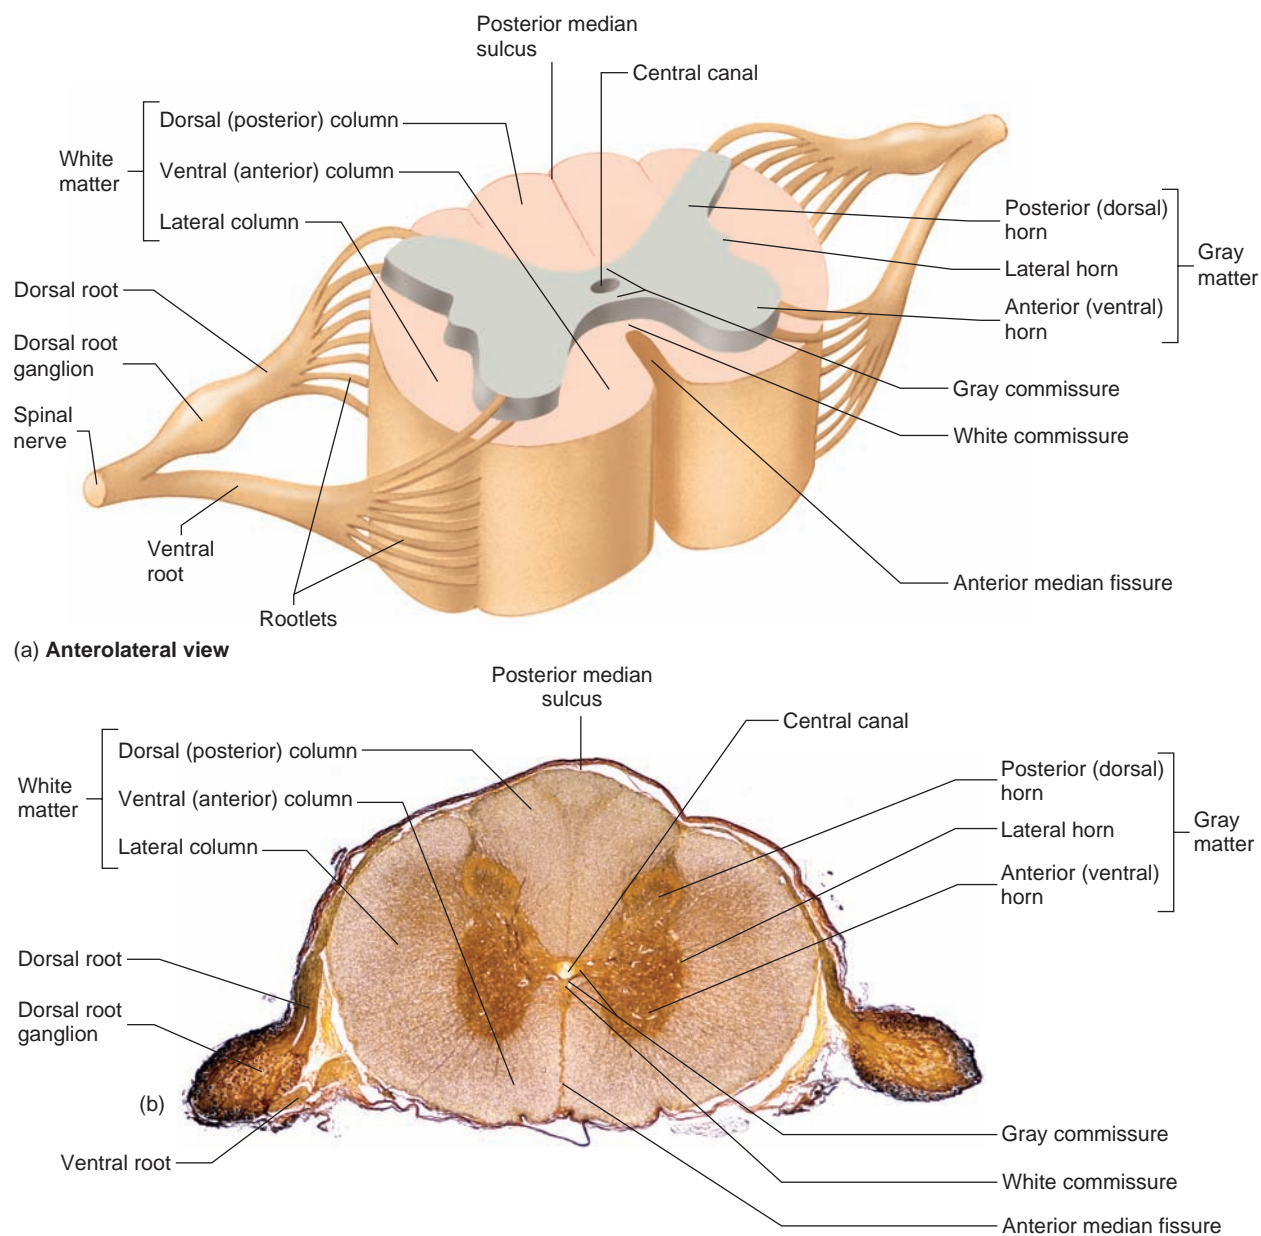

FIGURE 12.3 Cross Section of the Spinal Cord

(*a*) A segment of the spinal cord showing one dorsal and one ventral root on each side and the rootlets that form them. (*b*) Photograph of a cross section through the midlumbar region. The *lighter tan areas* are white matter, where tracts are located. The *darker area* is gray matter, where neuron cell bodies are located.

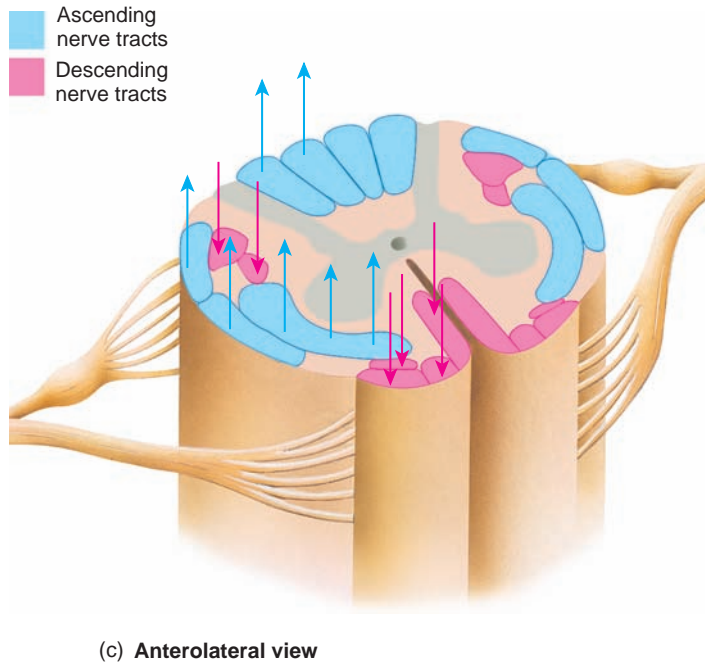

FIGURE 12.3 (continued)

(c) Ascending and descending tracts in the spinal cord. Ascending nerve tracts are *blue*; descending nerve tracts are *pink*. The arrows indicate the direction of each pathway.

that cross from one side of the spinal cord to the other. The **central canal** is in the center of the gray commissure.

Spinal nerves arise from numerous rootlets along the dorsal and ventral surfaces of the spinal cord (see figure 12.3a). Six to eight of these rootlets combine to form each **ventral root** on the ventral (anterior) side of the spinal cord, and another six to eight form each **dorsal root** on the dorsal (posterior) side of the cord at each segment. The ventral and dorsal roots extend laterally from the spinal cord, passing through the subarachnoid space, piercing the arachnoid mater and dura mater, and joining one another to form a spinal nerve. Each dorsal root contains a ganglion, called the **dorsal root**, or **spinal ganglion** (gang'glē-on; a swelling or knot).

The dorsal root ganglia are collections of cell bodies of the sensory neurons forming the dorsal roots of the spinal nerves (figure 12.4).

The axons of these unipolar neurons extend from various parts of the body and pass through spinal nerves to the dorsal root ganglia. The axons do not synapse in the dorsal root ganglion but pass through the dorsal root into the posterior horn of the spinal cord gray matter. The axons either synapse with interneurons in the posterior horn or pass into the white matter and ascend or descend in the spinal cord.

Motor neurons innervate muscles and glands. The cell bodies of the motor neurons are located in the anterior and lateral horns of the spinal cord gray matter (see figure 12.4). The cell bodies of multipolar somatic motor neurons are in the anterior horn, also called the motor horn, and autonomic neuron cell bodies are in the lateral horn. Axons of the motor neurons form the ventral roots and pass into the spinal nerves. Thus, dorsal roots contain sensory axons, ventral roots contain motor axons, and spinal nerves have both sensory and motor axons.

- 4 Describe the arrangement of white and gray matter in the spinal cord.
- 5 What are tracts and commissures?
- 6 Where are the cell bodies of sensory, somatic motor, and autonomic neurons located in the gray matter?
- 7 Where do dorsal and ventral roots exit the spinal cord? What kinds of axons are in the dorsal and ventral roots and in the spinal nerves?

PREDICT 3

Explain why the dorsal root ganglia are larger in diameter than the dorsal roots, and describe the direction of action potential propagation in the spinal nerves, dorsal roots, and ventral roots.

REFLEXES

The basic structural unit of the nervous system is the neuron. The **reflex arc** is the basic functional unit of the nervous system because it is the smallest, simplest portion capable of receiving a stimulus and producing a response. Because the reflex arc is the basic functional unit of the nervous system, it is possible to learn

FIGURE 12.4 Relationship of Sensory and Motor Neurons to the Spinal Cord

1. A stimulus is detected by a sensory receptor.
2. A sensory neuron conducts action potentials through the spinal nerve and dorsal root to the spinal cord.
3. In the spinal cord, the sensory neuron synapses with an interneuron.
4. The interneuron synapses with a motor neuron.
5. A motor neuron axon conducts action potentials through the ventral root and spinal nerve to an effector organ.

PROCESS FIGURE 12.5 Reflex Arc

The parts of a reflex arc are labeled in the order in which action potentials pass through them.

much about nervous system functions by examining how reflex arcs receive stimuli and produce responses. The reflex arc has five basic components: (1) a sensory receptor, (2) a sensory neuron, (3) an interneuron, (4) a motor neuron, and (5) an effector organ (figure 12.5).

A **reflex** is an automatic response to a stimulus produced by a reflex arc. It occurs without conscious thought. Action potentials initiated in sensory receptors are transmitted along the axons of sensory neurons to the CNS, where the axons usually synapse with interneurons. Interneurons synapse with motor neurons, which send axons out of the spinal cord and through the PNS to muscles or glands, where the action potentials of the motor neurons cause these effector organs to respond.

Reflexes are homeostatic. Some reflexes, called somatic reflexes, remove the body from painful stimuli that would cause tissue damage or keep the body from suddenly falling or moving because of external forces. A number of other reflexes, called autonomic reflexes, are responsible for maintaining relatively constant blood pressure, blood carbon dioxide levels, and water intake.

Individual reflexes vary in their complexity. **Monosynaptic reflexes** involve simple neuronal pathways in which sensory neurons synapse directly with motor neurons. **Polysynaptic reflexes** involve more complex pathways and integrative centers with one or more interneurons between the sensory and motor neurons.

Many reflexes are integrated within the spinal cord, and others are integrated within the brain. Some reflexes involve excitatory neurons and result in a response, such as when a muscle contracts (see chapter 11). Other reflexes involve inhibitory neurons and

result in the inhibition of a response, such as when a muscle is inhibited and relaxes. In addition, higher brain centers influence reflexes by either suppressing or exaggerating them. Major spinal cord reflexes include the stretch reflex, the Golgi tendon reflex, and the withdrawal reflex.

- 8** Name the parts of a reflex arc and explain how they produce a reflex.

Stretch Reflex

The simplest reflex is the **stretch reflex** (figure 12.6), a reflex in which muscles contract in response to a stretching force applied to them. The sensory receptor of this reflex is the **muscle spindle**, which consists of 3–10 small, specialized skeletal muscle cells. The cells are contractile only at their ends and are innervated by specific motor neurons called **gamma motor neurons** (the term *gamma* refers to motor neurons with small-diameter axons) originating from the spinal cord and controlling the sensitivity of the muscle spindle cells. Sensory neurons innervate the noncontractile centers of the muscle spindle cells. Axons of these sensory neurons extend to the spinal cord and synapse directly with motor neurons in the spinal cord called **alpha motor neurons**, which in turn innervate the muscle in which the muscle spindle is embedded. Neurons can be classified by the diameter of their axons, with alpha motor neurons having the largest diameter. The stretch reflex is a monosynaptic reflex because there is no interneuron between the sensory neuron and the alpha motor neuron.

Sudden stretch of a muscle results in:

1. Muscle spindles detect stretch of the muscle.
 2. Sensory neurons conduct action potentials to the spinal cord.
 3. Sensory neurons synapse directly with alpha motor neurons.
 4. Stimulation of the alpha motor neurons results in action potentials being conducted to the muscle, causing it to contract and resist being stretched.
- Note:* The muscle that contracts is the muscle that is stretched.

PROCESS FIGURE 12.6 Stretch Reflex

Stretching a muscle also stretches muscle spindles located among the muscle fibers. The stretch stimulates the sensory neurons that innervate the center of each of the muscle spindles. The increased frequency of action potentials carried to the spinal cord by sensory neurons stimulates the alpha motor neurons in the spinal cord. The alpha motor neurons transmit action potentials to skeletal muscle, causing a rapid contraction of the stretched muscle, which opposes the stretch of the muscle. The postural muscles demonstrate the adaptive nature of this reflex. If a person is standing upright and then begins to tip slightly to one side, the postural muscles associated with the vertebral column on the other side are stretched. As a result, stretch reflexes are initiated in those muscles, which cause them to contract and reestablish normal posture.

Collateral axons from the sensory neurons of the muscle spindles also synapse with neurons whose axons contribute to ascending nerve tracts, which enable the brain to perceive that a muscle has been stretched (see figure 12.3c). Descending neurons within the spinal cord synapse with the neurons of the stretch reflex modifying their activity. This activity is important in maintaining posture and in coordinating muscular activity.

Gamma motor neurons are responsible for regulating the sensitivity of the muscle spindles. As a skeletal muscle contracts, the tension on the centers of muscle spindles within the muscle decreases because the muscle spindles passively shorten as the muscle shortens.

The decrease in tension in the centers of the muscle spindles cause them to be less sensitive to stretch. Sensitivity is maintained because while alpha motor neurons are stimulating the muscle to contract gamma motor neurons stimulate the muscle spindles to contract. The contraction of the muscle fibers at the ends of the muscle spindles pulls on the center part of the muscle spindles and maintains the proper tension. The activity of the muscle spindles help control posture, muscle tension, and muscle length.

Knee-Jerk Reflex

The **knee-jerk reflex**, or **patellar reflex**, is a classic example of the stretch reflex. Clinicians use this reflex to determine whether the higher CNS centers that normally influence this reflex are functional. When the patellar ligament is tapped, the tendons and muscles of the quadriceps femoris muscle group are stretched. The muscle spindle fibers within these muscles are also stretched, and the stretch reflex is activated. Consequently, contraction of the muscles extends the leg, thus producing the characteristic knee-jerk response. When the stretch reflex is greatly exaggerated, it indicates that the neurons within the brain that innervate the gamma motor neurons and enhance the stretch reflex are overly active. On the other hand, if the neurons that innervate the gamma motor neurons are depressed, the stretch reflex can be suppressed or absent. Absence of the stretch reflex may also indicate that the reflex pathway is not intact.

Golgi Tendon Reflex

The **Golgi tendon reflex** prevents contracting muscles from applying excessive tension to tendons. **Golgi tendon organs** are encapsulated nerve endings that have at their ends numerous terminal branches with small swellings associated with bundles of collagen fibers in tendons. The Golgi tendon organs are located within tendons near the muscle–tendon junction (figure 12.7). As a muscle contracts, the attached tendons are stretched, resulting in increased tension in the tendon. The increased tension stimulates action potentials in the sensory neurons from the Golgi tendon organs. Golgi tendon organs have a high threshold and are sensitive only to intense stretch.

The sensory neurons of the Golgi tendon organs pass through the dorsal root to the spinal cord and enter the posterior gray matter, where they branch and synapse with inhibitory interneurons. The interneurons synapse with alpha motor neurons that innervate the muscle to which the Golgi tendon organ is attached. When a great amount of tension is applied to the tendon, the sensory neurons of the Golgi tendon organs are stimulated. The sensory neurons stimulate the interneurons to release inhibitory neurotransmitters, which inhibit the alpha motor neurons of the associated muscle and cause it to relax. This reflex protects muscles and tendons from damage caused by excessive tension. The sudden relaxation of the muscle reduces the tension applied to the muscle and tendons. A weight

lifter who suddenly drops a heavy weight after straining to lift it does so, in part, because of the effect of the Golgi tendon reflex.

Tremendous amounts of tension can be applied to muscles and tendons in the legs. Frequently, an athlete’s Golgi tendon reflex is inadequate to protect muscles and tendons from excessive tension. The large muscles and sudden movements of football players and sprinters can make them vulnerable to relatively frequent hamstring pulls and calcaneal (Achilles) tendon injuries.

Withdrawal Reflex

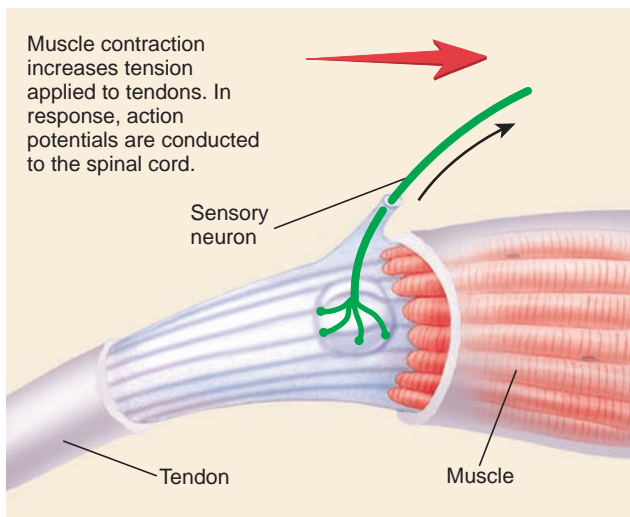

The function of the **withdrawal**, or **flexor, reflex** is to remove a limb or another body part from a painful stimulus. The sensory receptors are pain receptors (see chapter 15). Action potentials from painful stimuli are conducted by sensory neurons through the dorsal root to the spinal cord, where they synapse with excitatory interneurons, which in turn synapse with alpha motor neurons (figure 12.8). The alpha motor neurons stimulate muscles, usually flexor muscles, that remove the limb from the source of the painful stimulus. Collateral branches of the sensory neurons synapse with ascending fibers to the brain, providing conscious awareness of the painful stimuli.

Reciprocal Innervation

Reciprocal innervation is associated with the withdrawal reflex and reinforces its efficiency (figure 12.9). Collateral axons of sensory

Intense stretch of a skeletal muscle results in:

1. Golgi tendon organs detect tension applied to a tendon.
2. Sensory neurons conduct action potentials to the spinal cord.
3. Sensory neurons synapse with inhibitory interneurons that synapse with alpha motor neurons.
4. Inhibition of the alpha motor neurons causes muscle relaxation, relieving the tension applied to the tendon. *Note:* The muscle that relaxes is attached to the tendon to which tension is applied.

Golgi tendon organ

Stimulation of pain receptors results in:

1. Pain receptors detect a painful stimulus.
2. Sensory neurons conduct action potentials to the spinal cord.
3. Sensory neurons synapse with excitatory interneurons that synapse with alpha motor neurons.
4. Excitation of the alpha motor neurons results in contraction of the flexor muscles and withdrawal of the limb from the painful stimulus.

PROCESS FIGURE 12.8 Withdrawal Reflex

Reciprocal innervation

1. During the withdrawal reflex, sensory neurons conduct action potentials from pain receptors to the spinal cord.
2. Sensory neurons synapse with excitatory interneurons that are part of the withdrawal reflex.
3. Collateral branches of the sensory neurons also synapse with inhibitory interneurons that are part of reciprocal innervation.
4. The inhibitory interneurons synapse with alpha motor neurons supplying the extensor muscles, causing them to relax and not oppose the flexor muscles of the withdrawal reflex, which are contracting.

PROCESS FIGURE 12.9 Withdrawal Reflex with Reciprocal Innervation

neurons that carry action potentials from pain receptors synapse with inhibitory interneurons in the dorsal horn of the spinal cord. The inhibitory interneurons synapse with and inhibit alpha motor neurons of extensor (antagonist) muscles. When the withdrawal reflex is initiated, flexor muscles contract, and reciprocal innervation causes relaxation of the extensor muscles. This reduces the resistance to movement that the extensor muscles would otherwise generate.

Reciprocal innervation is also involved in the stretch reflex. When the stretch reflex causes a muscle to contract, reciprocal innervation causes opposing muscles to relax. In the patellar reflex, for example, the quadriceps femoris muscle contracts and the hamstring muscles relax.

Crossed Extensor Reflex

The **crossed extensor reflex** is another reflex associated with the withdrawal reflex (figure 12.10). Interneurons that stimulate alpha motor neurons, resulting in withdrawal of a limb, have collateral

axons that extend through the white commissure to the opposite side of the spinal cord and synapse with alpha motor neurons that innervate extensor muscles in the opposite side of the body. When a withdrawal reflex is initiated in one lower limb, the crossed extensor reflex causes extension of the opposite lower limb.

The crossed extensor reflex is adaptive in that it helps prevent falls by shifting the weight of the body from the affected to the unaffected limb. For example, when a person steps on a sharp object, the affected limb is withdrawn from the stimulus (withdrawal reflex) while the other limb is extended (crossed extensor reflex). Therefore, when a person steps on a sharp object with the right foot, the body weight is shifted from the right to the left lower limb. Initiating a withdrawal reflex in both legs at the same time would cause one to fall.

- 9 Contrast and give the functions of a stretch reflex and a Golgi tendon reflex. Describe the sensory receptors for each.
- 10 Describe the operation of gamma motor neurons. What do they accomplish?

Crossed extensor reflex

1. During the withdrawal reflex, sensory neurons from pain receptors conduct action potentials to the spinal cord.
2. Sensory neurons synapse with excitatory interneurons that are part of the withdrawal reflex.
3. The excitatory interneurons that are part of the withdrawal reflex stimulate alpha motor neurons that innervate flexor muscles, causing withdrawal of the limb from the painful stimulus.
4. Collateral branches of the sensory neurons also synapse with excitatory interneurons that cross to the opposite side of the spinal cord as part of the crossed extensor reflex.
5. The excitatory interneurons that cross the spinal cord stimulate alpha motor neurons supplying extensor muscles in the opposite limb, causing them to contract and support body weight during the withdrawal reflex.

PROCESS FIGURE 12.10 Withdrawal Reflex with Crossed Extensor Reflex

FIGURE 12.11 Spinal Reflex, with Ascending and Descending Axons

Diverging branches of sensory neurons synapse with neurons that ascend in the spinal cord to the brain. Axons from the brain descend in the spinal cord and synapse with interneurons, influencing their action on motor neurons.

- 11** What is a withdrawal reflex? How do reciprocal innervation and the crossed extensor reflex assist the withdrawal reflex?

INTERACTIONS WITH SPINAL CORD REFLEXES

Reflexes do not operate as isolated entities within the nervous system because of divergent and convergent pathways (see chapter 11). Diverging branches of the sensory neurons or interneurons in a reflex arc send action potentials along ascending nerve tracts to the brain (figure 12.11). A pain stimulus, for example, not only initiates a withdrawal reflex, which removes the affected part of the body from the painful stimulus, but also causes perception of the pain sensation as a result of action potentials sent to the brain.

Axons within descending tracts from the brain carry action potentials to motor neurons in the anterior horn of the spinal cord, converging with neurons of reflex arcs. The neurotransmitters released from the axons of these tracts either stimulate or inhibit the motor neurons in the anterior horn. Neurotransmitters change the sensitivity of the reflex by stimulating (EPSP) or inhibiting (IPSP) the motor neurons.

- 12** How do ascending and descending pathways relate to reflexes and other neuron functions?

FIGURE 12.12 Structure of a Peripheral Nerve

Nerve structure illustrating axons surrounded by various layers of connective tissue: epineurium surrounds the whole nerve, perineurium surrounds nerve fascicles, and endoneurium surrounds Schwann cells and axons. Loose connective tissue also surrounds the nerve fascicles.

STRUCTURE OF PERIPHERAL NERVES

Peripheral nerves consist of axons, Schwann cells, and connective tissue (figure 12.12). Each axon, or nerve fiber, and its Schwann cell sheath are surrounded by a delicate connective

tissue layer, the **endoneurium** (en-dō-noo'rē-ŭm). A heavier connective tissue layer, the **perineurium** (per-i-noo'rē-ŭm), surrounds groups of axons to form nerve **fascicles** (fas'i-klz). A third layer of dense connective tissue, the **epineurium** (ep-i-noo'rē-ŭm), binds the nerve fascicles together to form a nerve. The connective tissue of the epineurium is continuous with the dura mater surrounding the CNS. An analogy of this relationship is a coat (the dura) and its sleeve (epineurium). The connective tissue layers of nerves make them tougher than the nerve tracts in the CNS.

13 Describe the structure of peripheral nerves.

SPINAL NERVES

All of the 31 pairs of spinal nerves, except the first pair and those in the sacrum, exit the vertebral column through intervertebral foramina located between adjacent vertebrae (see figure 7.13). The first pair of spinal nerves exits between the skull and the first cervical vertebra. The nerves of the sacrum exit from the single bone of the sacrum through the sacral foramina (see chapter 7). Eight spinal nerve pairs exit the vertebral column in the cervical region, 12 in the thoracic region, 5 in the lumbar region, 5 in the sacral region, and 1 in the coccygeal region (figure 12.13). For convenience, each of the spinal nerves is designated by a letter and number. The letter indicates the region of the vertebral column from which the nerve emerges: C, cervical; T, thoracic; L, lumbar; and S, sacral. The single coccygeal nerve is often not designated, but when it is the symbol often used is Co. The number indicates the location in each region where the nerve emerges from the vertebral column, with the smallest number always representing the most superior origin. For example, the most superior nerve exiting from the thoracic region of the vertebral column is designated T1. The cervical nerves are designated C1–C8, the thoracic nerves T1–T12, the lumbar nerves L1–L5, and the sacral nerves S1–S5.

The nerves arising from each region of the spinal cord and vertebral column supply specific regions of the body. Each of the spinal nerves except C1 has a specific cutaneous sensory distribution. Figure 12.14 illustrates the **dermatomal** (der-mă-tō'māl) **map** for the sensory cutaneous distribution of the spinal nerves. A **dermatome** is the area of skin supplied with sensory innervation by a pair of spinal nerves.

PREDICT 4

The dermatomal map is important in clinical considerations of nerve damage. Loss of sensation in a dermatomal pattern can provide valuable information about the location of nerve damage. Predict the possible site of nerve damage for a patient who suffered whiplash in an automobile accident and subsequently developed anesthesia (no sensations) in the left arm, forearm, and hand (see figure 12.14 for help).

Figure 12.15 depicts an idealized section through the trunk. Each spinal nerve has a dorsal and a ventral **ramus** (ră'mūs; branch). Additional rami (ră'mī), called communicating rami, from the thoracic and upper lumbar spinal cord regions carry

FIGURE 12.13 Spinal Nerves

The regional designations and the numbers of the spinal nerves are shown on the left. The plexuses formed by the spinal nerves are shown on the right.

axons associated with the sympathetic division of the autonomic nervous system (see chapter 16). The **dorsal rami** (ră'mī) innervate most of the deep muscles of the dorsal trunk responsible for movement of the vertebral column. They also innervate the connective tissue and skin near the midline of the back.

The **ventral rami** are distributed in two ways. In the thoracic region, the ventral rami form **intercostal** (between ribs) **nerves** (see figure 12.15), which extend along the inferior margin of each rib and innervate the intercostal muscles and the skin over the thorax. The ventral rami of the remaining spinal nerves form five major **plexuses** (plek'sūs-ēz). The term *plexus* means braid and describes the organization produced by the intermingling of the nerves. The ventral rami of different spinal nerves, called the **roots** of the plexus, join with each other to form a plexus. These roots should not be confused with the dorsal and ventral roots from

FIGURE 12.14 Spinal Cord and Dermatomal Map

(a) Nerves and functions of the spinal cord. Regions are color-coded. (b) Letters and numbers indicate the spinal nerves innervating a given region of skin.

the spinal cord, which are more medial. Nerves that arise from plexuses usually have axons from more than one spinal nerve and thus more than one level of the spinal cord. The ventral rami of spinal nerves C1–C4 form the cervical plexus, C5–T1 form the brachial plexus, L1–L4 form the lumbar plexus, L4–S4 form the sacral plexus, and S5 and the coccygeal nerve (Co) form the coccygeal plexus.

Several smaller somatic plexuses, such as the pudendal plexus in the pelvis, are derived from more distal branches of the spinal nerves. Some of the somatic plexuses are mentioned where appropriate in this chapter. Autonomic plexuses (described in chapter 16) also exist in the thorax and abdomen.

The five major plexuses derived from the ventral rami of spinal nerves are described more fully in the following sections.

- 14** Describe the connective tissue layers within and surrounding spinal nerves.
- 15** Differentiate among rootlet, dorsal root, ventral root, and spinal nerve. Indicate whether each contains motor fibers, sensory fibers, or both.
- 16** List all of the spinal nerves by name and number. Where do they exit the vertebral column?
- 17** What is a dermatome? Why are dermatomes clinically important?

CLINICAL FOCUS

Spinal Cord Injury

Damage to the spinal cord can disrupt ascending tracts from the spinal cord to the brain, resulting in the loss of sensation, and/or descending tracts from the brain to motor neurons in the spinal cord, resulting in the loss of motor functions. About 10,000 new cases of **spinal cord injury** occur each year in the United States. Automobile and motorcycle accidents are leading causes, followed by gunshot wounds, falls, and swimming accidents. Spinal cord injury is classified according to the vertebral level at which the injury occurred, whether the entire cord is damaged at that level or only a portion of the cord, and the mechanism of injury. Most spinal cord injuries occur in the cervical region or at the thoracolumbar junction and are incomplete. The primary mechanisms include concussion (an injury caused by a blow), contusion (an injury resulting in hemorrhage), and laceration (a tear or cut) and involve excessive flexion, extension, rotation, or compression of the vertebral column. The majority of spinal cord injuries are acute contusions of the cord due to bone or disk displacement into the cord and involve a combination of excessive directional movements, such as simultaneous flexion and compression.

At the time of spinal cord injury, two types of tissue damage occur: (1) primary,

mechanical damage and (2) secondary, tissue damage. Secondary spinal cord damage, which begins within minutes of the primary damage, is caused by ischemia, edema, ion imbalances, the release of “excitotoxins” (such as glutamate), and inflammatory cell invasion. Secondary damage extends into a much larger region of the cord than the primary damage. It is the primary focus of current research in spinal cord injury. The only treatment for primary damage is prevention, such as wearing seat belts when riding in automobiles and not diving into shallow water. Once an accident occurs, however, little can be done about the primary damage. On the other hand, much of the secondary damage can be prevented or reversed.

Until the 1950s, many spinal cord injuries were ultimately fatal. Now, with quick treatment directed at the mechanisms of secondary tissue damage, much of the total damage to the spinal cord can be prevented. Treatment of the damaged spinal cord with large doses of anti-inflammatory steroids, such as methylprednisolone, within 8 hours of the injury can dramatically reduce the secondary damage to the cord. The objectives of this treatment are to reduce inflammation and edema. Current treatment includes

anatomical realignment and stabilization of the vertebral column, decompression of the spinal cord, and administration of anti-inflammatory steroids. Rehabilitation is based on retraining the patient to use whatever residual connections exist across the site of damage.

It had long been thought that the spinal cord was incapable of regeneration following severe damage. However, it is now known that, following injury, most neurons of the adult spinal cord survive and begin to regenerate, growing about 1 mm into the site of damage, but then they regress to an inactive, atrophic state. In addition, fetuses and newborns exhibit considerable regenerative ability and functional improvement. A major block to adult spinal cord regeneration is the formation of a scar, consisting mainly of myelin and astrocytes, at the site of injury. Myelin in the scar is apparently the primary inhibitor of regeneration. Implantation of peripheral nerves, Schwann cells, or fetal CNS tissue can bridge the scar and stimulate some regeneration. Certain growth factors can also stimulate some regeneration. Current research continues to look for the right combination of chemicals and other factors to stimulate regeneration of the spinal cord following injury.

- 18 **Contrast dorsal and ventral rami of spinal nerves. What muscles do the dorsal rami innervate?**
- 19 **Describe the distribution of the ventral rami of the thoracic region.**
- 20 **What is a plexus? What happens to the axons of spinal nerves as they pass through a plexus?**
- 21 **Name the main spinal plexuses and the spinal nerves associated with each one.**

Cervical Plexus

The **cervical plexus** is a relatively small plexus originating from spinal nerves C1–C4 (figure 12.16). Branches derived from this plexus innervate superficial neck structures, including several

of the muscles attached to the hyoid bone. The cervical plexus innervates the skin of the neck and posterior portion of the head (see figure 12.14). An unusual part of the cervical plexus, the **ansa** (an’sah; bucket handle) **cervicalis**, is a loop between C1 and C3. Nerves to the infrahyoid muscles branch from the ansa cervicalis (see chapter 10).

One of the most important derivatives of the cervical plexus is the **phrenic** (fren’ik) **nerve**, which originates from spinal nerves C3–C5, derived from both the cervical and brachial plexus. The phrenic nerves descend along each side of the neck to enter the thorax. They descend along the sides of the mediastinum to reach the diaphragm, which they innervate. Contraction of the diaphragm is largely responsible for the ability to breathe.

FIGURE 12.16 Cervical Plexus

The roots of the plexus are formed by the ventral rami of the spinal nerves C1–C4. Branches of the cervical plexus innervate the muscles (infrahyoid) and skin of the neck. The phrenic nerve (C3–C5) innervates the diaphragm.

Phrenic Nerve Damage

Damage to the phrenic nerve severely limits a person's ability to breathe. Care must be taken not to damage the phrenic nerve during open thoracic surgery or open heart surgery. Cancer of the bronchus is the most common type of cancer in men, accounting for about 30% of all male cancers, and it most often occurs in men who smoke cigarettes. Tumors at the base of the lung can compress the phrenic nerve.

PREDICT 5

Explain how damage to or compression of the right phrenic nerve affects the diaphragm. Describe the effect on breathing of a completely severed spinal cord at the level of C2 versus at the level of C6.

- 22** Name the structures innervated by the cervical plexus. Describe the innervation of the phrenic nerve.

Brachial Plexus

The **brachial plexus** originates from spinal nerves C5–T1 (figure 12.17). The five ventral rami that constitute the brachial plexus join to form three **trunks**, which separate into six **divisions** and then join again to create three **CORDS** (posterior, lateral, and medial) from which five **branches**, or nerves of the upper limb, emerge.

FIGURE 12.17 Brachial Plexus

The roots of the plexus are formed by the ventral rami of the spinal nerves C5–T1 and join to form an upper, middle, and lower trunk. Each trunk divides into anterior and posterior divisions. The divisions join together to form the posterior, lateral, and medial cords from which the major brachial plexus nerves arise. The major brachial plexus nerves include the axillary, radial, musculocutaneous, median, and ulnar nerves. These nerves innervate the muscles and skin of the upper limb.

The five major nerves emerging from the brachial plexus to supply the upper limb are the axillary, radial, musculocutaneous, ulnar, and median nerves. The axillary nerve innervates part of the shoulder; the radial nerve innervates the posterior arm, forearm, and hand; the musculocutaneous nerve innervates the anterior arm; and the ulnar and median nerves innervate the anterior forearm and hand. Smaller nerves from the brachial plexus innervate the shoulder and pectoral muscles.

Brachial Anesthesia

The entire upper limb can be anesthetized by injecting an anesthetic near the brachial plexus. This is called **brachial anesthesia**. The anesthetic can be injected between the neck and the shoulder posterior to the clavicle.

Axillary Nerve

Origin

Posterior cord of brachial plexus, C5–C6

Movements/Muscles Innervated

Laterally rotates arm

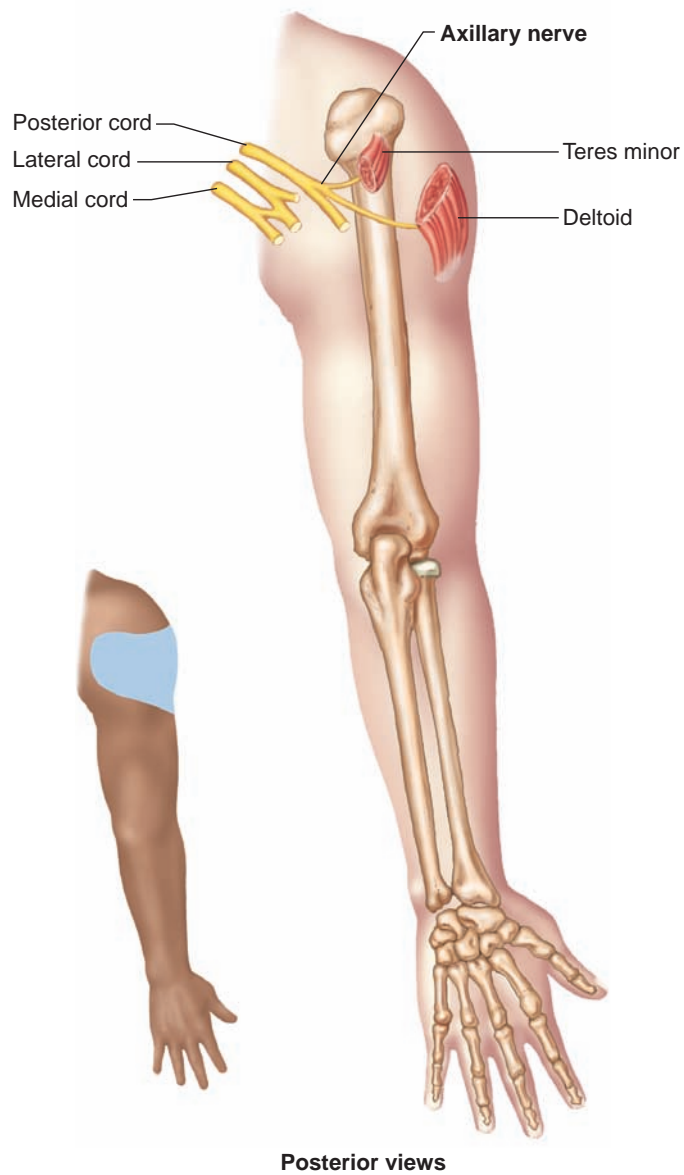

- *Teres minor*

Abducts arm

- *Deltoid*

Cutaneous (Sensory) Innervation

Inferior lateral shoulder

lateral two-thirds of dorsum of hand

FIGURE 12.19 Radial Nerve

The route of the radial nerve and the muscles it innervates are illustrated and listed. The insets depict the cutaneous (sensory) distribution of the nerve (blue area).

Radial Nerve

The **radial nerve** emerges from the posterior cord of the brachial plexus and descends within the deep aspect of the posterior arm (figure 12.19). About midway down the shaft of the humerus, it lies against the bone in the radial groove. The radial nerve innervates all of the extensor muscles of the upper limb, the supinator muscle, and the brachioradialis. Its cutaneous sensory distribution is to the posterior portion of the upper limb, including the posterior surface of the hand.

Radial Nerve Damage

Because the radial nerve lies near the humerus in the axilla, it can be damaged if it is compressed against the humerus. Improper use of crutches (i.e., when the crutch is pushed tightly into the axilla) can result in **crutch paralysis**. In this disorder, the radial nerve is compressed between the top of the crutch and the humerus. As a result, the radial nerve is damaged, and the muscles it innervates lose their function. The major symptom of crutch paralysis is **wrist drop**, in which the extensor muscles of the wrist and fingers, which are innervated by the radial nerve, fail to function; as a result, the elbow, wrist, and fingers are constantly flexed.

Musculocutaneous Nerve

Origin

Lateral cord of brachial plexus, C5–C7

Movements/Muscles Innervated

Flexes shoulder

- *Biceps brachii*
- *Coracobrachialis*

Flexes elbow and supinates forearm and-hand

- *Biceps brachii*

Flexes elbow

- *Brachialis* (also small amount of innervation from radial nerve)

Cutaneous (Sensory) Innervation

Lateral surface of forearm

FIGURE 12.20 Musculocutaneous Nerve

The route of the musculocutaneous nerve and the muscles it innervates are illustrated and listed. The insets depict the cutaneous (sensory) distribution of the nerve (*blue area*).

PREDICT 6

Wrist drop can also result from a compound fracture of the humerus. Explain how and where damage to the nerve can occur.

Musculocutaneous Nerve

The **musculocutaneous** (mŭs'kŭ-lō-kŭ-tā'nē-ŭs) **nerve** provides motor innervation to the anterior muscles of the arm, as well as cutaneous sensory innervation to part of the forearm (figure 12.20).

Ulnar Nerve

Origin

Medial cord of brachial plexus, C8–T1

Movements/Muscles Innervated

Flexes and adducts wrist

- *Flexor carpi ulnaris*

Flexes fingers

- Part of the *flexor digitorum profundus* controlling the distal phalanges of little and ring fingers

Adducts thumb

- *Adductor pollicis*

Controls hypothenar muscles

- *Flexor digiti minimi brevis*
- *Abductor digiti minimi*
- *Opponens digiti minimi*

Flexes metacarpophalangeal joints and extends interphalangeal joints

- Two medial (ulnar) lumbricales

Abducts and adducts fingers

- *Interossei*

Cutaneous (Sensory) Innervation

Medial third of hand, little finger, and medial half of ring finger

FIGURE 12.21 Ulnar Nerve

The route of the ulnar nerve and the muscles it innervates are illustrated and listed. The insets depict the cutaneous (sensory) distribution of the nerve (*blue area*).

Ulnar Nerve

The **ulnar nerve** innervates two forearm muscles plus most of the intrinsic hand muscles, except some associated with the thumb. Its sensory distribution is to the ulnar side of the hand (figure 12.21).

Ulnar Nerve Damage

The ulnar nerve is the most easily damaged of all the peripheral nerves, but such damage is almost always temporary. Slight damage to the ulnar nerve may occur where it passes posterior to the medial epicondyle of the humerus. The nerve can be felt just below the skin at this point, and, if this region of the elbow is banged against a hard object, temporary ulnar nerve damage may occur. This damage results in painful tingling sensations radiating down the ulnar side of the forearm and hand. Because of this sensation, this area of the elbow is often called the **funny bone** or **crazy bone**.

Median Nerve

Origin

Medial and lateral cords of brachial plexus, C5–T1

Movements/Muscles Innervated

Pronates forearm and hand

- *Pronator teres*
- *Pronator quadratus*

Flexes and abducts wrist

- *Flexor carpi radialis*

Flexes wrist

- *Palmaris longus*

Flexes fingers

- Part of *flexor digitorum profundus* controlling the distal phalanx of the middle and index fingers
- *Flexor digitorum superficialis*

Controls thumb muscle

- *Flexor pollicis longus*

Controls thenar muscles

- *Abductor pollicis brevis*
- *Opponens pollicis*
- *Flexor pollicis brevis*

Flexes metacarpophalangeal joints and extends interphalangeal joints

- Two lateral (radial) lumbricales

Cutaneous (Sensory) Innervation

Lateral two-thirds of palm of hand, thumb, index and middle fingers, and the lateral half of ring finger and dorsal tips of the same fingers

FIGURE 12.22 Median Nerve

The route of the median nerve and the muscles it innervates are illustrated and listed. The insets depict the cutaneous (sensory) distribution of the nerve (blue area).

Median Nerve

The **median nerve** innervates all but one of the flexor muscles of the forearm and most of the hand muscles at the base of the thumb, called the thenar area of the hand. Its cutaneous sensory distribution is to the radial portion of the palm of the hand (figure 12.22).

Median Nerve Damage

Damage to the median nerve occurs most commonly where it enters the wrist through the **carpal tunnel**. This tunnel is created by the concave organization of the carpal bones and the flexor retinaculum on the anterior surface of the wrist. None of the connective tissue components of the carpal tunnel expands readily. The tendons passing through the carpal tunnel may become inflamed and enlarged as a result of repetitive movements. This inflammation can produce pressure within the carpal tunnel, thereby compressing the median nerve and resulting in numbness, tingling, and pain in the fingers. The thenar muscles, innervated by the median nerve, have reduced function, resulting in weakness in thumb flexion and opposition. This condition is referred to as **carpal tunnel syndrome**. Carpal tunnel syndrome is common among people who perform repetitive movements of the wrists and fingers, such as keyboard operators. Surgery is often required to relieve the pressure.

People attempting suicide by cutting the wrists commonly cut the median nerve proximal to the carpal tunnel.

CASE STUDY

Cervical Rib Syndrome

Sarah, who is 26, noticed that over a period of time she experienced pain, tingling, and numbness in the ring finger and little finger of her right hand. She also had pain in her elbow, which radiated down the anterolateral portion of her forearm and hand. She made an appointment with her physician. After careful examination of Sarah's upper limb, her physician ordered an x-ray of her neck. The x-ray disclosed a cervical rib on the right, which was attached to the C7 vertebra. Cervical ribs are not uncommon, occurring in about 1% of the population. Most people exhibit no symptoms, but symptoms may develop in some people. If the extra rib compresses the inferior roots of the brachial plexus (see figure 12.17), the condition is called **cervical rib syndrome**—one of several **thoracic outlet syndromes**. An alternative thoracic outlet syndrome may involve the brachial artery rather than the brachial plexus.

PREDICT 7

Use figures 12.14, 12.17, 12.19, 12.20, and 12.21 to answer these questions.

- Name the brachial plexus nerves supplying the skin of the hand.
- Damage to which of these nerves could produce the symptoms seen in Sarah's hand?
- What made Sarah's physician suspect cervical rib syndrome rather than damage to an individual nerve?
- Cervical rib syndrome can also affect muscles, producing muscle weakness and paralysis. Muscles supplied by what nerves could be affected by a cervical rib?

Other Nerves of the Brachial Plexus

Several nerves, other than the five just described, arise from the brachial plexus (see figure 12.17). They supply most of the muscles acting on the scapula and arm and include the pectoral, long thoracic, thoracodorsal, subscapular, and suprascapular nerves. In addition, brachial plexus nerves supply the cutaneous innervation of the medial arm and forearm.

- 23** Name the five major nerves that emerge from the brachial plexus. List the muscles they innervate and the areas of the skin they supply. In addition to these five nerves, name the muscles and skin areas supplied by the remaining brachial plexus nerves.

Lumbar and Sacral Plexuses

The **lumbar plexus** originates from the ventral rami of spinal nerves L1–L4 and the **sacral plexus** from L4–S4. Because of their close, overlapping relationship and their similar distribution, however, the two plexuses often are considered together as a single **lumbosacral plexus** (L1–S4; figure 12.23). Four major

FIGURE 12.23 Lumbosacral Plexus

The roots of the plexus are formed by the ventral rami of the spinal nerves L1–S4 and form anterior and posterior divisions, which give rise to the lumbosacral nerves. The lumbosacral trunk joins the lumbar and sacral plexuses.

Obturator Nerve

Origin

Lumbosacral plexus, L2–L4

Movements/Muscles Innervated

Rotates thigh laterally

- *Obturator externus*

Adducts thigh

- *Adductor magnus (adductor part)*
- *Adductor longus*
- *Adductor brevis*

Adducts thigh and flexes knee

- *Gracilis*

Cutaneous (Sensory) Innervation

Superior medial side of thigh

FIGURE 12.24 Obturator Nerve

The route of the obturator nerve and the muscles it innervates are illustrated and listed. The inset depicts the cutaneous (sensory) distribution of the nerve (*blue area*).

nerves exit the lumbosacral plexus and enter the lower limb: the obturator, femoral, tibial, and common fibular (peroneal). The obturator nerve innervates the medial thigh; the femoral nerve innervates the anterior thigh; the tibial nerve innervates the posterior thigh, leg, and foot; and the common fibular nerve innervates the posterior thigh, anterior and lateral leg, and foot. Other lumbosacral nerves supply the lower back, hip, and lower abdomen.

Obturator Nerve

The **obturator** (ob'too-ră-tôr) **nerve** supplies the muscles that adduct the thigh. Its cutaneous sensory distribution is to the medial side of the thigh (figure 12.24).

Femoral Nerve

Origin

Lumbosacral plexus, L2–L4

Movements/Muscles Innervated

Flexes hip

- *Psoas major*
- *Iliacus*
- *Pectineus*

Flexes hip and flexes knee

- *Sartorius*

Extends knee

- *Vastus lateralis*
- *Vastus intermedius*
- *Vastus medialis*

Extends knee and flexes hip

- *Rectus femoris*

Cutaneous (Sensory) Innervation

Anterior and lateral branches supply the anterior and lateral thigh; saphenous branch supplies the medial leg and foot

FIGURE 12.25 Femoral Nerve

The route of the femoral nerve and the muscles it innervates are illustrated and listed. The insets depict the cutaneous (sensory) distribution of the nerve (blue area).

Femoral Nerve

The **femoral nerve** innervates the iliopsoas and sartorius muscles and the quadriceps femoris group. Its cutaneous sensory distribution is the anterior and lateral thigh and the medial leg and foot (figure 12.25).

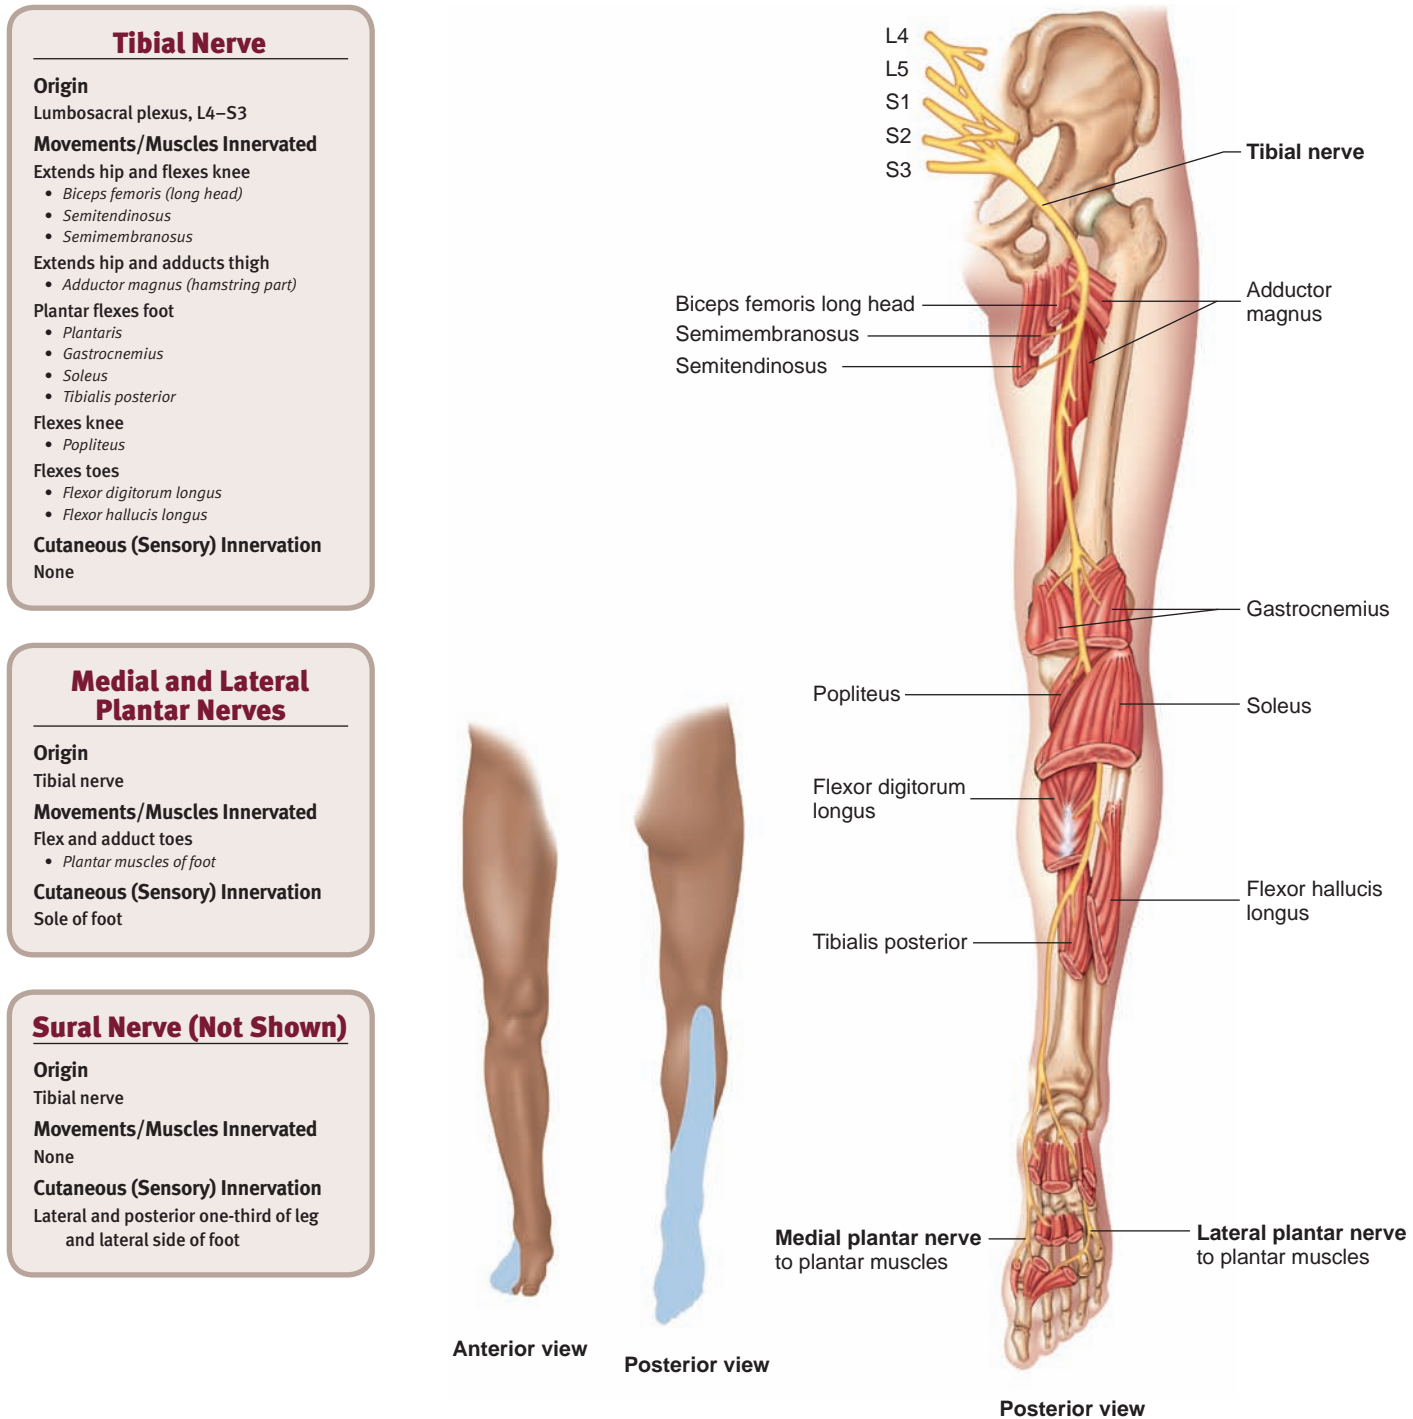

FIGURE 12.26 Tibial Nerve

The route of the tibial nerve and the muscles it innervates are illustrated and listed. The insets depict the cutaneous (sensory) distribution of the nerve (*blue area*).

Tibial and Common Fibular Nerves

The **tibial** and **common fibular (peroneal)** (per-ō-nē'āl) **nerves** originate from spinal segments L4–S3 and are bound together within a connective tissue sheath for the length of the thigh (figures 12.26 and 12.27; see figure 12.23). These two nerves, combined within the same sheath, are referred to jointly as the **sciatic**

(sī-at'ik; hip), or **ischiodic** (is-kē-ad'ik) **nerve** (see figure 12.23). The sciatic nerve, by far the largest peripheral nerve in the body, passes through the greater sciatic notch in the pelvis and descends in the posterior thigh to the popliteal fossa, where the two portions of the sciatic nerve separate.

Common Fibular (Peroneal) Nerve

Origin

Lumbosacral plexus, L4–S2

Movements/Muscles Innervated

Extends hip and flexes knee

- *Biceps femoris (short head)*

Cutaneous (Sensory) Innervation

Lateral surface of knee

Deep Fibular (Peroneal) Nerve

Origin

Common fibular (peroneal) nerve

Movements/Muscles Innervated

Dorsiflexes foot

- *Tibialis anterior*
- *Fibularis tertius*

Extends toes

- *Extensor digitorum longus*
- *Extensor hallucis longus*
- *Extensor digitorum brevis*

Cutaneous (Sensory) Innervation

Great and second toe

Superficial Fibular (Peroneal) Nerve

Origin

Common fibular (peroneal) nerve

Movements/Muscles Innervated

Plantar flexes and everts foot

- *Fibularis longus*
- *Fibularis brevis*

Cutaneous (Sensory) Innervation

Dorsal anterior third of leg and dorsum of foot

FIGURE 12.27 Fibular Nerve

The route of the common fibular (peroneal) nerve and the muscles it innervates are illustrated and listed. The insets depict the cutaneous (sensory) distribution of the nerve (*blue area*).

The tibial nerve innervates most of the posterior thigh and leg muscle (see figure 12.26). It branches in the foot to form the **medial** and **lateral plantar** (plan'tär) **nerves**, which innervate the plantar muscles of the foot and the skin over the sole of the foot. Another branch, the **sural** (soo'räl) **nerve**, supplies part of the cutaneous innervation over the calf of the leg and the plantar surface of the foot.

The common fibular nerve divides into the **deep** and **superficial fibular (peroneal) nerves**. These branches innervate the anterior and lateral muscles of the leg and foot. The cutaneous distribution of the common fibular nerve and its branches is the lateral and anterior leg and the dorsum of the foot (see figure 12.27).

CLINICAL FOCUS

Nerve Replacement

Patients paralyzed by strokes or spinal cord lesions are able to regain certain limited functions through the use of microcomputers that stimulate certain programmed activities, such as grasping and walking. The microcomputer initiates electric impulses, which are conveyed through fine wire leads either to peripheral nerves or directly to the muscles responsible for the desired movement. The subtle movement of muscles not affected

by the paralysis initiate the program. Sensors connected to the microcomputer are attached to the skin overlying functional muscles and are able to detect electrical activity associated with movement of the underlying muscles. For example, a person with both legs paralyzed may have such a sensor attached to the abdomen. The abdominal muscles normally involved in stabilizing and moving the pelvis during walking are stimulated by descending

tracts when walking is initiated by CNS centers. The resultant abdominal muscle activity is detected by the sensor, which activates the program that stimulates the appropriate sequence of muscles in the lower limbs, and the paralyzed person walks. Similarly, a quadriplegic using subtle movements of the shoulder, neck, or face, where specific sensors can be placed, can initiate certain upper limb and grasping actions.

Sciatic Nerve Damage

If a person sits on a hard surface for a considerable time, the sciatic nerve may be compressed against the ischial portion of the coxal bone. When the person stands up, a tingling sensation, described as “pins and needles,” can be felt throughout the lower limb, and the limb is said to have “gone to sleep.”

The sciatic nerve may be seriously injured in a number of ways. A ruptured intervertebral disk or pressure from the uterus during pregnancy may compress the roots of the sciatic nerve. Other causes of sciatic nerve damage include hip injury and an improperly administered injection in the hip region (see p. 243).

Pudendal Nerve Anesthesia

Branches of the pudendal nerve are anesthetized before a doctor performs an episiotomy for childbirth. An **episiotomy** (e-piz-ē-ot'ō-mē, epis-ē-ot'ō-mē) is a cut in the perineum that makes the opening of the birth canal larger.

Other Lumbosacral Plexus Nerves

In addition to the nerves just described, the lumbosacral plexus gives rise to **gluteal nerves**, which supply the hip muscles that act on the femur, and the **pudendal** (pū-den'dāl) **nerves**, which supply the muscles of the abdominal floor (see figure 12.23). The **iliohypogastric** (il'ē-ō-hī-pō-gas'trik), **ilioinguinal** (il'ē-ō-ing'gwī-nāl), **genitofemoral** (jen'i-tō-fem'ō-rāl), **cutaneous femoral**, and pudendal nerves innervate the skin of the suprapubic area, the external genitalia, the superior medial thigh, and the posterior thigh. The pudendal nerve plays a vital role in sexual stimulation and response.

Coccygeal Plexus

The **coccygeal** (kok-sij'ē-āl) **plexus** is a very small plexus formed from the ventral rami of spinal nerve S5 and the coccygeal nerve (Co). This small plexus supplies motor innervation to the muscles of the pelvic floor and sensory cutaneous innervation to the skin over the coccyx. The dorsal rami of the coccygeal nerves innervate some skin over the coccyx.

- 24 **Name the four major nerves that arise from the lumbosacral plexus, and describe the muscles and skin area they supply. What is the name applied to the tibial and common fibular nerves bound together?**
- 25 **Describe the structures innervated by the remaining lumbosacral nerves.**
- 26 **What structures are innervated by the coccygeal plexus?**

CLINICAL FOCUS

Peripheral Nervous System Disorders—Spinal Nerves

GENERAL TYPES OF PNS DISORDERS

Anesthesia is the loss of sensation (the Greek word *esthesia* means sensation). It may be a pathologic condition if it happens spontaneously, or it may be induced to facilitate surgery or some other medical treatment.

Hyperesthesia (hī'per-es-thē'zē-ă) is an abnormal acuteness to sensation, especially an increased sensitivity to pain, pressure, or light.

Paresthesia (par-es-the'zē-ă) is an abnormal spontaneous sensation, such as tingling, prickling, or burning.

Neuralgia (noo-ral'jē-ă) consists of severe spasms of throbbing or stabbing pain resulting from inflammation or damage along the pathway of a nerve.

Sciatica, or **ischiodica** (is'kē-ad'i-kă), is a neuralgia of the sciatic nerve, with pain radiating down the back of the thigh and leg. The most common cause is a herniated lumbar disk, resulting in pressure on the spinal nerves contributing to the lumbar plexus. Sciatica may also be produced by sciatic neuritis arising from a number of causes, including mechanical stretching of the nerve during exertion, vitamin deficiency, or metabolic disorders (such as gout or diabetes).

Neuritis (noo-rī'tis) is a general term referring to inflammation of a nerve that has a wide variety of causes, including mechanical injury or pressure, viral or bacterial infection, poisoning by drugs or other chemicals,

and vitamin deficiencies. Neuritis in sensory nerves is characterized by neuralgia or may result in anesthesia and loss of reflexes in the affected area. Neuritis in motor nerves results in loss of motor function.

INFECTIONS

Herpes is a family of diseases characterized by skin lesions, which are caused by a group of closely related viruses (the herpes viruses). The term is derived from the Greek word *herpo*, meaning to creep, and indicates a spreading skin eruption. The viruses apparently reside in the ganglia of sensory nerves and cause lesions along the course of the nerves. **Herpes simplex II**, or genital herpes, is usually responsible for a sexually transmitted disease causing lesions on the external genitalia.

The varicella-zoster virus causes the diseases chicken pox in children and **shingles** in older adults, a disease also called **herpes zoster**. Normally, this virus first enters the body in childhood to cause chicken pox. The virus then lies dormant in the spinal ganglia for many years and can become active during a time of reduced resistance to cause shingles, a unilateral patch of skin blisters and discoloration along the path of one or more spinal nerves, most commonly around the waist. The symptoms can persist for 3–6 months.

Poliomyelitis (pō'lē-ō-mī'ē-lī'tis; "polio" or infantile paralysis; the Greek word *polio*

means gray matter) is a disease caused by an *Enterovirus*. It is actually a CNS infection, but its major effect is on the peripheral nerves and the muscles they supply. The virus infects the motor neurons in the anterior horn of the spinal cord. The infection causes degeneration of the motor neurons, which results in paralysis and atrophy of the muscles innervated by those nerves.

Anesthetic leprosy is a bacterial infection of the peripheral nerves caused by *Mycobacterium leprae*. The infection results in anesthesia, paralysis, ulceration, and gangrene.

GENETIC AND AUTOIMMUNE DISORDERS

Myotonic dystrophy is an autosomal dominant hereditary disease characterized by muscle weakness, dysfunction, and atrophy and by visual impairment as a result of nerve degeneration.

Myasthenia (mī-as-thē'nē-ă) **gravis** is an autoimmune disorder resulting in a reduction in the number of functional acetylcholine receptors in the postsynaptic terminals and morphological changes in the neuromuscular synapse. T cells of the immune system break down acetylcholine receptor proteins into two fragments, which trigger antibody production by the immune system. Myasthenia gravis results in fatigue and progressive muscular weakness because of the neuromuscular dysfunction.

SUMMARY

Spinal Cord (p. 412)

General Structure

1. The spinal cord gives rise to 31 pairs of spinal nerves. The spinal cord has cervical and lumbosacral enlargements where nerves of the limbs enter and leave.
2. The spinal cord is shorter than the vertebral column. Nerves from the end of the spinal cord form the cauda equina.

Meninges of the Spinal Cord

Three meningeal layers surround the spinal cord: the dura mater, arachnoid mater, and pia mater.

Cross Section of the Spinal Cord

1. The spinal cord consists of peripheral white matter and central gray matter.
2. White matter is organized into funiculi, which are subdivided into fasciculi, or nerve tracts, which carry action potentials to and from the brain.
3. Gray matter is divided into horns.
 - The dorsal horns contain sensory axons that synapse with interneurons. The ventral horns contain the neuron cell bodies of somatic motor neurons, and the lateral horns contain the neuron cell bodies of autonomic neurons.
 - The gray and white commissures connect each half of the spinal cord.

- The dorsal root conveys sensory input into the spinal cord, and the ventral root conveys motor output away from the spinal cord.

Reflexes (p. 415)

- A reflex arc is the functional unit of the nervous system.
 - Sensory receptors respond to stimuli and produce action potentials in sensory neurons.
 - Sensory neurons propagate action potentials to the CNS.
 - Interneurons in the CNS synapse with sensory neurons and with motor neurons.
 - Motor neurons carry action potentials from the CNS to effector organs.
 - Effector organs, such as muscles or glands, respond to the action potentials.
- Reflexes do not require conscious thought, and they produce a consistent and predictable result.
- Reflexes are homeostatic.
- Reflexes are integrated within the brain and spinal cord. Higher brain centers can suppress or exaggerate reflexes.

Stretch Reflex

Muscle spindles detect the stretch of skeletal muscles and cause the muscle to shorten reflexively.

Golgi Tendon Reflex

Golgi tendon organs respond to increased tension within tendons and cause skeletal muscles to relax.

Withdrawal Reflex

- Activation of pain receptors causes contraction of muscles and the removal of some part of the body from a painful stimulus.
- Reciprocal innervation causes relaxation of muscles that would oppose the withdrawal movement.
- In the crossed extensor reflex, during flexion of one limb caused by the withdrawal reflex, the opposite limb is stimulated to extend.

Interactions with Spinal Cord Reflexes (p. 421)

Convergent and divergent pathways interact with reflexes.

Structure of Peripheral Nerves (p. 421)

In the PNS, individual axons are surrounded by the endoneurium. Groups of axons, called fascicles, are bound together by the perineurium. The fascicles form the nerve and are held together by the epineurium.

Spinal Nerves (p. 422)

- Eight cervical, 12 thoracic, 5 lumbar, 5 sacral pairs, and 1 coccygeal pair make up the spinal nerves.
- Spinal nerves have specific cutaneous distributions called dermatomes.
- Spinal nerves branch to form rami.

- The dorsal rami supply the muscles and skin near the midline of the back.
- The ventral rami in the thoracic region form intercostal nerves, which supply the thorax and upper abdomen. The remaining ventral rami join to form plexuses. Communicating rami supply sympathetic nerves.

Cervical Plexus

Spinal nerves C1–C4 form the cervical plexus, which supplies some muscles and the skin of the neck and shoulder. The phrenic nerves innervate the diaphragm.

Brachial Plexus

- Spinal nerves C5–T1 form the brachial plexus, which supplies the upper limb.
- The axillary nerve innervates the deltoid and teres minor muscles and the skin of the shoulder.
- The radial nerve supplies the extensor muscles of the arm and forearm and the skin of the posterior surface of the arm, forearm, and hand.
- The musculocutaneous nerve supplies the anterior arm muscles and the skin of the lateral surface of the forearm.
- The ulnar nerve innervates most of the intrinsic hand muscles and the skin on the ulnar side of the hand.
- The median nerve innervates the pronator and most of the flexor muscles of the forearm, most of the thenar muscles, and the skin of the radial side of the palm of the hand.
- Other nerves supply most of the muscles that act on the arm, the scapula, and the skin of the medial arm and forearm.

Lumbar and Sacral Plexuses

- Spinal nerves L1–S4 form the lumbosacral plexus.
- The obturator nerve supplies the muscles that adduct the thigh and the skin of the medial thigh.
- The femoral nerve supplies the muscles that flex the thigh and extend the leg and the skin of the anterior and lateral thigh and the medial leg and foot.
- The tibial nerve innervates the muscles that extend the thigh and flex the leg and the foot. It also supplies the plantar muscles and the skin of the posterior leg and the sole of the foot.
- The common fibular nerve supplies the short head of the biceps femoris, the muscles that dorsiflex and plantar flex the foot, and the skin of the lateral and anterior leg and the dorsum of the foot.
- In the thigh, the tibial nerve and the common fibular nerve are combined as the sciatic nerve.
- Other lumbosacral nerves supply the lower abdominal muscles, the hip muscles, and the skin of the suprapubic area, external genitalia, and upper medial thigh.

Coccygeal Plexus

Spinal nerve S5 and the coccygeal nerve form the coccygeal plexus, which supplies the muscles of the pelvic floor and the skin over the coccyx.

REVIEW AND COMPREHENSION

- The spinal cord extends from the
 - medulla oblongata to the coccyx.
 - level of the third cervical vertebra to the coccyx.
 - level of the axis to the lowest lumbar vertebra.
 - medulla oblongata to the level of the second lumbar vertebra.
 - axis to the sacral hiatus.
- The structure that anchors the inferior end of the spinal cord to the coccyx is the
 - conus medullaris.
 - cauda equina.
 - filum terminale.
 - lumbar enlargement.
 - posterior median sulcus.
- Axons of sensory neurons synapse with the cell bodies of interneurons in the _____ of spinal cord gray matter.
 - anterior horn
 - lateral horn
 - posterior horn
 - gray commissure
 - lateral funiculi
- Cell bodies for spinal sensory neurons are located in the
 - anterior horn of spinal cord gray matter.
 - lateral horn of spinal cord gray matter.
 - posterior horn of spinal cord gray matter.
 - dorsal root ganglia.
 - posterior columns.
- Given these components of a reflex arc:
 - effector organ
 - interneuron
 - motor neuron
 - sensory neuron
 - sensory receptor

Choose the correct order an action potential follows after a sensory receptor is stimulated.

 - 5,4,3,2,1
 - 5,4,2,3,1
 - 5,3,4,1,2
 - 5,2,4,3,1
 - 5,3,2,1,4
- A reflex response accompanied by the conscious sensation of pain is possible because of
 - convergent pathways.
 - divergent pathways.
 - a reflex arc that contains only one neuron.
 - sensory perception in the spinal cord.
- Several of the events that occurred between the time that a physician struck a patient's patellar tendon with a rubber hammer and the time the quadriceps femoris contracted (knee-jerk reflex) are listed below:
 - increased frequency of action potentials in sensory neurons
 - stretch of the muscle spindles
 - increased frequency of action potentials in the alpha motor neurons
 - stretch of the quadriceps femoris
 - contraction of the quadriceps femoris

Which of these lists most closely describes the sequence of events as they normally occur?

 - 4,1,2,3,5
 - 4,1,3,2,5
 - 1,4,3,2,5
 - 4,2,3,1,5
 - 4,2,3,1,5
- _____ are responsible for regulating the sensitivity of the muscle spindle.
 - Alpha motor neurons
 - Sensory neurons
 - Gamma motor neurons
 - Golgi tendon organs
 - Inhibitory interneurons
- Which of these events occurs when a person steps on a tack with the right foot?
 - The right foot is pulled away from the tack because of the Golgi tendon reflex.
 - The left leg is extended to support the body because of the stretch reflex.
 - The flexor muscles of the right thigh contract, and the extensor muscles of the right thigh relax because of reciprocal innervation.
 - Extensor muscles contract in both thighs because of the crossed extensor reflex.
- Which of these is a correct count of the spinal nerves?
 - 9 cervical, 12 thoracic, 5 lumbar, 5 sacral, 1 coccygeal
 - 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, 1 coccygeal
 - 7 cervical, 12 thoracic, 5 lumbar, 5 sacral, 1 coccygeal
 - 8 cervical, 11 thoracic, 4 lumbar, 6 sacral, 1 coccygeal
 - 7 cervical, 11 thoracic, 5 lumbar, 6 sacral, 1 coccygeal
- Given these structures:
 - dorsal ramus
 - dorsal root
 - plexus
 - ventral ramus
 - ventral root

Choose the arrangement that lists the structures in the order that an action potential passes through them, given that the action potential originates in the spinal cord and propagates to a peripheral nerve.

 - 2,1,3
 - 2,3,1
 - 3,4,5
 - 5,3,4
 - 5,4,3
- Damage to the dorsal ramus of a spinal nerve results in
 - loss of sensation.
 - loss of motor function.
 - both a and b.
- A collection of spinal nerves that join together after leaving the spinal cord is called a
 - ganglion.
 - nucleus.
 - projection nerve.
 - plexus.
- A dermatome
 - is the area of skin supplied by a pair of spinal nerves.
 - exists for each spinal nerve except C1.
 - can be used to locate the site of spinal cord or nerve root damage.
 - all of the above.
- Which of these nerves arises from the cervical plexus?
 - median
 - musculocutaneous
 - phrenic
 - obturator
 - ulnar
- The skin on the posterior surface of the hand is supplied by the
 - median nerve.
 - musculocutaneous nerve.
 - ulnar nerve.
 - axillary nerve.
 - radial nerve.
- Most thenar muscles and most of the flexor muscles in the forearm are supplied by the
 - musculocutaneous nerve.
 - radial nerve.
 - median nerve.
 - ulnar nerve.
 - axillary nerve.
- Most intrinsic hand muscles are supplied by the
 - musculocutaneous nerve.
 - radial nerve.
 - median nerve.
 - ulnar nerve.
 - axillary nerve.

19. The sciatic nerve is actually two nerves combined within the same sheath. The two nerves are the
- femoral and obturator.
 - femoral and gluteal.
 - common fibular (peroneal) and tibial.
 - common fibular (peroneal) and obturator.
 - tibial and gluteal.
20. The muscles of the anterior compartment of the thigh are supplied by the
- obturator nerve.
 - gluteal nerve.
 - sciatic nerve.
 - femoral nerve.
 - ilioinguinal nerve.

Answers in Appendix E

CRITICAL THINKING

- Describe how stimulation of a neuron that has its cell body in the cerebrum could inhibit a reflex that is integrated within the spinal cord.
- A cancer patient has his left lung removed. To reduce the space remaining where the lung is removed, the diaphragm on the left side is paralyzed to allow the abdominal viscera to push the diaphragm upward. What nerve is cut? Where is a good place to cut it, and when would the surgery be done?
- Based on sensory response to pain in the skin of the hand, how could you distinguish between damage to the ulnar, median, and radial nerves?
- During a difficult delivery, the baby's arm delivered first. The attending physician grasped the arm and forcefully pulled it. Later a nurse observed that the baby could not abduct or adduct the medial four fingers and flexion of the wrist was impaired. What nerve was damaged?
- Two patients are admitted to the hospital. According to their charts, both have herniated disks that are placing pressure on the roots of the sciatic nerve. One patient has pain in the buttocks and the posterior aspect of the thigh. The other patient experiences pain in the posterior and lateral aspects of the leg and the lateral part of the ankle and foot. Explain how the same condition, a herniated disk, could produce such different symptoms.
- In an automobile accident a woman suffers a crushing hip injury. For each of the conditions given here, state what nerve is damaged.
 - Unable to adduct the thigh
 - Unable to extend the leg
 - Unable to flex the leg
 - Loss of sensation from the skin of the anterior thigh
 - Loss of sensation from the skin of the medial thigh
- A skier breaks his ankle. As part of his treatment, the ankle and leg are placed in a plaster cast. Unfortunately, the cast is too tight around the proximal portion of the leg and presses in against the neck of the fibula. Where would you predict the patient would experience tingling or numbness in the leg? Explain.

Answers in Appendix F

Visit this book's website at www.mhhe.com/seeley8 for chapter quizzes, interactive learning exercises, and other study tools.

Brain and Cranial Nerves

13

The brain is that part of the CNS contained within the cranial cavity (figure 13.1). It is the control center for many of the body's functions. The brain is much like a complex central computer but with additional functions that no computer can as yet match. Indeed, one goal in computer technology is to make computers that can function more like the human brain. The brain consists of the brainstem, the cerebellum, the diencephalon, and the cerebrum (table 13.1). The brainstem includes the medulla oblongata, pons, midbrain, and reticular formation. The structure of the brain is described in this chapter. Its functions are primarily discussed in chapter 14.

Twelve pairs of cranial nerves, which are part of the PNS, arise directly from the brain. Two pairs arise from the cerebrum, nine pairs arise from the brainstem, and one pair arises from the spinal cord.

This chapter describes the *development of the CNS* (p. 445), *brainstem* (p. 445), *cerebellum* (p. 449), *diencephalon* (p. 449), *cerebrum* (p. 453), *meninges, ventricles, and cerebrospinal fluid* (p. 456), *blood supply to the brain* (p. 461), and *cranial nerves* (p. 462).

TABLE 13.1 Divisions and Functions of the Brain	
<p>Brainstem</p>  <p>Connects the spinal cord to the cerebrum; consists of the medulla oblongata, pons, and midbrain, with the reticular formation scattered throughout the three regions; has many important functions as listed under each subdivision; is the location of cranial nerve nuclei</p>	<p>Cerebellum</p>  <p>Control of muscle movement and tone; balance; regulates extent of intentional movement; involved in learning motor skills</p>
<p>Medulla oblongata</p>  <p>Pathway for ascending and descending nerve tracts; center for several important reflexes (e.g., heart rate, breathing, swallowing, vomiting)</p>	<p>Diencephalon</p> 
<p>Pons</p>  <p>Contains ascending and descending nerve tracts; relay between cerebrum and cerebellum; reflex centers</p>	<p>Thalamus</p> <p>Major sensory relay center; influences mood and movement</p>
<p>Midbrain</p>  <p>Contains ascending and descending nerve tracts; visual reflex center; part of auditory pathway</p>	<p>Subthalamus</p> <p>Contains nerve tracts and nuclei</p>
<p>Reticular formation</p>  <p>Scattered throughout brainstem; controls cyclic activities, such as the sleep-wake cycle</p>	<p>Epithalamus</p> <p>Contains nuclei responding to olfactory stimulation and contains pineal body</p>
	<p>Hypothalamus</p> <p>Major control center for maintaining homeostasis and regulating endocrine function</p>
	<p>Cerebrum</p>  <p>Conscious perception, thought, and conscious motor activity; can override most other systems</p>
	<p>Basal nuclei</p> <p>Control of muscle activity and posture; largely inhibit unintentional movement when at rest</p>
	<p>Limbic system</p> <p>Autonomic response to smell, emotion, mood, memory, and other such functions</p>

DEVELOPMENT OF THE CNS

The CNS develops from a flat plate of ectodermal tissue, the **neural plate**, on the dorsal surface of the embryo, influenced in part by the underlying rod-shaped **notochord** (figure 13.2). The lateral sides of the neural plate become elevated as waves, forming **neural folds**. The crest of each fold is called a **neural crest**, and the center of the neural plate becomes the **neural groove**. The neural folds move toward each other in the midline, and the crests fuse to create a **neural tube** (see figure 13.2*b*). The cephalic portion of the neural tube becomes the brain, and the caudal portion becomes the spinal cord. **Neural crest cells** are cells that separate from the neural crests and give rise to sensory and autonomic neurons of the peripheral nervous system. They also give rise to all pigmented cells of the body, the adrenal medulla, facial bones, and the dentin of the teeth.

A series of pouches develops in the anterior part of the neural tube (figure 13.3). The pouch walls become the various portions of the adult brain (table 13.2), and the pouch cavities become fluid-filled **ventricles** (ven'tri-klz). The ventricles are continuous with each other and with the **central canal** of the spinal cord. The neural tube develops flexures that cause the brain to be oriented almost 90 degrees to the spinal cord.

Three brain regions can be identified in the early embryo (see table 13.2 and figure 13.3*a*): a forebrain, or **prosencephalon** (pros-en-sef'ă-lon); a midbrain, or **mesencephalon** (mez-en-sef'ă-lon); and a hindbrain, or **rhombencephalon** (rom-ben-sef'ă-lon). During development, the forebrain divides into the **telencephalon** (tel-en-sef'ă-lon), which becomes the cerebrum, and the **diencephalon** (dī-en-sef'ă-lon). The midbrain remains as a

single structure, but the hindbrain divides into the **metencephalon** (met'en-sef'ă-lon), which becomes the pons and cerebellum, and the **myelencephalon** (mī'el-en-sef'ă-lon), which becomes the medulla oblongata (see figure 13.3*b* and *c*).

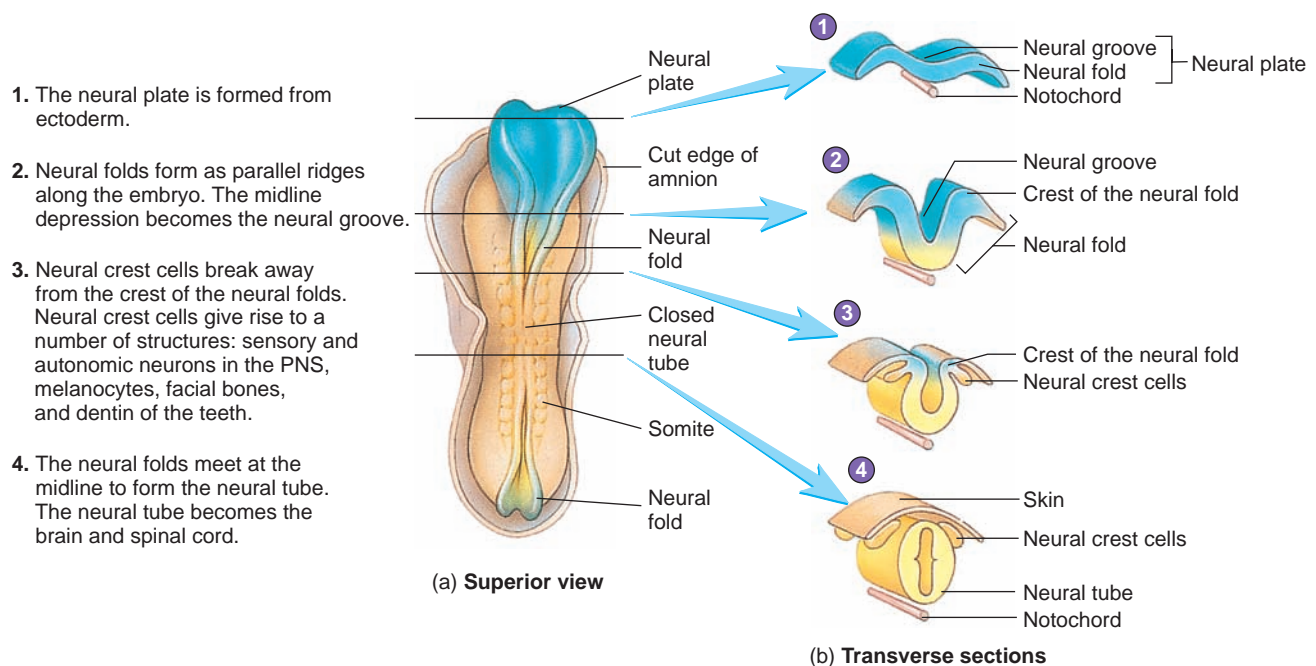

- 1 Explain how the neural tube forms. Name the five divisions of the neural tube and the part of the brain that each division becomes.
- 2 What do the cavities of the neural tube become in the adult brain?

BRAINSTEM

The medulla oblongata, pons, and midbrain constitute the **brainstem** (figure 13.4). The brainstem connects the spinal cord to the remainder of the brain and is responsible for many essential functions. Damage to small brainstem areas often causes death because many reflexes essential for survival are integrated in the brainstem, whereas relatively large areas of the cerebrum or cerebellum may be damaged without life-threatening consequences.

Medulla Oblongata

The **medulla oblongata** (ob-long-gah'tă), often called the medulla, is about 3 cm long, is the most inferior part of the brainstem, and is continuous inferiorly with the spinal cord. It contains sensory and motor tracts; cranial nerve nuclei; other, related nuclei; and part of the reticular formation (see chapter 14). Superficially, the spinal cord blends into the medulla, but internally several

TABLE 13.2 Development of the Central Nervous System (See Figure 13.3)				
Early Embryo	Late Embryo	Adult	Cavity	Function
Prosencephalon (forebrain)	Telencephalon	Cerebrum	Lateral ventricles	Higher brain functions
	Diencephalon	Diencephalon (thalamus, subthalamus, epithalamus, hypothalamus)	Third ventricle	Relay center, autonomic nerve control, endocrine control
Mesencephalon (midbrain)	Mesencephalon	Mesencephalon (midbrain)	Cerebral aqueduct	Nerve pathways, reflex centers
Rhombencephalon (hindbrain)	Metencephalon	Pons and cerebellum	Fourth ventricle	Nerve pathways, reflex centers, muscle coordination, balance
	Myelencephalon	Medulla oblongata	Central canal	Nerve pathways, reflex centers

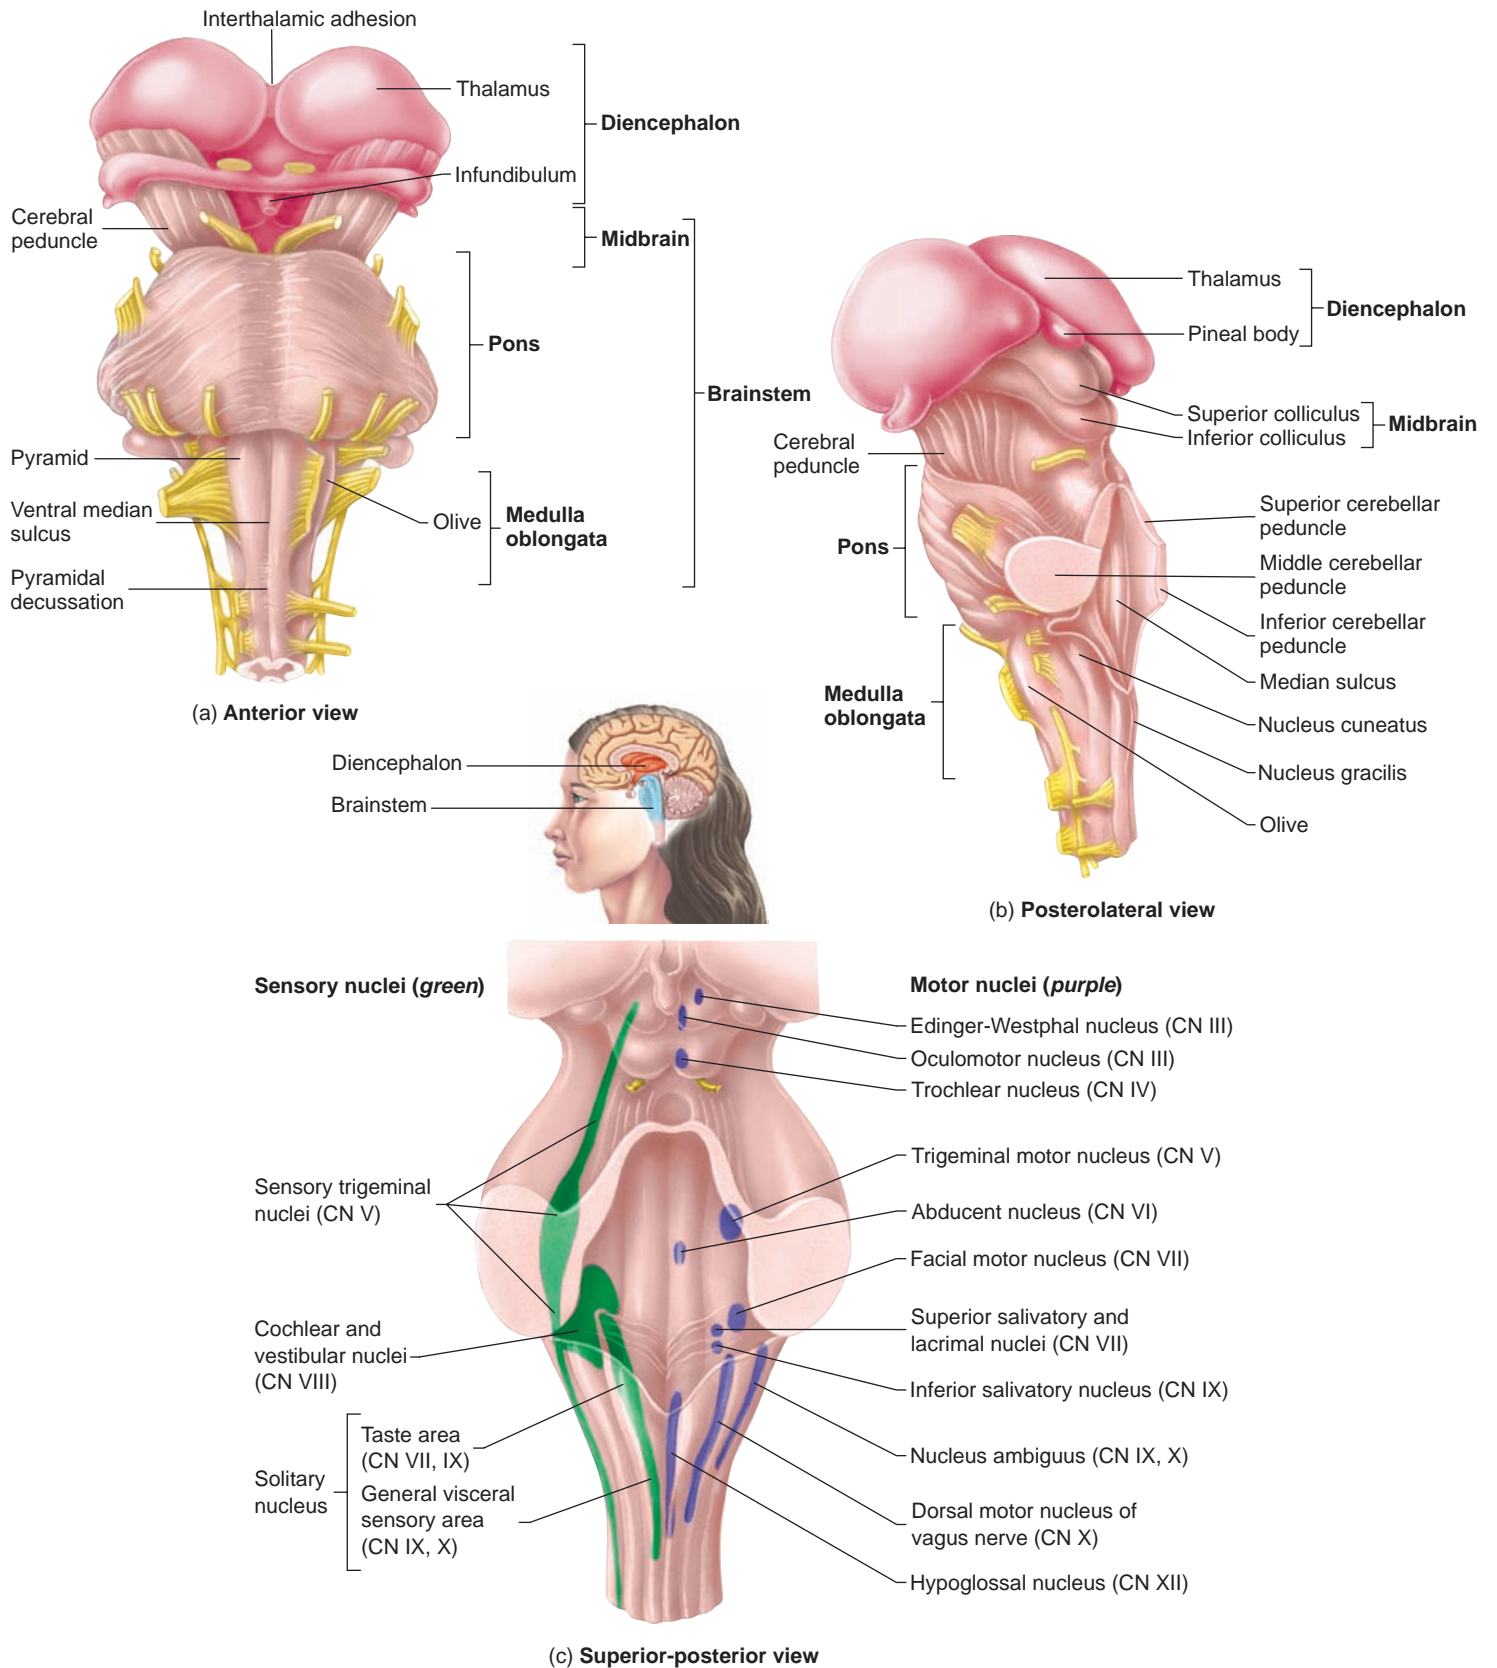

FIGURE 13.4 Brainstem and Diencephalon

(a) Anterior view. (b) Posterolateral view. (c) Brainstem nuclei. The sensory nuclei are shown on the left (green). The motor nuclei are shown on the right (purple). Even though the nuclei are shown on only one side, each half of the brainstem has both sensory and motor nuclei. The inset shows the location of the diencephalon (red) and brainstem (blue). (CN = cranial nerve.)

differences exist. Discrete **nuclei** (see figure 13.4), clusters of gray matter composed mostly of neuron cell bodies and having specific functions, are found in the medulla oblongata, whereas the gray matter of the spinal cord extends as a continuous mass in the center of the cord. In addition, the tracts within the medulla do not have the same organization as those of the spinal cord. Several medullary nuclei function as centers for reflexes, such as those involved in the regulation of heart rate, blood vessel diameter, respiration, swallowing, vomiting, hiccuping, coughing, and sneezing.

Two prominent enlargements on the anterior surface of the medulla oblongata are called **pyramids** because they are broader near the pons and taper toward the spinal cord (see figure 13.4a). The pyramids are descending tracts involved in the conscious control of skeletal muscles. Near their inferior ends, most of the fibers of the descending tracts cross to the opposite side, or **decussate** (dē'kū-sāt, dē-kūs'āt; the Latin word *decussatus* means to form an X, as in the Roman numeral X). This decussation accounts, in part, for the fact that each half of the brain controls the opposite half of the body. Its role as a conduction pathway is discussed in the description of ascending and descending tracts (see chapter 14).

Two rounded, oval structures, called **olives**, protrude from the anterior surface of the medulla oblongata just lateral to the superior ends of the pyramids (see figure 13.4a and b). The olives are nuclei involved in functions such as balance, coordination, and modulation of sound from the inner ear (see chapter 15). Nuclei of cranial nerves V (trigeminal), IX (glossopharyngeal), X (vagus), XI (accessory), and XII (hypoglossal) also are located within the medulla (see figure 13.4c).

Pons

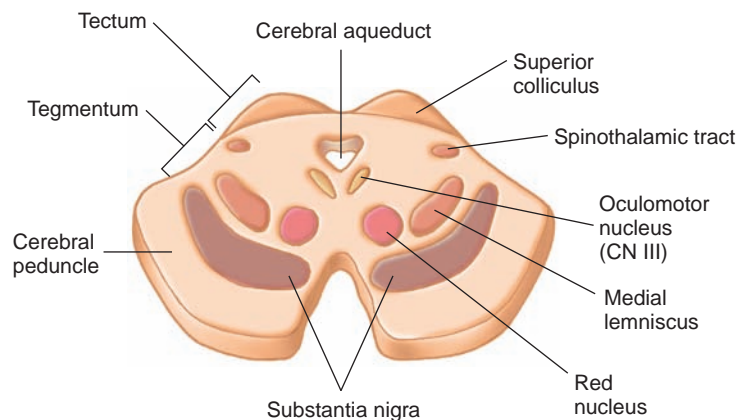

The part of the brainstem just superior to the medulla oblongata is the **pons** (see figure 13.4a), which contains ascending and descending tracts and several nuclei. The pontine nuclei, located in the anterior portion of the pons, relay information from the cerebrum to the cerebellum.

Nuclei for cranial nerves V (trigeminal), VI (abducent), VII (facial), VIII (vestibulocochlear), and IX (glossopharyngeal) are contained within the posterior pons. Other important pontine areas include the pontine sleep center and respiratory center, which work with the respiratory centers in the medulla to help control respiratory movements (see chapter 23).

Midbrain

The **midbrain**, or **mesencephalon**, is the smallest region of the brainstem (see figure 13.4b). It is located just superior to the pons and contains the nuclei of cranial nerves III (oculomotor), IV (trochlear), and V (trigeminal).

The **tectum** (tek'tūm; roof; figure 13.5) of the midbrain consists of four nuclei that form mounds on the dorsal surface, collectively called **corpora** (kōr'pōr-ă; bodies) **quadrigemina** (kwah'dri-jem'i-nă; four twins). Each mound is called a **colliculus** (ko-lik'ū-lūs; hill); the two superior mounds are called **superior colliculi**, and the two inferior mounds are called **inferior colliculi** (see figure 13.4b). The superior colliculi are

Anterosuperior view of oblique section

FIGURE 13.5 Oblique Section Through the Midbrain

Inset shows the level of section.

involved in visual reflexes. These reflexes control the movement of the head, eyes, and body toward visual, auditory, or tactile stimuli such as loud noises, flashing lights, or startling pain. The superior colliculi receive input from the eyes, the inferior colliculi, the skin, and the cerebrum. The inferior colliculi are involved in hearing and are an integral part of the auditory pathways in the CNS. Neurons conducting action potentials from the structures of the inner ear (see chapter 15) to the brain synapse in the inferior colliculi. Collateral fibers from the inferior colliculi to the superior colliculi provide auditory input that stimulates visual reflexes.

Reflex Movements of the Eyes and Head

The superior colliculi regulate the reflex movements of the eyes and head in response to various stimuli. When a bright object suddenly appears in a person's field of vision, a reflex turns the eyes to focus on it. When a person hears a sudden, loud noise, a reflex turns the head and eyes toward it. When a part of the body, such as the shoulder, is touched, a reflex turns the person's head and eyes toward that part of the body. In each situation, the pathway involves the superior colliculus.

The **tegmentum** (teg-men'tūm; floor) of the midbrain largely consists of ascending tracts, such as the spinothalamic tract and the medial lemniscus, which carry sensory information from the spinal cord to the brain. The tegmentum also contains the

paired **red nuclei** (see figure 13.5), which are so-named because in fresh brain specimens they are pinkish in color as a result of an abundant blood supply. The red nuclei aid in the unconscious regulation and coordination of motor activities. **Cerebral peduncles** (pe-dŭng'klz, pē'dŭng-klz; the foot of a column) constitute the portion of the midbrain ventral to the tegmentum. They consist primarily of descending tracts, which carry motor information from the cerebrum to the brainstem and spinal cord. The **substantia nigra** (nī'grā; black substance) is a nuclear mass between the tegmentum and cerebral peduncles, containing cytoplasmic melanin granules that give it a dark gray or black color (see figure 13.5). The substantia nigra is interconnected with other basal nuclei of the cerebrum, described later in this chapter, and it is involved in maintaining muscle tone and in coordinating movements.

Reticular Formation

The **reticular formation** (see table 13.1) is a diffuse system consisting of several loosely packed nuclei scattered throughout the length of the brainstem. The reticular formation receives axons from a large number of sources and especially from nerves that innervate the face. The functions of the reticular formation involve “cycles” of activity, such as the sleep–wake cycle, and are discussed in chapter 14.

3 Describe the major components of the medulla oblongata, pons, midbrain, and reticular formation. What are the general functions of each region?

CEREBELLUM

The term **cerebellum** (ser-e-bel'ŭm; figure 13.6) means little brain. The cerebellum is attached to the brainstem posterior to the pons. It communicates with other regions of the CNS through three large tracts: the **superior, middle, and inferior cerebellar peduncles** (see figure 13.4b), which connect the cerebellum to the midbrain, pons, and medulla oblongata, respectively. The cerebellum has a gray cortex and nuclei, with white medulla in between. The cerebellar cortex has ridges called **folia**. The white matter of the medulla resembles a branching tree and is called the **arbor vitae** (ar'bōr vī'te; tree of life). The **nuclei** of the cerebellum are located in the deep inferior center of the white matter.

The cerebellar cortex contains several cell types, including stellate cells, basket cells, granule cells, Golgi cells, and Purkinje cells. It also contains mossy fibers, which are afferent axons that branch extensively within the cerebellum. **Purkinje** (pŭr-kin'jē; Johannes Purkinje, a Bohemian anatomist and physiologist, 1787–1869) **cells** are the largest and probably most interesting cells in the CNS. Purkinje cells receive 200,000 synapses, are inhibitory neurons, and are the only cerebellar cortex neurons that send axons to the cerebellar nuclei. The cerebellar cortex contains more than 10¹² neurons, more neurons than the entire cerebral cortex.

The cerebellum consists of three parts: a small inferior part, the **flocculonodular** (flok'ŭ-lō-nod'ŭ-lār; floccular, a tuft of wool) **lobe**; a narrow central **vermis** (worm-shaped); and two large **lateral hemispheres** (see figure 13.6b and c).

The flocculonodular lobe, the simplest part of the cerebellum, helps control balance and eye movements. The vermis and medial

portion of the lateral hemispheres are involved in the control of posture, locomotion, and fine motor coordination, thereby producing smooth, flowing movements. The major portions of the lateral hemispheres of the cerebellum function in concert with the frontal lobes of the cerebral cortex in planning, practicing, and learning complex movements.

Each lateral hemisphere is divided by a **primary fissure** into an **anterior lobe** and a **posterior lobe**. The lobes are subdivided into **lobules**, which contain the folia.

4 What are the major regions of the cerebellum? Describe the major functions of each.

DIENCEPHALON

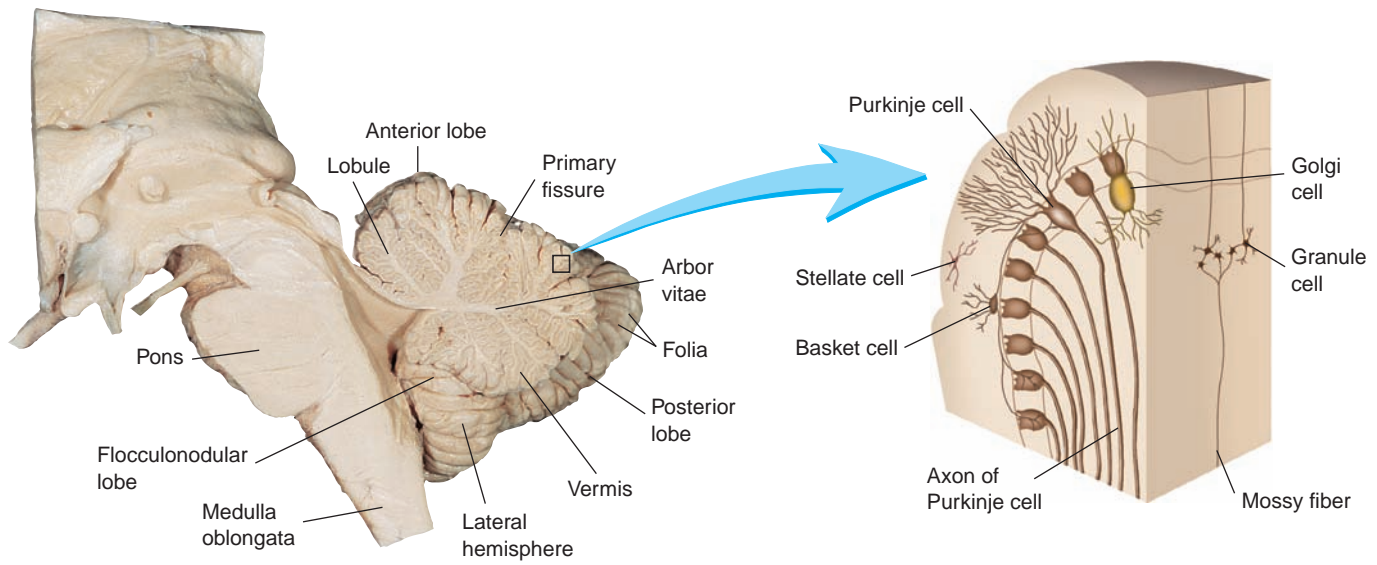

The **diencephalon** (dī-en-sef'ā-lon) is the part of the brain located between the brainstem and the cerebrum (see figure 13.1; figure 13.7). Its main components are the thalamus, subthalamus, epithalamus, and hypothalamus.

Thalamus

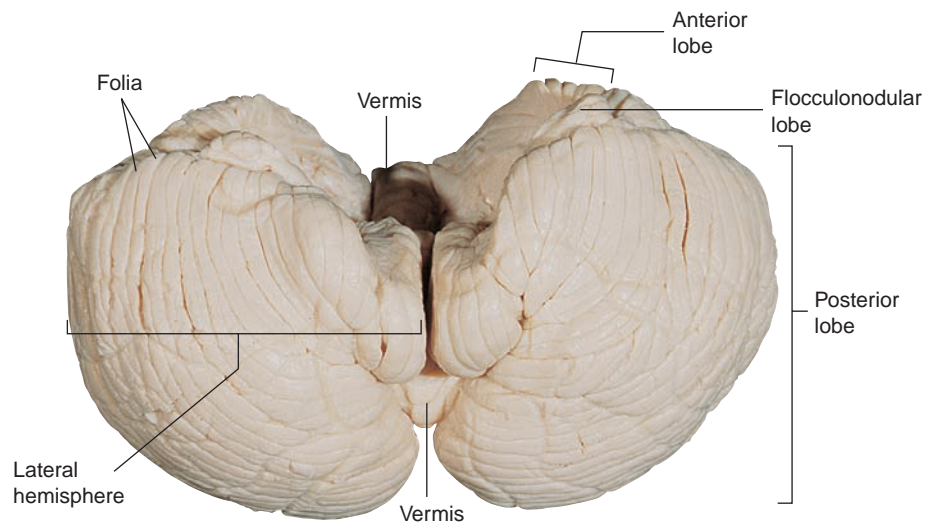

The **thalamus** (thal'ā-mŭs; see figure 13.7a and b) is by far the largest part of the diencephalon, constituting about four-fifths of its weight. It consists of a cluster of nuclei shaped somewhat like a yo-yo, with two large, lateral portions connected in the center by a small stalk called the **interthalamic adhesion**, or **intermediate mass**. The space surrounding the interthalamic adhesion and separating the two large portions of the thalamus is the third ventricle of the brain.

Except for the olfactory neurons, all sensory neurons that project to the cerebrum first synapse in the thalamus. Thalamic neurons then send projections to the appropriate areas of the cerebral cortex where sensory input is localized (see chapter 14). For this reason, the thalamus is considered the **sensory relay center** of the brain. Axons carrying auditory information synapse in the **medial geniculate** (je-nik'ŭ-lāt; Latin, *genu*, meaning bent like a knee) **nucleus** of the thalamus. Axons carrying visual information synapse in the **lateral geniculate nucleus**. Most other sensory impulses synapse in the **ventral posterior nucleus**. Axons originating in the ventral posterior nucleus project to the **dorsal tier** of nuclei, which register pain (see figure 13.7b). Other axons project to the cerebral cortex where sensory input is localized (see chapter 14). The **ventral anterior** and **ventral lateral nuclei** are involved with motor functions, communicating between the basal nuclei, cerebellum, and the motor cortex (these areas are described later in this chapter).

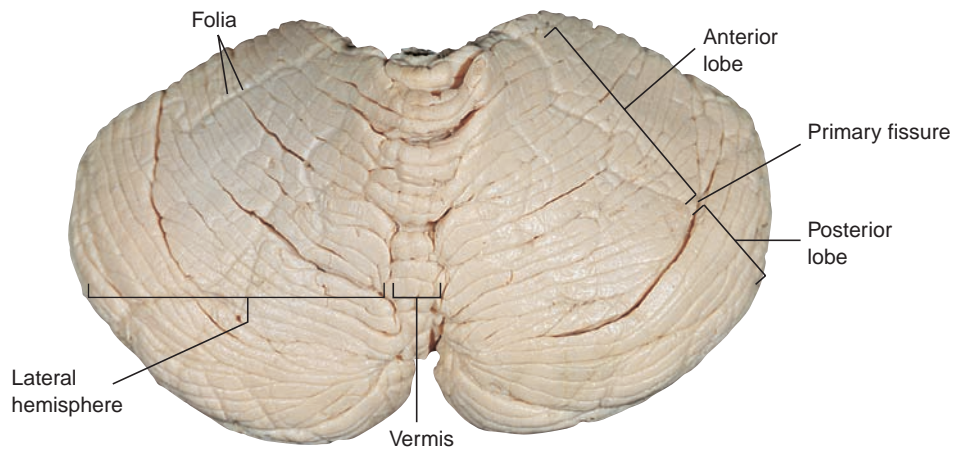

The thalamus also influences mood and actions associated with strong emotions, such as fear and rage. The **anterior** and **medial nuclei** are connected to the limbic system and to the prefrontal cortex (described later in this chapter and in chapter 14). These nuclei are involved in mood modification. The **lateral dorsal nuclei** are connected to other thalamic nuclei and to the cerebral cortex and are involved in regulating emotions. The **lateral posterior nuclei** and the **pulvinar** (pŭl-vī'nār; pillow) also have connections to other thalamic nuclei and are involved in sensory integration.

**FIGURE 13.7** Diencephalon

(a) General overview of the right half of the diencephalon as seen in a median section. (b) Thalamus showing the nuclei. (c) Hypothalamus showing the nuclei and right half of the pituitary.

Subthalamus

The **subthalamus** is a small area immediately inferior to the thalamus (see figure 13.7a) that contains several ascending and descending tracts and the **subthalamic nuclei**. A small portion of

the red nucleus and substantia nigra of the midbrain extend into this area.

The subthalamic nuclei are associated with the basal nuclei and are involved in controlling motor functions.

Epithalamus

The **epithalamus** is a small area superior and posterior to the thalamus (see figure 13.7a). It consists of habenular nuclei and the pineal body. The **habenular** (hä-ben'ü-lär) **nuclei** are influenced by the sense of smell and are involved in emotional and visceral responses to odors. The **pineal** (pin'ē-äl) **gland**, or **pineal body**, is shaped somewhat like a pinecone, from which the name *pineal* is derived. It appears to play a role in controlling the onset of puberty, but data are inconclusive, so active research continues in this field. The pineal body also may influence the sleep–wake cycle and other biorhythms.

Brain Sand in the Pineal

In about 75% of adults, the pineal body contains granules of calcium and magnesium salts called “brain sand.” These granules can be seen on radiographs and are useful as landmarks in determining whether or not the pineal body has been displaced by a pathologic enlargement of a part of the brain, such as a tumor or a hematoma.

Hypothalamus

The **hypothalamus**, the most inferior portion of the diencephalon (see figure 13.7a and c), contains several small nuclei and tracts. The most conspicuous nuclei, called the **mammillary bodies**, appear as bulges on the ventral surface of the diencephalon. They are involved in olfactory reflexes and emotional responses to odors. They may also

be involved in memory. A funnel-shaped stalk, the **infundibulum** (in-fün-dib'ü-lüm), extends from the floor of the hypothalamus and connects it to the **posterior pituitary gland**, or **neurohypophysis** (noor'ō-hī-pof'i-sis). The hypothalamus plays an important role in controlling the endocrine system because it regulates the pituitary gland's secretion of hormones, which influence functions as diverse as metabolism, reproduction, responses to stressful stimuli, and urine production (table 13.3; see chapter 18).

Sensory neurons that terminate in the hypothalamus provide input from (1) internal organs; (2) taste receptors of the tongue; (3) the limbic system, which is involved in responses to smell; (4) specific cutaneous areas, such as the nipples and external genitalia; (5) the eyes; and (6) the prefrontal cortex of the cerebrum carrying information relative to “mood” through the thalamus. Efferent fibers from the hypothalamus extend into the brainstem and the spinal cord, where they synapse with neurons of the autonomic nervous system (see chapter 16). These connections regulate functions such as heart rate and digestive functions (see table 13.3). Other fibers extend through the infundibulum to the posterior portion of the pituitary gland (see chapter 18); some extend to trigeminal and facial nerve nuclei to help control the muscles involved in swallowing; and some extend to motor neurons of the spinal cord to stimulate shivering.

Hypothalamic nuclei directly control temperature by stimulating sweating or shivering. Other hypothalamic nuclei are involved in the control of thirst, hunger, and sex drive. The hypothalamus is also very important in a number of functions related to mood, motivation, and emotion. This is one reason

TABLE 13.3 Hypothalamic Functions

Function	Hypothalamic Nuclei	Description
Autonomic	Preoptic area and anterior nucleus (parasympathetic) Lateral area and posterior nucleus (sympathetic)	Helps control heart rate, urine release from the bladder, movement of food through the digestive tract, and blood vessel diameter
Endocrine	Paraventricular nucleus Supraoptic nucleus	Helps regulate pituitary gland secretions and influences metabolism, ion concentration, sexual development, and sexual functions; site of antidiuretic hormone and oxytocin production (see chapter 18)
Muscle control	Lateral area	Controls the muscles involved in swallowing and stimulates shivering
Temperature regulation	Preoptic area Anterior nucleus Posterior nucleus	Promotes heat loss when the hypothalamic temperature increases by increasing sweat production (anterior nucleus) and promotes heat production when the hypothalamic temperature decreases by promoting shivering (posterior nucleus); aspirin affects the preoptic area to reduce fever
Regulation of food and water intake	Ventromedial nucleus Lateral area	Hunger center promotes eating and satiety center inhibits eating; thirst center promotes water intake
Emotions	Lateral area Medial area	Large range of emotional influences over body functions; directly involved in stress-related and psychosomatic illnesses and with feelings of fear and rage
Regulation of the sleep–wake cycle	Lateral area Suprachiasmatic nucleus	Coordinates responses to the sleep–wake cycle with the other areas of the brain (e.g., the reticular activating system); suprachiasmatic nucleus receives direct input from the eyes concerning light/dark cycles and is implicated in jet lag
Sexual development and behavior	Preoptic area Dorsomedial nucleus Ventromedial nucleus	Stimulates sexual development, sexual arousal, and sexual behavior; the preoptic area is larger in males than in females

that strong emotional experiences may affect a person's desire or ability to eat, drink, or experience sexual pleasure, and vice versa. Sensations such as sexual pleasure, relaxation after a meal, rage, and fear are related to hypothalamic functions. The hypothalamus interacts with the reticular activating system in the brainstem to coordinate the sleep–wake cycle (see table 13.3)

- 5 Name the four main components of the diencephalon.
- 6 What are the functions of the thalamus and hypothalamus? Explain why the hypothalamus is an important link between the nervous system and the endocrine system.
- 7 List the general functions of the subthalamus. Name the parts of the epithalamus and give their functions.

CEREBRUM

The cerebrum (figure 13.8) is the part of the brain that most people think of when the term *brain* is mentioned. The cerebrum accounts for the largest portion of total brain weight, which is about 1200 g in females and 1400 g in males. Brain size is related to body size; larger brains are associated with larger bodies, not with greater intelligence.

The cerebrum is divided into left and right hemispheres by a **longitudinal fissure** (see figure 13.8a). The most conspicuous features on the surface of each hemisphere are numerous folds called **gyri** (jī'ri; sing. *gyrus*), which greatly increase the surface area of the cortex. The grooves between the gyri are called **sulci**

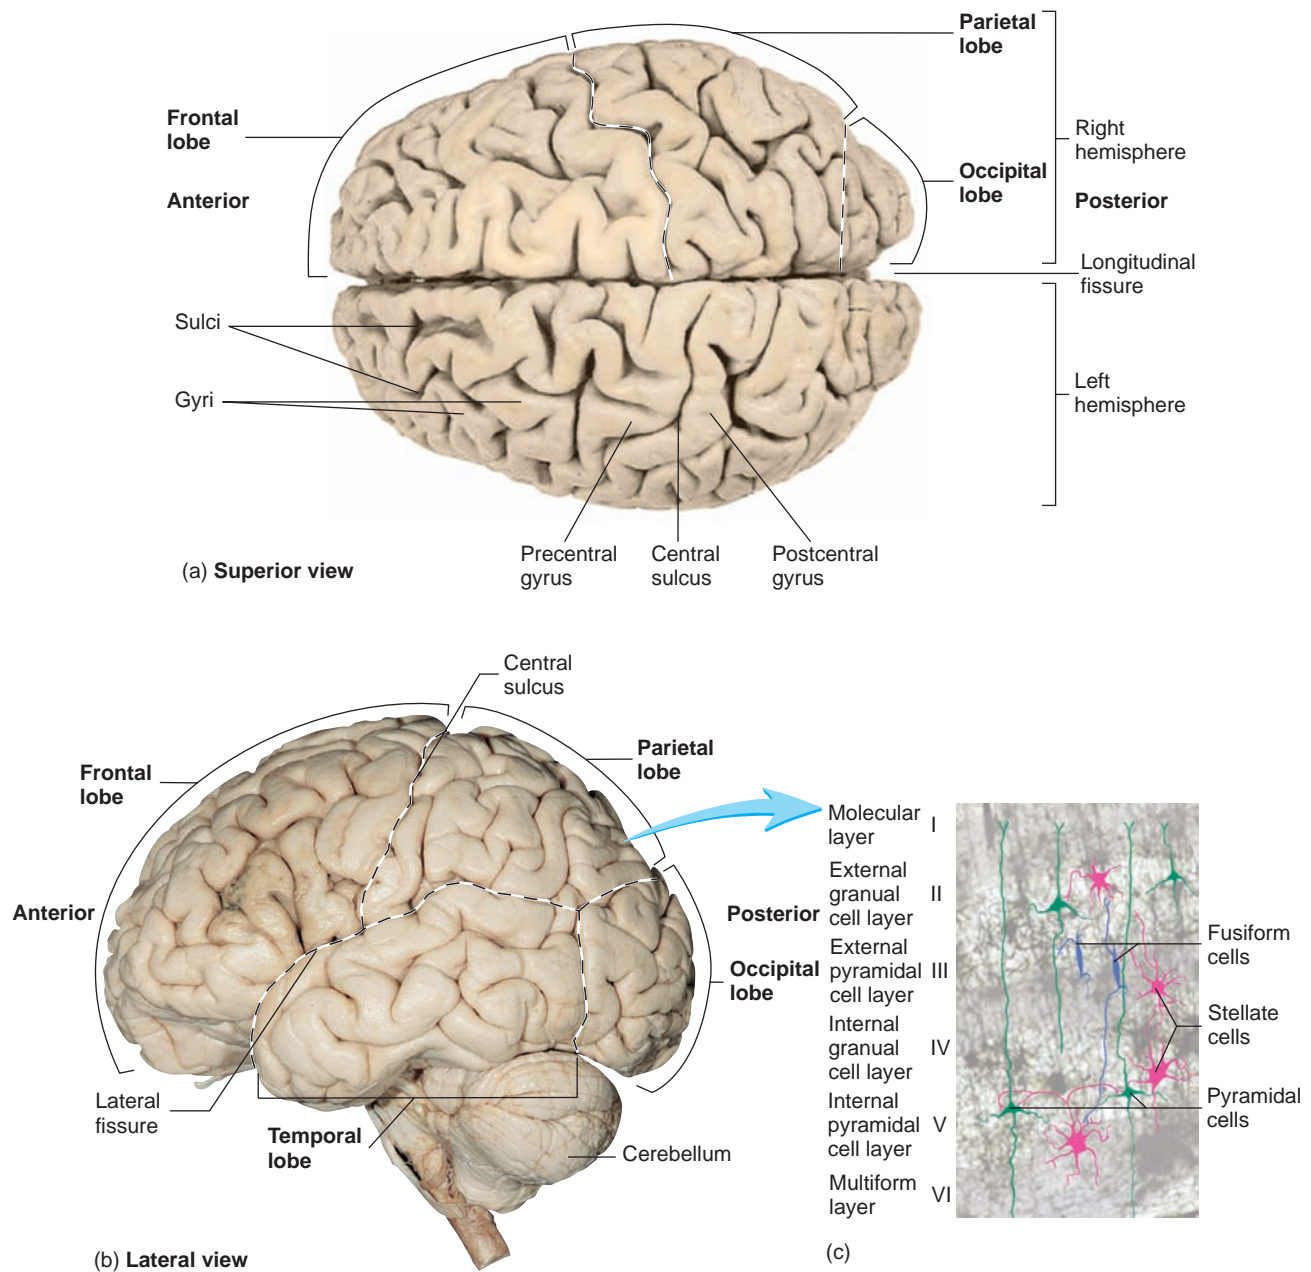

FIGURE 13.8 Brain

(a) Superior view. (b) Lateral view of the left cerebral hemisphere. (c) Histology of the cerebral cortex.

(sül'sī; sing. *sulcus*). The **central sulcus**, which extends across the lateral surface of the cerebrum from superior to inferior, is located about midway along the length of the brain. The central sulcus is located between the **precentral gyrus** anteriorly, which is the **primary motor cortex**, and a **postcentral gyrus** posteriorly, which is the **primary somatic sensory cortex** (see chapter 14). The general pattern of the gyri is similar in all normal human brains, but some variation exists between individuals and even between the two hemispheres of the same cerebrum.

Each cerebral hemisphere is divided into lobes, which are named for the skull bones overlying each one (see figure 13.8b). The **frontal lobe** is important in voluntary motor function, motivation, aggression, the sense of smell, and mood. The **parietal lobe** is the major center for the reception and evaluation of most sensory information, except for smell, hearing, and vision. The frontal and parietal lobes are separated by the central sulcus. The **occipital lobe** functions in the reception and integration of visual input and is not distinctly separate from the other lobes. The **temporal lobe** receives and evaluates input for smell and hearing and plays an important role in memory. Its anterior and inferior portions are referred to as the “psychic cortex,” and they are associated with such brain functions as abstract thought and judgment. The temporal lobe is separated from the rest of the cerebrum by a **lateral fissure**, and deep within the fissure is the **insula** (in'soo-lā; island), often referred to as a fifth lobe.

The gray matter on the outer surface of the cerebrum is the **cortex**, and clusters of gray matter deep inside the brain are nuclei.

The cerebral cortex contains a number of neuron types, named largely for their shape, such as fusiform cells, stellate cells, and pyramidal cells (see figure 13.8c). These cells are distributed in layers within the cerebral cortex. The thickness of the cortex is not uniform throughout the cerebrum but ranges from two or three layers in the most “primitive” parts of the cortex to six layers in the more “advanced” regions.

The white matter of the brain between the cortex and nuclei is the **cerebral medulla**. This term should not be confused with the medulla oblongata; *medulla* is a general term meaning the center of a structure. The cerebral medulla consists of tracts that connect areas of the cerebral cortex to each other or to other parts of the CNS (figure 13.9). The fibers in these tracts fall into three main categories: (1) **Association fibers** connect areas of the cerebral cortex within the same hemisphere. (2) **Commissural fibers** connect one cerebral hemisphere to the other. The largest bundle of commissural fibers connecting the two cerebral hemispheres is the **corpus callosum** (kōr'pūs ka-lō'süm; see figures 13.1 and 13.9). (3) **Projection fibers** are between the cerebrum and other parts of the brain and spinal cord (see figure 13.9). The projection fibers form the **internal capsule**.

8 Define gyri and sulci. What structures do the longitudinal fissure, central sulcus, and lateral fissure separate?

9 Define cerebral cortex and cerebral medulla.

10 Name the five lobes of the cerebrum, and describe their locations and functions.

11 List three categories of tracts in the cerebral medulla.

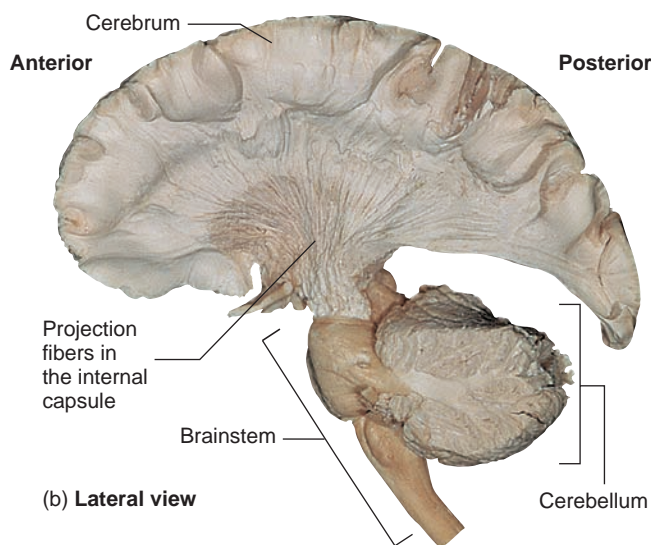

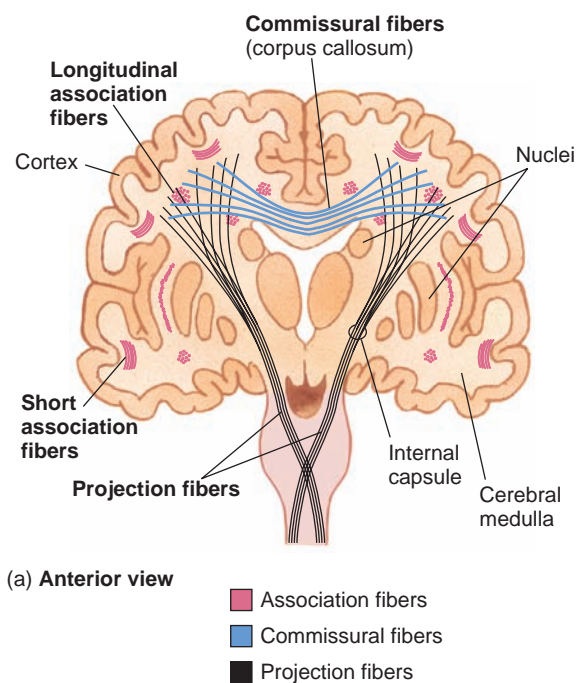

FIGURE 13.9 Cerebral Medullary Tracts

(a) “Transparent 3-D” drawing of the basal nuclei inside the left hemisphere. (b) Photograph of a frontal section of the brain showing the basal nuclei and other structures. (c) The same photograph as in (b) with nuclei highlighted.

Basal Nuclei

The **basal nuclei** are a group of functionally related nuclei located bilaterally in the inferior cerebrum, diencephalon, and midbrain (figure 13.10). These nuclei are involved in the control of motor functions (see chapter 14). The nuclei in the cerebrum are collectively called the **corpus striatum** (kōr’pūs strī-ā’tūm; striped body) and include the **caudate** (kaw’dāt; having a tail) **nucleus** and **lentiform** (len’ti-fōrm; lens-shaped) **nucleus**. The lentiform nucleus, in turn, is divided into a lateral **putamen** (pū-tā’men; that which falls off in pruning) and the medial **globus pallidus** (glō’būs pal’li-dūs; pale globe). The basal nuclei are the largest nuclei of the brain and occupy a large part of the cerebrum. The **subthalamic nucleus** and the **substantia nigra** function in conjunction with the caudate and lentiform nuclei in the control of movement. The subthalamic nucleus is located in the diencephalon, and the substantia nigra is located in the midbrain.

12 List the basal nuclei and state their general function.

Limbic System

Parts of the cerebrum and diencephalon are grouped together under the title **limbic** (lim’bik) **system** (figure 13.11). The limbic system plays a central role in basic survival functions, such as memory, reproduction, and nutrition. It is also involved in emotional interpretation of sensory input and emotions in general. *Limbus* means border, and the term *limbic* refers to deep portions of the cerebrum that form a ring around the diencephalon. Structurally, the limbic system consists of (1) certain cerebral cortical areas, including the **cingulate** (sin’gū-lāt; to surround) **gyrus**, located along the inner surface of the longitudinal fissure just above the corpus callosum, and the **parahippocampal gyrus**, located on the medial side of the temporal lobe; (2) various nuclei, such as anterior nuclei of the thalamus, the habenula in the epithalamus, and the **dentate nucleus** of the **hippocampus**; (3) parts of the basal nuclei, such as the **amygdala**, or **amygdaloid nuclear complex**; (4) the hypothalamus, especially the mammillary bodies; (5) the **olfactory cortex**; and (6) tracts connecting the various cortical areas and nuclei, such as the

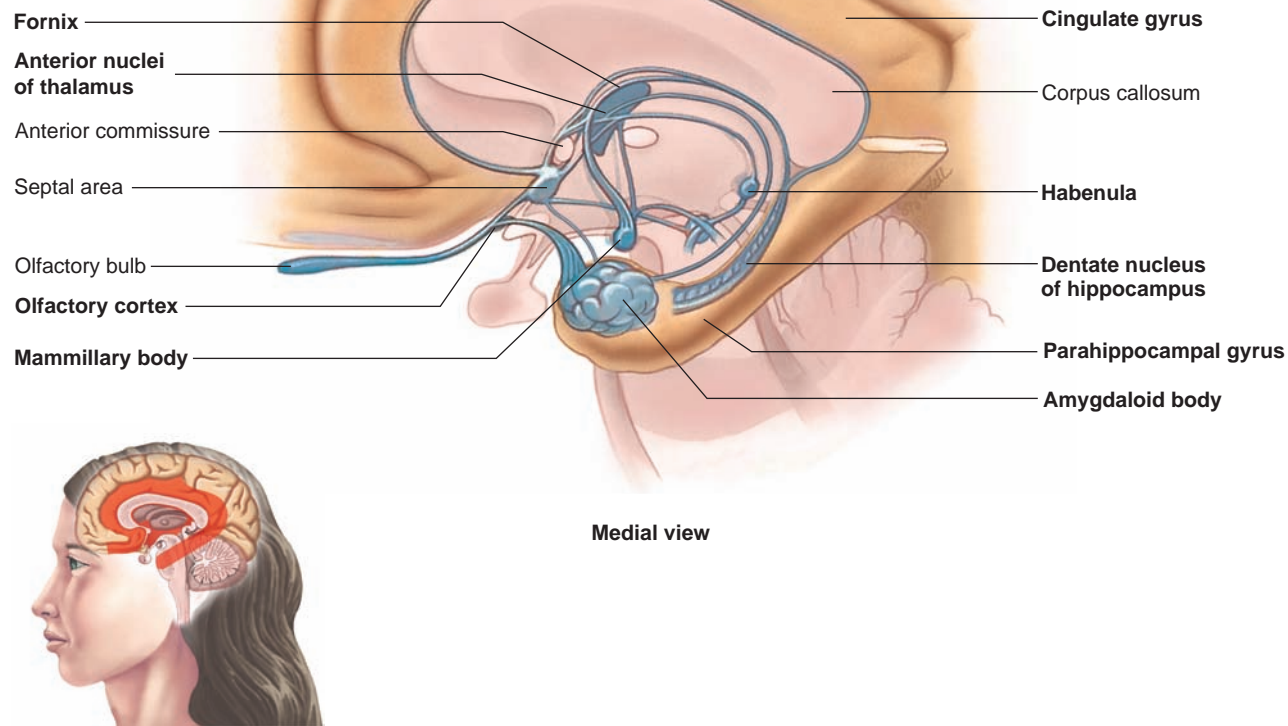

FIGURE 13.11 Limbic System and Associated Structures of the Right Hemisphere as Seen in a Median Section

fornix, which connects the hippocampus to the thalamus and mammillary bodies.

13 *List the parts of the limbic system. What are the functions of the limbic system?*

MENINGES, VENTRICLES, AND CEREBROSPINAL FLUID

Meninges

Three connective tissue membranes, the **meninges** (mě-nin'jēz), surround and protect the brain and spinal cord (figure 13.12). The most superficial and thickest membrane is the **dura mater** (doo'ra mā'ter; tough mother). The dura mater is composed of dense irregular connective tissue. Within the vertebral canal, the dura mater is distinctly separate from the vertebrae, forming an **epidural space**. Within the cranial cavity, the dura mater is tightly adherent to the cranial bones, so the epidural space there is only a potential space. The dura mater within the cranial cavity consists of two layers. The outer layer is called the **periosteal dura**, and

it is the inner periosteum of the cranial bones. The inner layer is the **meningeal dura**. The meningeal dura is continuous with the dura of the spinal cord. The meningeal dura is separated from the periosteal dura in several regions to form structures called dural folds and dural venous sinuses.

Dural folds are tough connective tissue partitions that extend into the major brain fissures. The dura mater and dural folds help hold the brain in place within the skull and keep it from moving around too freely. The largest of the dural folds is the **falx cerebri** (falks se-rē'brē; sickle-shaped), which lies in the longitudinal fissure and is anchored anteriorly to the crista galli of the ethmoid bone. The **tentorium cerebelli** (ten-tō'rē-ŭm, ser'ě-bel'ē; tent) is oriented horizontally between the cerebrum and the cerebellum. The **falx cerebelli** lies between the two cerebellar hemispheres.

Dural venous sinuses are spaces that form where the two layers of the dura mater are separated from each other. The largest of the sinuses is the **superior sagittal sinus**, which forms between the falx cerebri and the periosteal dura and runs along the median plane (see figure 13.12b). The dural venous sinuses are lined with endothelium; they transport venous blood and cerebrospinal

fluid (CSF; see “Cerebrospinal Fluid,” p. 459) away from the brain. All veins draining blood from the brain empty into dural venous sinuses. The dural sinuses subsequently drain into the internal jugular veins, which are the major veins that exit the cranial cavity to carry blood back to the heart (see chapter 21).

The next meningeal membrane is a very thin, wispy **arachnoid** (ă-rak’noyd; spiderlike; i.e., cobwebs) **mater**. The

space between this membrane and the dura mater is the **subdural space**; it contains only a very small amount of serous fluid. The third meningeal layer, the **pia** (pī’ă, pē’ă; affectionate) **mater** is bound very tightly to the surface of the brain. Between the arachnoid mater and the pia mater is the **subarachnoid space**, which contains weblike strands of arachnoid mater and the blood vessels supplying the brain and is filled with CSF.

Traumatic Brain Injuries and Hematomas

Head injuries are classified as **open** (when cranial cavity contents are exposed to the outside) or **closed** (when the cranial cavity remains intact) (see “CSF and Skull Fractures”). Closed injuries are more common and involve the head striking a hard surface or an object striking the head. Such injuries may result in brain trauma. The main trauma may be **coup** (kū), occurring at the site of impact, or **contrecoup** (kon'tra-kū), occurring on the opposite side of the brain from the impact and resulting from movement of the brain within the skull. Traumatic brain injury is three times more common in males than in females. The most common type of traumatic brain injury (75%–90%) is a **concussion**, which is defined as an immediate, but transient, impairment of neural function, such as a loss of consciousness or blurred vision.

Traumatic brain injury may be diffuse or focal. **Diffuse brain injury** usually results from shaking, such as when a person shakes a child or when a person is thrown about in an automobile accident. As the name suggests, such injury is not localized to one focal point but involves damage to many small vessels and nerves, especially around the brainstem. **Focal** traumatic brain injury may involve cortical **contusions** (bruising), involving direct impact injury to the brain, or hemorrhages in or around the brain. Contusions are usually superficial and involve only the gyri.

Hemorrhagic brain injury results from bleeding outside the dura (extradural or epidural), between the dura and the brain (subdural), or within the brain (intracerebral). A hemorrhage, which is bleeding, results in a hematoma, an accumulation of blood. **Extradural hemorrhages**, or **epidural hematomas**, occur in about 1%–2% of major head injuries. They usually occur in the middle cranial fossa and involve a tear of the middle meningeal artery (85%) or in the middle meningeal vein or dural sinus (15%). **Subdural hematomas** are much more common, occurring in 10%–20% of major head injuries. They most commonly involve tears of the cortical veins or dural venous sinuses, occur in the superior portion of the cranial cavity, and appear within hours of the head injury. **Chronic subdural hematomas**, which involve slow bleeding over an extended period of time (weeks to months), are common in elderly people and in people who abuse alcohol. **Intracerebral hematomas** occur in about 2%–3% of major head injuries and are often associated with contusions. They involve the damage of small vessels within the brain itself and are most common in the frontal and temporal lobes. They occur within 3–10 days of the head trauma.

Ventricles

The CNS is formed as a hollow tube that may be quite reduced in some areas of the adult CNS and expanded in other areas (see “Development of the CNS” p. 445). The interior of the tube is lined with a single layer of epithelial cells called **ependymal** (ep-en'di-mäl; see chapter 11) **cells**. Each cerebral hemisphere contains a relatively large cavity, the **lateral ventricle** (figure 13.13). The lateral ventricles are separated from each other by thin **septa pellucida** (sep'tā pe-loo'sid-ā; sing. *septum pellucidum*; translucent walls), which lie in the midline just inferior to the corpus callosum and usually are fused with each other. A smaller midline cavity, the **third ventricle**, is located in the center of the

CASE STUDY

Traumatic Brain Injury

The body of an 80-year-old female was being examined by the hospital pathologist to determine the cause of death. Her medical records indicated no significant history of cardiovascular disease, stroke, Alzheimer disease, or cancer. She had been taken to the emergency room after having been found lying in her bathtub and not breathing. Bleeding over the occipital region of her scalp led the pathologist to hypothesize that she had slipped and fallen while getting into the bath and had hit the back of her head on the edge of the tub. Because the pathologist suspected a traumatic brain injury as the cause of death, he focused most of his attention on the contents of the cranial cavity. The pathologist noted superficial bruising and bleeding of the scalp in the occipital region of the woman's head and then proceeded to open the cranial cavity. Inside the cranial cavity, the pathologist noted a large subdural hematoma above the right frontal lobe of the woman's brain. In addition, he noted that the brain had shifted as a result of the extensive bleeding such that the medulla oblongata had been pushed inferiorly (herniated) through the foramen magnum into the vertebral canal. After completing a thorough inspection of the remainder of the woman's body, the pathologist determined the cause of death to be a subdural hematoma caused by a traumatic brain injury.

PREDICT 1

- Explain why the subdural hematoma was found in the frontal region of the brain when the blow to the head occurred over the occipital region.
- What were the consequences of the herniation of the medulla oblongata into the vertebral canal, and how did this contribute to the woman's death?

diencephalon between the two halves of the thalamus. The two lateral ventricles communicate with the third ventricle through two **interventricular foramina** (foramina of Monro). The lateral ventricles can be thought of as the first and second ventricles in the numbering scheme, but they are not designated as such. The **fourth ventricle** is in the inferior part of the pontine region and the superior region of the medulla oblongata at the base of the cerebellum. The third ventricle communicates with the fourth ventricle through a narrow canal, the **cerebral aqueduct** (aqueduct of Sylvius), which passes through the midbrain. The fourth ventricle is continuous with the central canal of the spinal cord, which extends nearly the full length of the cord. The fourth ventricle is also continuous with the subarachnoid space through two lateral apertures and one median aperture.

FIGURE 13.13 Ventricles of the Brain Viewed from the Left

Cerebrospinal Fluid

Cerebrospinal (ser'ē-brō-spī-nāl; sē-rē'brō-spī-nāl) **fluid (CSF)** is a fluid similar to blood serum with most of the proteins removed. It bathes the brain and the spinal cord and provides a protective cushion around the CNS. CSF allows the brain to float within the cranial cavity so it does not rest directly on the surface of the skull or dura mater. In addition, it protects the brain against the shock of rapid movements of the head. It also provides some nutrients to CNS tissues. About 80%–90% of the CSF is produced by specialized ependymal cells within the lateral ventricles, with the remainder produced by similar cells in the third and fourth ventricles. These specialized ependymal cells, their support tissue, and the associated blood vessels are collectively called the **choroid** (kō'royd; lacy) **plexuses** (plek'sūs-ez; figure 13.14). The choroid plexuses are formed by invaginations of the vascular pia mater into the ventricles, thus producing a vascular connective tissue core covered by ependymal cells.

CSF and Skull Fractures

Open head trauma involves a fracture or hole in the skull, which exposes the contents of the cranial cavity (brain, blood, and/or CSF) to the exterior. Head injuries involving scalp lacerations or damage to the eye, ear, or nose should be carefully evaluated for the possibility of open head trauma involving the cranial cavity. In skull fractures in which the meninges are torn, CSF may leak from the nose if the fracture is in the frontal area or from the ear if the fracture is in the temporal area. Leakage of CSF indicates serious mechanical damage to the head and presents a risk for meningitis because bacteria may pass from the nose or ear through the tear and into the meninges. A skull fracture involving the base of the skull may result in cranial nerves damage where the nerves exit the skull.

CSF is formed through a variety of mechanisms. The majority of the fluid enters the ventricles by following a Na^+ concentration gradient. Ependymal cells of the choroid plexus actively transport Na^+ into the ventricles and water passively follows. Large molecules are transported by pinocytosis. The precise mechanisms for the transport of glucose and other substances into CSF remain unknown.

Endothelial cells of the blood vessels in the choroid plexuses, which are joined by tight junctions (see chapter 4), form the **blood–brain barrier**, or, more correctly, the **blood–cerebrospinal fluid barrier**. Consequently, substances do not pass between the cells but must pass through the cells.

CSF fills the ventricles, the subarachnoid space of the brain and spinal cord, and the central canal of the spinal cord. Approximately 23 mL of fluid fills the ventricles, and 117 mL fills the subarachnoid space. The route taken by the CSF from its origin in the choroid plexuses to its return to the circulation is depicted in figure 13.14. The flow rate of CSF from its origin to the point at which it enters the bloodstream is about 0.4 mL/min. CSF passes from the lateral ventricles through the interventricular foramina into the third ventricle and then through the cerebral aqueduct into the fourth ventricle. It can exit the interior of the brain only from the fourth ventricle. One **median aperture** (foramen of Magendie), which opens through the roof of the fourth ventricle, and two **lateral apertures** (foramina of Luschka), which open through the walls, allow the CSF to pass from the fourth ventricle to the subarachnoid space. Some CSF continues to flow inferiorly into the central canal of the spinal cord. However, parts of the central canal are closed off in adults, so the amount circulating there is very small. Masses of arachnoid tissue, **arachnoid granulations**, penetrate into the dural venous sinuses, especially the superior sagittal sinus. CSF passes into the blood of the dural venous sinuses through these granulations. The sinuses

1. Cerebrospinal fluid (CSF) is produced by the choroid plexuses of each of the four ventricles (*inset*).
2. CSF from the lateral ventricles flows through the interventricular foramina to the third ventricle.
3. CSF flows from the third ventricle through the cerebral aqueduct to the fourth ventricle.
4. CSF exits the fourth ventricle through the lateral and median apertures and enters the subarachnoid space. Some CSF enters the central canal of the spinal cord.
5. CSF flows through the subarachnoid space to the arachnoid granulations in the superior sagittal sinus, where it enters the venous circulation (*inset*).

PROCESS FIGURE 13.14 Flow of CSF

CSF flows through the ventricles and subarachnoid space is shown by *white arrows*. Those going through the foramina in the wall and roof of the fourth ventricle depict the CSF entering the subarachnoid space. CSF passes back into the blood through the arachnoid granulations (*white and black arrows*), which penetrate the dural sinus. The *black arrows* show the direction of blood flow in the sinuses.

are blood-filled; thus, it is within these dural sinuses that the CSF reenters the bloodstream. From the dural venous sinuses, the blood drains into the internal jugular veins to enter the veins of the general circulation.

Hydrocephalus

If the apertures of the fourth ventricle or the cerebral aqueduct are blocked, CSF can accumulate within the ventricles. This condition is called **internal**, or noncommunicating, **hydrocephalus**, and it results in increased CSF pressure. The production of CSF continues, even when the passages that normally allow it to exit the brain are blocked. Consequently, fluid builds inside the brain, causing pressure, which compresses the nervous tissue and dilates the ventricles. Compression of the nervous tissue usually results in irreversible brain damage. If the skull bones are not completely ossified when the hydrocephalus occurs, the pressure may also severely enlarge the head. The cerebral aqueduct may be blocked at the time of birth or may become blocked later in life because of a tumor growing in the brainstem.

Internal hydrocephalus can be successfully treated by placing a drainage tube (shunt) between the brain ventricles and abdominal cavity to eliminate the high internal pressures. There is some risk of infection being introduced into the brain through these shunts, however, and the shunts must be replaced as the person grows. A subarachnoid hemorrhage may block the return of CSF to the circulation. If CSF accumulates in the subarachnoid space, the condition is called **external**, or communicating, **hydrocephalus**. In this condition, pressure is applied to the brain externally, compressing neural tissues and causing brain damage.

- 14 Describe the three meninges that surround the CNS. What are the *falx cerebri*, *tentorium cerebelli*, and *falx cerebelli*?
- 15 Describe and list the contents of the dural sinuses subdural space, and subarachnoid space.
- 16 Name the four ventricles of the brain, and describe their locations and the connections between them. What are the *septa pellucida*?
- 17 Describe the production and circulation of CSF. Where does the CSF return to the blood?

BLOOD SUPPLY TO THE BRAIN

The brain requires a tremendous amount of blood to maintain its normal functions. The brain has a very high metabolic rate and brain cells are not capable of storing high-energy molecules for any length of time. In addition, brain cells depend almost entirely on glucose as their energy source (see chapter 25). Thus, the brain requires a constant blood supply to meet the demands of brain cells for both glucose and oxygen. Even though the brain accounts for only about 2% of the total weight of the body, it receives approximately 15%–20% of blood pumped by the heart. Interruption of the brain's blood supply for only seconds can cause unconsciousness, and interruption of the blood supply for minutes can cause irreversible brain damage.

The brain's blood supply is illustrated in chapter 21 (see figures 21.10 and 21.11). Blood reaches the brain through

the **internal carotid arteries**, which ascend to the head along the anterior-lateral part of the neck, and the **vertebral arteries**, which ascend along the posterior part of the neck, through the transverse foramina of the cervical vertebrae. The internal carotid arteries enter the cranial cavity through the carotid canals, and the vertebral arteries enter through the foramen magnum. The vertebral arteries join together to form the **basilar artery**, which lies on the ventral surface of the pons. The basilar artery and internal carotid arteries contribute to the **cerebral arterial circle** (circle of Willis). Branches from this circle and from the basilar artery supply blood to the brain.

The cerebral cortex on each side of the brain is supplied by three branches that arise from the cerebral arterial circle: the **anterior**, **middle**, and **posterior cerebral arteries**. The middle cerebral artery supplies most of the lateral surface of each cerebral hemisphere. The anterior cerebral artery supplies the medial portion of the parietal and frontal lobes. The posterior cerebral artery supplies the occipital lobe and the medial surface of the temporal lobe.

The arteries to the brain and their larger branches are located in the subarachnoid space. Small cortical arterial branches leave the subarachnoid space and enter the pia mater, where they branch extensively. Precapillary branches leave the pia mater and enter the substance of the brain. Most of these branches are short and remain in the cortex. Fewer, longer branches extend into the medulla.

The arteries within the substance of the brain quickly divide into capillaries. The epithelial cells of these capillaries are surrounded by the foot processes of astrocytes (see figure 11.6). The astrocytes promote the formation of tight junctions between the epithelial cells. The epithelial cells with their tight junctions form the **blood–brain barrier**, which regulates the movement of materials from the blood into the brain. Materials that would enter many tissues by passing between the epithelial cells of capillaries can not pass through the blood–brain barrier because of the tight junctions. Most materials that enter the brain pass through the epithelial cells. Lipid-soluble substances, such as nicotine, ethanol, and heroin, can diffuse through the plasma membranes of the epithelial cells and enter the brain. Water-soluble molecules, such as amino acids and glucose, move across the plasma membranes of the epithelial cells by mediated transport (see chapter 3).

Drugs and the Blood–Brain Barrier

The permeability characteristics of the blood–brain barrier must be considered when developing drugs designed to affect the CNS. For example, Parkinson disease is caused by a lack of the neurotransmitter dopamine, which normally is produced by certain neurons of the brain. A lack of dopamine results in decreased muscle control and shaking movements. Administering dopamine is not helpful because dopamine cannot cross the blood–brain barrier. Levodopa (L-dopa), a precursor to dopamine, is administered instead because it can cross the blood–brain barrier. CNS neurons then convert levodopa to dopamine, which helps reduce the symptoms of Parkinson disease.

- 18 Describe the blood supply to the brain. List the arteries supplying each part of the cerebral cortex.
- 19 Describe the blood–brain barrier.

CLINICAL FOCUS

General CNS Disorders

INFECTIONS

Encephalitis (en-sef-ă-lī'tis) is an inflammation of the brain; it is most often caused by a virus and less often by bacteria or other agents. A large variety of symptoms may result, including fever, paralysis, coma, or even death.

Myelitis (mī-ĕ-lī'tis) is an inflammation of the spinal cord caused by trauma, multiple sclerosis, or a number of infectious agents, including viruses, bacteria, or other agents. A large variety of symptoms may result depending on the extent and level of injury or infection.

Meningitis (men-in-jī'tis) is an inflammation of the meninges. It may be virally induced but is more often bacterial. Symptoms usually include stiffness in the neck, headache, and fever. Pus may accumulate in the subarachnoid space, block CSF flow, and result in hydrocephalus. In severe cases, meningitis may also cause paralysis, coma, or death.

OTHER CNS DISORDERS

An **aneurysm** (an'ū-rizm) is a dilation, or ballooning, of an artery. The arteries around the brain are common sites for

aneurysms, and hypertension can cause one of these “balloons” to burst or leak, causing a hemorrhage around the brain. With hemorrhaging, blood may enter the epidural space (epidural hematoma), subdural space (subdural hematoma), subarachnoid space, or the brain tissue. Blood in the subdural or subarachnoid space can apply pressure to the brain, causing damage to brain tissue. Blood is toxic to brain tissue, so blood entering the brain can directly damage brain tissue.

A **concussion** is a blow to the head producing momentary loss of consciousness without immediate detectable damage to the brain. Often, no more problems occur after the person regains consciousness; however, in some cases, **postconcussion syndrome** may occur a short time after the injury. The syndrome includes increased muscle tension or migraine headaches, reduced alcohol tolerance, difficulty in learning new things, reduction in creativity; as well as motivation, fatigue, and personality changes. The symptoms may be gone in a month or may persist for as much as a year. In some cases,

postconcussion syndrome is the result of a slowly occurring subdural hematoma that may be missed by an early examination. The blood may accumulate from small leaks in the dural sinuses.

Cerebral compression may occur as a result of hematomas, hydrocephalus, tumors, or edema of the brain, which can occur as a result of a severe blow to the head. The intracranial pressure increases, which may directly damage brain tissue. The cerebellum may compress the fourth ventricle, blocking the foramina and causing internal hydrocephalus, which further increases intracranial pressure. The greatest problem comes from compression of the brainstem. Compression of the midbrain can kink the oculomotor nerves, resulting in dilation of the pupils with no light response. Compression of the medulla oblongata may disrupt cardiovascular and respiratory centers, which can cause death. Compression of any part of the CNS that results in ischemia for as little as 3–5 minutes can result in local neuronal cell death. This is a major problem in spinal cord injuries.

CRANIAL NERVES

The 12 pairs of cranial nerves by convention are indicated by Roman numerals (I–XII) from anterior to posterior (figure 13.15). The first two pairs of cranial nerves connect directly to the cerebrum (I) or diencephalon (II). Nine pairs of the cranial nerves connect to the brainstem. One pair of cranial nerves (XI) is connected to the spinal cord and has no direct connection to brain structures. A given cranial nerve may have one or more of three functions: (1) sensory, (2) somatic motor, and (3) parasympathetic (table 13.4). **Sensory** functions include the special senses, such as vision, and the more general senses, such as touch and pain. **Somatic** (sō-mat'ik) **motor** functions are the control of skeletal muscles through motor neurons. **Proprioception** (prō-prē-ō-sep'shun) informs the brain about the position of various body parts, including joints and muscles. The cranial nerves innervating skeletal muscles also contain

proprioceptive sensory fibers, which convey action potentials to the CNS from those muscles. Because proprioception is the only sensory function of several otherwise somatic motor cranial nerves, however, that function is usually ignored, and the nerves are designated by convention as motor only. **Parasympathetic** function involves the regulation of glands, smooth muscles, and cardiac muscle. These functions are part of the autonomic nervous system and are discussed in chapter 16. Several of the cranial nerves have associated ganglia, and these ganglia are of two types: parasympathetic and sensory. Table 13.5 lists specific information about each cranial nerve.

The **olfactory (I)** and **optic (II) nerves** are exclusively sensory and are involved in the special senses of smell and vision, respectively. The functions of these nerves are discussed in chapter 15.

The **oculomotor nerve (III)** innervates four of the six muscles that move the eyeball (the superior, inferior, and medial rectus

FIGURE 13.15 Inferior Surface of the Brain Showing the Origin of the Cranial Nerves

muscles and the inferior oblique muscle; see chapter 10) and the levator palpebrae superioris muscle, which raises the superior eyelid. In addition, parasympathetic nerve fibers in the oculomotor nerve innervate smooth muscles in the eye and regulate the size of the pupil and the shape of the lens of the eye.

The **trochlear** (trōk'lē-ar) **nerve (IV)** is a somatic motor nerve that innervates one of the six eye muscles responsible for moving the eyeball (superior oblique).

The **trigeminal** (trī-jem'i-nāl) **nerve (V)** has somatic motor, proprioceptive, and cutaneous sensory functions. It supplies motor innervation to the muscles of mastication, one middle ear muscle, one palatine muscle, and two throat muscles. In addition to proprioception associated with its somatic motor functions, the trigeminal nerve also carries proprioception from the temporomandibular joint, tongue, and cheek, which allow you to chew food without biting your tongue or cheek. Damage to the trigeminal nerve may impede chewing.

The trigeminal nerve has the greatest general sensory function of all the cranial nerves and is the only cranial nerve involved in **sensory cutaneous innervation** of the head. All other cutaneous innervation comes from spinal nerves (see figure 12.14). *Trigeminal* means three twins, and the sensory

TABLE 13.5 Cranial Nerves and Their Functions

distribution of the trigeminal nerve in the face is divided into three regions, each supplied by a branch of the nerve. The three branches—ophthalmic, maxillary, and mandibular—arise directly from the trigeminal ganglion, which serves the same function as the dorsal root ganglia of the spinal nerves. Only the mandibular branch contains motor axons, which bypass the trigeminal ganglion, much as the ventral root of a spinal nerve bypasses a dorsal root ganglion.

In addition to these cutaneous functions, the maxillary and mandibular branches are important in dentistry. The maxillary nerve supplies sensory innervation to the maxillary teeth, palate, and gingiva (jin'ji-vä; gum). The mandibular branch supplies sensory innervation to the mandibular teeth, tongue, and gingiva. The various nerves innervating the teeth are referred to as **alveolar nerves** (al-vē'ō-lär; the sockets in which the teeth are located). The **superior alveolar nerves** to the maxillary teeth are derived from the maxillary branch of the trigeminal nerve, and the **inferior alveolar nerves** to the mandibular teeth are derived from the mandibular branch of the trigeminal nerve.

The **abducent** (ab-doo'sent) **nerve** (VI), like the trochlear nerve, is a somatic motor nerve that innervates one of the six eye muscles responsible for moving the eyeball (lateral rectus).

Dental Anesthesia

Dentists inject anesthetic to block sensory transmission by the alveolar nerves. The superior alveolar nerves are not usually anesthetized directly because they are difficult to approach with a needle. For this reason, the maxillary teeth are usually anesthetized locally by inserting the needle beneath the oral mucosa surrounding the teeth. The inferior alveolar nerve probably is anesthetized more often than any other nerve in the body. To anesthetize this nerve, the dentist inserts the needle somewhat posterior to the patient's last molar and extends the needle near where the mandibular branch of the trigeminal nerve enters the mandibular foramen.

Several nondental nerves are usually anesthetized during an inferior alveolar block. The mental nerve, which supplies cutaneous innervation to the anterior lip and chin, is a distal branch of the inferior alveolar nerve. When the inferior alveolar nerve is blocked, the mental nerve is blocked also, resulting in a numb lip and chin. Nerves lying near the point where the inferior alveolar nerve enters the mandible often are also anesthetized during inferior alveolar anesthesia. For example, the lingual nerve can be anesthetized to produce a numb tongue. The facial nerve lies some distance from the inferior alveolar nerve, but in rare cases anesthetic can diffuse far enough posteriorly to anesthetize that nerve. The result is a temporary facial palsy (paralysis or paresis), with the injected side of the face drooping because of flaccid muscles, which disappears when the anesthesia wears off. If the facial nerve is cut by an improperly inserted needle, permanent facial palsy may occur.

PREDICT 2

A drooping upper eyelid on one side of the face is a sign of possible oculomotor nerve damage. Describe how this could be evaluated by examining other oculomotor nerve functions. Describe the eye movements that would distinguish among oculomotor, trochlear, and abducent nerve damage.

The **facial nerve (VII)** is somatic motor, sensory, and parasympathetic. It controls all the muscles of facial expression, a small muscle in the middle ear, and two hyoid muscles. It is sensory for the sense of taste in the anterior two-thirds of the tongue (see chapter 15). The facial nerve supplies parasympathetic innervation to the submandibular and sublingual salivary glands of the mouth and to the lacrimal glands of the eye.

The **vestibulocochlear (ves-tib'ū-lō-kok'lē-är) nerve (VIII)**, like the olfactory and optic nerves, is exclusively sensory and transmits action potentials from the inner ear responsible for the special senses of hearing and balance (see chapter 15).

The **glossopharyngeal (glos'ō-fā-rin'jē-äl) nerve (IX)**, like the facial nerve, is somatic motor, sensory, and parasympathetic and has both sensory and parasympathetic ganglia. The glossopharyngeal nerve is somatic motor to one muscle of the pharynx and supplies parasympathetic innervation to the parotid salivary glands. The glossopharyngeal nerve is sensory for the sense of taste in the posterior third of the tongue. It also supplies tactile sensory innervation from the posterior tongue, middle ear, and pharynx and transmits sensory stimulation from receptors in the carotid arteries, which monitor blood pressure and blood carbon dioxide, oxygen, and pH levels (see chapter 21).

The **vagus (vā'gūs) nerve (X)**, like the facial and glossopharyngeal nerves, is somatic motor, sensory, and parasympathetic and has both sensory and parasympathetic ganglia. Most muscles of the soft palate, pharynx, and larynx are innervated by the vagus nerve. Damage to the laryngeal branches of the vagus nerve can interfere with normal speech. The vagus nerve is sensory for taste from the root of the tongue (see chapter 15). It is sensory for the inferior pharynx and the larynx and transmits sensory input from receptors in the aortic arch, which monitor blood pressure and carbon dioxide, oxygen, and pH levels in the blood (see chapter 21). In addition, the vagus nerve conveys sensory information from the thoracic and abdominal organs. The parasympathetic part of the vagus nerve is very important in regulating the functions of the thoracic and abdominal organs. It carries parasympathetic fibers to the heart and lungs in the thorax and to the digestive organs and kidneys in the abdomen.

The **accessory (XI) nerve** is a somatic motor nerve. The accessory nerve has been thought for many years to have both a cranial and a spinal component. The cranial component was thought to join the vagus nerve (hence the name *accessory*) and participate in its function. An understanding of the accessory nerve's structure was based on dissections conducted nearly 150 years ago and, apparently, not repeated until very recently. Extensive dissections of 15 human brainstems have failed to find

any connection between the brainstem and the accessory nerve. These data suggest that the accessory nerve is not actually a cranial nerve but originates entirely from the superior part of the cervical spinal cord, enters the cranial cavity through the foramen magnum, and then exits through the jugular foramen. The accessory nerve provides the major innervation to the sternocleidomastoid and trapezius muscles of the neck and shoulder.

The **hypoglossal (XII) nerve** is a somatic motor nerve that arises from the ventral surface of the medulla oblongata. It supplies the intrinsic tongue muscles, three of the four extrinsic tongue muscles, and the thyrohyoid and the geniohyoid muscles.

20 *What are the three major functions of the cranial nerves?*

21 *Which cranial nerves are sensory only? With what sense is each of these nerves associated?*

22 *Name the cranial nerves that are somatic motor and proprioceptive only. What muscles or muscle groups does each nerve supply?*

23 *The sensory cutaneous innervation of the face is provided by what cranial nerve? How is this nerve important in dentistry? Name the muscles that would not function if this nerve were damaged.*

24 *Which four cranial nerves have a parasympathetic function? Describe the function of each of these nerves.*

25 *Name the cranial nerves that control the movement of the eyeball.*

26 *Which cranial nerves are involved in the sense of taste? What part of the tongue does each supply?*

27 *Speech production involves which cranial nerves? Describe the branches of these nerves.*

PREDICT 3

Injury to the accessory nerve may result in sternocleidomastoid muscle dysfunction, a condition called "wry neck." If the head of a person with wry neck is turned to the left, does this position indicate injury to the left or right spinal component of the accessory nerve?

PREDICT 4

Unilateral damage to the hypoglossal nerve results in loss of tongue movement on one side, which is most obvious when the tongue is protruded. If the tongue is deviated to the right, is the left or right hypoglossal nerve damaged?

Reflexes integrated within the spinal cord were discussed in chapter 12. Many of the body's functions, especially those involved in maintaining homeostasis, involve reflexes that are integrated within the brain. Some of these reflexes, such as those involved in the control of heart rate (see chapter 20), blood pressure (see chapter 21), and respiration (see chapter 23), are integrated in the brainstem and many involve cranial nerve X (vagus nerve).

CLINICAL FOCUS

Peripheral Nervous System Disorders—Cranial Nerves

General issues of PNS disorders are described in chapter 12. This chapter addresses only those specific to the cranial nerves.

Trigeminal neuralgia, also called tic douloureux, involves one or more of the trigeminal nerve branches and consists of sharp bursts of pain in the face. This disorder often has a trigger point in or around the mouth, which, when touched, elicits the pain response in some other part of the face. The cause of trigeminal neuralgia is unknown.

Facial palsy (called Bell palsy) is a unilateral paralysis of the facial muscles. The affected side of the face droops because of the absence of muscle tone. Facial palsy involves the facial nerve and may result from facial nerve neuritis. The facial nerve passes from deep to superficial through the parotid gland. Although the cause of facial palsy is often unknown, it can result from a stroke or tumor in the cerebral cortex or brainstem (see chapter 14). Temporary facial palsy can result from inflammation of the parotid gland or from anesthesia accidentally introduced into the gland during dental anesthesia. Temporary facial palsy can even result from extreme cold in the face, where the superficial branches of the facial nerve are located.

INFECTIONS

Herpes simplex I is usually characterized by one or more lesions (sores) on the lips or nose. The virus apparently remains dormant in the trigeminal ganglion. Eruptions are usually recurrent and often occur in times of stress or of reduced resistance, such as during a case of the common cold. For this reason, they are called cold sores or fever blisters.

CLINICAL GENETICS

Neurofibromatosis

Neurofibromatosis type 1 (noor'ō-fī-brō-mă-tō'sis; von Recklinghausen disease) is an autosomal-dominant trait localized to chromosome 17. Neurofibromatosis type 1 is characterized by hyperpigmented skin present at birth and by multiple benign tumors (neurofibromas), which grow on nerves just under the skin and along nerves throughout the body. The skin of affected individuals is covered with characteristic large, flat, dark brown spots called café au lait spots, which are a type of birthmark. The neurofibromas increase in size and abundance with age and can cause severe disfigurement. Neurofibromatosis type 1 results from a mutation in the *neurofibromin 1* (NF1) gene, which encodes the protein neurofibromin. Neurofibromin is produced by neurons and glial cells, such as Schwann cells and oligodendrocytes. Neurofibromin is a tumor suppressor protein, which means it plays a role in keeping cells from growing uncontrollably. A mutated NF1 gene produces a defective neurofibromin protein, which then allows the glial cells to grow unchecked and form neurofibromas. Neurofibromatosis type 1 has an incidence of 1:2500–3300 individuals. Approximately 50% of the mutated genes are inherited from an affected parent,

but the remaining 50% are caused by new mutations. Two mutated copies of the gene are necessary to cause the disorder, but most individuals born with one NF1 mutation eventually develop a second mutation and begin to develop neurofibromas and café au lait spots.

A second form of neurofibromatosis, **neurofibromatosis type 2** (NF2), has the same inheritance characteristics of NF1, but is much rarer (incidence of 1:50,000–120,000 individuals). NF2 is localized to chromosome 22 and encodes the protein merlin (schwannomin), which is also a tumor suppressor protein. Individuals with neurofibromatosis type 2 do not develop café au lait spots. Instead, the disease is characterized by the development of bilateral tumors surrounding the vestibular division of CN VIII (vestibular schwannomas). Tumors on CN VIII cause ringing in the ears (tinnitus), hearing loss, and vertigo from the pressure of the tumor on the nerve as it travels through the internal acoustic meatus. Treatment of neurofibromatosis consists of surgery to remove tumors that are causing the patient severe pain, loss of function, or disfigurement or to remove tumors that are thought to have become malignant.

Many of the brainstem reflexes are associated with cranial nerve function. The circuitry of most of these reflexes is too complex for our discussions. In general, these reflexes involve sensory input from the cranial nerves or spinal cord, and the motor output of the cranial nerves.

Turning of the eyes toward a flash of light, sudden noise, or a touch on the skin are examples of brainstem reflexes. Moving the eyes to track a moving object is another complex brainstem reflex. Some of the sensory neurons from cranial nerve VIII form a reflex arc with neurons of cranial nerves V and VII, which

send axons to muscles of the middle ear and dampen the effects of very loud, sustained noises on delicate inner ear structures (see chapter 15). Reflexes that occur during the process of chewing allow the jaws to react to foods of various hardness and protect the teeth from breakage from very hard food items. Both the sensory and motor components of the reflex arc are carried by cranial nerve V. Reflexes involving input through cranial nerve V and output through cranial nerve XII move the tongue about to position food between the teeth for chewing and then move the tongue out of the way so it is not bitten.

SUMMARY

Development of the CNS (p. 445)

The brain and spinal cord develop from the neural tube. The ventricles and central canal develop from the lumen of the neural tube.

Brainstem (p. 445)

Medulla Oblongata

1. The medulla oblongata is continuous with the spinal cord and contains ascending and descending tracts.
2. The pyramids are tracts controlling voluntary muscle movement.
3. The olives are nuclei that function in equilibrium, coordination, and modulation of sound from the inner ear.
4. Medullary nuclei regulate the heart, blood vessels, respiration, swallowing, vomiting, coughing, sneezing, and hiccuping. The nuclei of cranial nerves V and IX–XII are in the medulla.

Pons

1. The pons is superior to the medulla.
2. Ascending and descending tracts pass through the pons.
3. Pontine nuclei regulate sleep and respiration. The nuclei of cranial nerves V–IX are in the pons.

Midbrain

1. The midbrain is superior to the pons.
2. The midbrain contains the nuclei for cranial nerves III, IV, and V.
3. The tectum consists of four colliculi. The two inferior colliculi are involved in hearing and the two superior colliculi in visual reflexes.
4. The tegmentum contains ascending tracts and the red nuclei, which are involved in motor activity.
5. The cerebral peduncles are the major descending motor pathway.
6. The substantia nigra connects to other basal nuclei and is involved with muscle tone and movement.

Reticular Formation

The reticular formation consists of nuclei scattered throughout the brainstem. The reticular system functions in the sleep–wake cycle and other cycles of activity.

Cerebellum (p. 449)

1. The cerebellar cortex contains more neurons than does the cerebral cortex. The Purkinje cells are the largest cells in the CNS.
2. The cerebellum has three parts that control balance, gross motor coordination, and fine motor coordination.
3. The cerebellum corrects discrepancies between intended movements and actual movements.
4. The cerebellum can “learn” highly specific complex motor activities.

Diencephalon (p. 449)

The diencephalon is located between the brainstem and the cerebrum.

Thalamus

1. The thalamus consists of two lobes connected by the intermediate mass. The thalamus functions as an integration center.
2. Most sensory input synapses in the thalamus. Pain is registered in the thalamus.
3. The thalamus also has some motor functions.

Subthalamus

The subthalamus is inferior to the thalamus and is involved in motor function.

Epithalamus

The epithalamus is superior and posterior to the thalamus and contains the habenular nuclei, which influence emotions through the sense of smell. The pineal body may play a role in the onset of puberty.

Hypothalamus

1. The hypothalamus, the most inferior portion of the diencephalon, contains several nuclei and tracts.
2. The mammillary bodies are reflex centers for olfaction.
3. The hypothalamus regulates many endocrine functions (e.g., metabolism, reproduction, response to stress, and urine production). The pituitary gland attaches to the hypothalamus.
4. The hypothalamus regulates body temperature, hunger, thirst, satiety, swallowing, and emotions.

Cerebrum (p. 453)

1. The cortex of the cerebrum is folded into ridges called gyri and grooves called sulci, or fissures.
2. The longitudinal fissure divides the cerebrum into left and right hemispheres. Each hemisphere has five lobes.
 - The frontal lobes are involved in smell, voluntary motor function, motivation, aggression, and mood.
 - The parietal lobes contain the major sensory areas receiving general sensory input, taste, and balance.
 - The occipital lobes contain the visual centers.
 - The temporal lobes receive olfactory and auditory input and are involved in memory, abstract thought, and judgment.
3. Tracts connect areas of the cortex within the same hemisphere (association fibers), between hemispheres (commissural fibers), and with other parts of the brain and the spinal cord (projection fibers).

Basal Nuclei

1. Basal nuclei include the subthalamic nuclei, substantia nigra, and corpus striatum.
2. The basal nuclei are important in controlling motor functions.

Limbic System

1. The limbic system includes parts of the cerebral cortex, basal nuclei, the thalamus, the hypothalamus, and the olfactory cortex.
2. The limbic system controls visceral functions through the autonomic nervous system and the endocrine system and is involved in emotions and memory.

Meninges, Ventricles, and Cerebrospinal Fluid (p. 456)

Meninges

1. The brain and spinal cord are covered by the dura, arachnoid, and pia mater.
2. The dura mater attaches to the skull and has two layers that can separate to form dural sinuses.
3. Beneath the arachnoid mater the subarachnoid space contains CSF that helps cushion the brain.
4. The pia mater attaches directly to the brain.

Ventricles

1. The lateral ventricles in the cerebrum are connected to the third ventricle in the diencephalon by the interventricular foramen.
2. The third ventricle is connected to the fourth ventricle in the pons by the cerebral aqueduct. The central canal of the spinal cord is connected to the fourth ventricle.

Cerebrospinal Fluid

1. CSF is produced from the blood in the choroid plexus of each ventricle. CSF moves from the lateral to the third and then to the fourth ventricle.
2. From the fourth ventricle, CSF enters the subarachnoid space through three apertures.
3. CSF leaves the subarachnoid space through arachnoid granulations and returns to the blood in the dural venous sinuses.

Blood Supply to the Brain (p. 461)

1. The brain receives blood from the internal carotid and vertebral arteries. The latter form the basilar artery. The basilar and internal carotid arteries contribute to the cerebral arterial circle. Branches from the circle and basilar artery supply the brain.
2. The blood–brain barrier is formed from the endothelial cells of the capillaries in the brain, the astrocytes in the brain tissue, and the basement membrane in between.

Cranial Nerves (p. 462)

1. Cranial nerves perform sensory, somatic motor, proprioceptive, and parasympathetic functions.
2. The olfactory (I) and optic (II) nerves are involved in the sense of smell and vision.

3. The oculomotor nerve (III) innervates four of six extrinsic eye muscles and the upper eyelid. The oculomotor nerve also provides parasympathetic supply to the iris and lens of the eye.
4. The trochlear nerve (IV) controls an extrinsic eye muscle.
5. The trigeminal nerve (V) supplies the muscles of mastication, as well as a middle ear muscle, a palatine muscle, and two throat muscles. The trigeminal nerve has the greatest cutaneous sensory distribution of any cranial nerve. The trigeminal nerve has three branches. Two of the three trigeminal nerve branches innervate the teeth.
6. The abducent nerve (VI) controls an extrinsic eye muscle.
7. The facial nerve (VII) supplies the muscles of facial expression, an inner ear muscle, and two throat muscles. It is involved in the sense of taste. It is parasympathetic to two sets of salivary glands and to the lacrimal glands.
8. The vestibulocochlear nerve (VIII) is involved in the sense of hearing and balance.
9. The glossopharyngeal nerve (IX) is involved in taste and supplies tactile sensory innervation from the posterior tongue, middle ear, and pharynx. It is also sensory for receptors that monitor blood pressure and gas levels in the blood. The glossopharyngeal nerve is parasympathetic to the parotid salivary glands.
10. The vagus nerve (X) innervates the muscles of the pharynx, palate, and larynx. It is also involved in the sense of taste. The vagus nerve is sensory for the pharynx and larynx and for receptors that monitor blood pressure and gas levels in the blood. The vagus nerve is sensory for thoracic and abdominal organs. The vagus nerve provides parasympathetic innervation to the thoracic and abdominal organs.
11. The accessory nerve (XI) has only a spinal component. It supplies the sternocleidomastoid and trapezius muscles.
12. The hypoglossal nerve (XII) supplies the intrinsic tongue muscles, three of four extrinsic tongue muscles, and two throat muscles.
13. Many reflexes involved in homeostasis involve the cranial nerves and occur in the brainstem.

REVIEW AND COMPREHENSION

1. Which of these parts of the embryonic brain is correctly matched with the structure it becomes in the adult brain?
 - a. mesencephalon—midbrain
 - b. metencephalon—medulla oblongata
 - c. myelencephalon—cerebrum
 - d. telencephalon—pons and cerebellum
 - e. atom.
2. If a section is made that separates the brainstem from the rest of the brain, the cut is between the
 - a. medulla oblongata and pons.
 - b. pons and midbrain.
 - c. midbrain and diencephalon.
 - d. thalamus and cerebrum.
 - e. medulla oblongata and spinal cord.
3. Important centers for heart rate, blood pressure, respiration, swallowing, coughing, and vomiting are located in the
 - a. cerebrum.
 - b. medulla oblongata.
 - c. midbrain.
 - d. pons.
 - e. cerebellum.
4. In which of these parts of the brain does decussation of descending tracts involved in the conscious control of skeletal muscles occur?
 - a. cerebrum
 - b. diencephalon
 - c. midbrain
 - d. pons
 - e. medulla oblongata
5. Important respiratory centers are located in the
 - a. cerebrum.
 - b. cerebellum.
 - c. pons and medulla oblongata.
 - d. midbrain.
 - e. limbic system.
6. The cerebral peduncles are a major descending motor pathway found in the
 - a. cerebrum.
 - b. cerebellum.
 - c. pons.
 - d. midbrain.
 - e. medulla oblongata.
7. The superior colliculi are involved in _____, whereas the inferior colliculi are involved in _____.
 - a. hearing, visual reflexes
 - b. visual reflexes, hearing
 - c. balance, motor pathways
 - d. motor pathways, balance
 - e. respiration, sleep
8. The cerebellum communicates with other regions of the CNS through the
 - a. flocculonodular lobe.
 - b. cerebellar peduncles.
 - c. vermis.
 - d. lateral hemispheres.
 - e. folia.
9. The major relay station for sensory input that projects to the cerebral cortex is the
 - a. hypothalamus.
 - b. thalamus.
 - c. pons.
 - d. cerebellum.
 - e. midbrain.

10. Which part of the brain is involved with olfactory reflexes and emotional responses to odors?
- inferior colliculi
 - superior colliculi
 - mammillary bodies
 - pineal body
 - pituitary gland
11. The part of the diencephalon directly connected to the pituitary gland is the
- hypothalamus.
 - epithalamus.
 - subthalamus.
 - thalamus.
12. Which of the following is a function of the hypothalamus?
- regulates autonomic nervous system functions
 - regulates the release of hormones from the posterior pituitary
 - regulates body temperature
 - regulates food intake (hunger) and water intake (thirst)
 - all of the above
13. The grooves on the surface of the cerebrum are called the
- nuclei.
 - commissures.
 - tracts.
 - sulci.
 - gyri.
14. Which of these areas is located in the postcentral gyrus of the cerebral cortex?
- olfactory cortex
 - visual cortex
 - primary motor cortex
 - primary somatic sensory cortex
 - primary auditory cortex
15. Which of these cerebral lobes is important in voluntary motor function, motivation, aggression, sense of smell, and mood?
- frontal
 - insula
 - occipital
 - parietal
 - temporal
16. Fibers that connect areas of the cerebral cortex within the same hemisphere are
- projection fibers.
 - commissural fibers.
 - association fibers.
 - all of the above.
17. The basal nuclei are located in the
- inferior cerebrum.
 - diencephalon.
 - midbrain.
 - all of the above.
18. The most superficial of the meninges is a thick, tough membrane called the
- pia mater.
 - dura mater.
 - arachnoid mater.
 - epidural mater.
19. The ventricles of the brain are interconnected. Which of these ventricles are *not* correctly matched with the structures that connect them?
- lateral ventricle to the third ventricle—interventricular foramina
 - left lateral ventricle to right lateral ventricle—central canal
 - third ventricle to fourth ventricle—cerebral aqueduct
 - fourth ventricle to subarachnoid space—median and lateral apertures
20. Cerebrospinal fluid is produced by the _____, circulates through the ventricles, and enters the subarachnoid space. The cerebrospinal fluid leaves the subarachnoid space through the _____
- choroid plexuses, arachnoid granulations
 - arachnoid granulations, choroid plexuses
 - dural venous sinuses, dura mater
 - dura mater, dural venous sinuses
21. Given these spaces:
- third ventricle
 - epidural space
 - subarachnoid space
 - subdural space
 - superior sagittal sinus
- Which of these spaces contains only cerebrospinal fluid (CSF)?
- 1, 3
 - 1,2,3
 - 1,3,5
 - 1,2,3,5
 - 2,3,4,5
22. Some portions of the blood plasma move across the blood–brain barrier by
- diffusion.
 - endocytosis.
 - exocytosis.
 - symport.
 - filtration.
23. The cranial nerve involved in chewing food is the
- trochlear (IV).
 - trigeminal (V).
 - abducent (VI).
 - facial (VII).
 - vestibulocochlear (VIII).
24. The cranial nerve responsible for focusing the eye (innervates the ciliary muscle of the eye) is the
- optic (II).
 - oculomotor (III).
 - trochlear (IV).
 - abducent (VI).
 - facial (VII).
25. The cranial nerve involved in moving the tongue is the
- trigeminal (V).
 - facial (VII).
 - glossopharyngeal (IX).
 - accessory (XI).
 - hypoglossal (XII).
26. The cranial nerve involved in feeling a toothache is the
- trochlear (IV).
 - trigeminal (V).
 - abducent (VI).
 - facial (VII).
 - vestibulocochlear (VIII).
27. From this list of cranial nerves:
- olfactory (I)
 - optic (II)
 - oculomotor (III)
 - abducent (VI)
 - vestibulocochlear (VIII)
- Select the nerves that are sensory only.
- 1,2,3
 - 2,3,4
 - 1,2,5
 - 2,3,5
 - 3,4,5
28. From this list of cranial nerves:
- optic (II)
 - oculomotor (III)
 - trochlear (IV)
 - trigeminal (V)
 - abducent (VI)
- Select the nerves that are involved in moving the eyes.
- 1,2,3
 - 1,2,4
 - 2,3,4
 - 2,4,5
 - 2,3,5
29. From this list of cranial nerves:
- trigeminal (V)
 - facial (VII)
 - glossopharyngeal (IX)
 - vagus (X)
 - hypoglossal (XII)
- Select the nerves that are involved in the sense of taste.
- 1,2,3
 - 1,4,5
 - 2,3,4
 - 2,3,5
 - 3,4,5
30. From this list of cranial nerves:
- trigeminal (V)
 - facial (VII)
 - glossopharyngeal (IX)
 - vagus (X)
 - hypoglossal (XII)
- Select the nerves that innervate the salivary glands.
- 1,2
 - 2,3
 - 3,4
 - 4,5
 - 3,5
31. From this list of cranial nerves:
- oculomotor (III)
 - trigeminal (V)
 - facial (VII)
 - vestibulocochlear (VIII)
 - glossopharyngeal (IX)
 - vagus (X)
- Select the nerves that are part of the parasympathetic division of the ANS.
- 1,2,4,5
 - 1,3,5,6
 - 1,4,5,6
 - 2,3,4,5
 - 2,3,5,6

CRITICAL THINKING

1. A patient loses all sense of feeling in the left side of the back, below the upper limb, and extending in a band around to the chest, as well as below the upper limb. All sensation on the right is normal. The line between normal and absent sensation is the anterior and posterior midline. Explain this condition.
2. What happens to the developing brain if the CSF is not properly drained, resulting in early hydrocephalus?
3. A patient exhibits enlargement of the lateral and third ventricles, but no enlargement of the fourth ventricle. What do you conclude?
4. During a spinal tap of a patient, blood is discovered in the CSF. What does this finding suggest?
5. Describe a clinical test to evaluate each of the 12 cranial nerves.
6. A patient presented to her physician with a loss of muscle tone and coordination. She was unable to perform coordinated tasks, such as touching the tip of her finger to her nose. The physician concluded that a part of her brain had been damaged. Which part of the brain was damaged?
7. A baseball player was accidentally hit with a baseball, which struck him on the bridge of his nose. He suffered fractures of several facial bones as a result. Soon after sustaining the injury, he noticed he had lost his sense of smell. Explain how this probably happened.

14 Integration of Nervous System Functions

The nervous system is involved in almost all bodily functions. Although humans have larger, more complex brains than other animals, most human nervous system functions are similar to those of other animals. The sensory input we receive and most of the ways we respond to that input are similar to that in other animals, yet the human brain is capable of unique and complex functions, such as recording history, reasoning, and planning, to a degree unparalleled in the animal kingdom. Many of these functions can be studied only in humans. That is why much of human brain function remains elusive and is one of the most challenging frontiers of anatomy and physiology.

This chapter presents the concept of *sensation* (p. 477) and then discusses the *control of skeletal muscles* (p. 490), the *brainstem functions* (p. 498), *other brain functions* (p. 500), and the *effects of aging on the nervous system* (p. 506).

Colorized SEM of presynaptic terminals associated with a postsynaptic neuron.

SENSATION

Sensation, or **perception**, is the conscious awareness of the effects of stimuli on sensory receptors. The brain constantly receives action potentials from a wide variety of sensory receptors both inside and outside the body. Sensory receptors respond to stimuli by generating action potentials that are propagated along nerves to the spinal cord and brain. Sensations result when action potentials reach the cerebral cortex. Some other parts of the brain are involved in sensation. For example, the thalamus and amygdala are involved in the sensation of pain.

The **senses** are the means by which the brain perceives information about the environment and the body. Historically, five senses were recognized: smell, taste, sight, hearing, and touch. Today, the senses are divided into two basic groups: general and special senses. The **general senses** are those with receptors distributed over a large part of the body. They are divided into two groups: the somatic and the visceral senses (table 14.1 and figure 14.1). The **somatic senses**, which provide sensory information about the body and the environment, include touch, pressure, itch, vibration, temperature, proprioception, and pain. The **visceral senses**, which provide information about various internal organs, consist primarily of pain and pressure.

The **special senses** are more specialized in structure, have specialized nerve endings, and are localized to specific organs (see table 14.1). The special senses are smell, taste, sight, hearing, and balance. Chapter 15 considers the special senses in detail.

Awareness

As you read this paragraph, you are probably not aware of the weight of the book in your hands, if you are holding it, or the weight of your forearms on the desk or on your lap, if you are reading at a desk. It is also unlikely that you are aware of the small noises around you or the clothes touching your body until your attention is drawn to them. You certainly are not aware of changes in your blood pressure and your body fluid pH and blood glucose levels. This is because not all of the sensory information detected by sensory receptors results in sensory perception. Some action potentials reach areas of the brain where they are not consciously perceived.

Although we can be consciously aware of body position and movements, much of this sensory information is propagated to the cerebellum, where it is processed at an unconscious level. Sensory information from receptors that monitor blood pressure, blood oxygen, and pH levels are processed unconsciously in the medulla oblongata. For example, blood pressure must be regulated constantly to maintain homeostasis. If we had to regulate blood pressure consciously, we could not be able to think of much else. Homeostasis, therefore, is controlled largely without our conscious involvement.

Even the cerebral cortex screens much of what it receives, ignoring many of the action potentials that reach it. In addition, humans exhibit selective awareness. We are more aware of sensations on which we focus our attention than on other sensations. If we were aware of all the sensations that arrived at the cerebral cortex, we would probably not be able to function.

Sensation requires the following steps:

1. Stimuli originating either inside or outside the body are detected by sensory receptors and action potentials are produced, which are propagated to the CNS by nerves (see “Sensory Receptors”).
2. Within the CNS, tracts conduct action potentials to the cerebral cortex and to other areas of the CNS (see “Sensory Tracts,” p. 482).
3. Many action potentials reaching the cerebral cortex are ignored. Others are translated so the person becomes aware of the stimulus (see “Sensory Areas of the Cerebral Cortex,” p. 486).

Sensory Receptors

Types of Sensory Receptors

The various senses depend on sensory receptors specialized to respond to specific types of stimuli (see table 14.1). **Mechanoreceptors** respond to mechanical stimuli, such as compression, bending, or stretching of cells. The senses of touch, tickle, itch, vibration, pressure, proprioception, hearing, and balance all depend on a variety of mechanoreceptors. **Chemoreceptors** respond to chemicals that become attached to receptors on their membranes. Smell and taste depend on chemoreceptors. **Thermoreceptors** respond to changes in temperature at the site of the receptor and are necessary for the sense of temperature. **Photoreceptors** respond to light striking the receptor cells and are necessary for vision. **Nociceptors** (nō-si-sep'ters; Latin, *noceo* means hurt), or **pain receptors**, respond to painful mechanical, chemical, and thermal stimuli. Most sensory receptors typically respond to one type of stimulus, but some nociceptors respond to more than one.

At least eight major types of sensory receptors, which differ in their structure and the types of stimuli to which they are most sensitive, are involved in general sensation (table 14.2 and figure 14.2). Many of these sensory receptors are associated with the skin; others are associated with deeper structures, such as tendons, ligaments, and muscles; and some can be found in both the skin and deeper structures. In general, sensory receptors are classified into three groups based on their location: **Exteroreceptors** (cutaneous receptors) are associated with the skin, **visceroreceptors** are associated with the viscera or organs, and **proprioceptors** are associated with joints, tendons, and other connective tissue. Exteroreceptors provide information about the external environment, visceroreceptors provide information about the internal environment, and proprioceptors provide information about body position, movement, and the extent of stretch or the force of muscular contractions.

Structurally, the simplest and most common sensory receptors are the **free nerve endings** (see figure 14.2), which are relatively unspecialized neuronal branches similar to dendrites. Free nerve endings are distributed throughout almost all parts of the body. Most visceroreceptors consist of free nerve endings, which are responsible for a number of sensations, including pain, temperature, itch, and movement. The free nerve endings responsible for temperature detection respond to three types of sensations. One type, the **cold receptors**, increases its rate of action potential

TABLE 14.1 Classification of the Senses

Types of Sense	Nerve Endings	Receptor Type	Initiation of Response
Somatic			
Touch		Mechanoreceptors	Compression of receptors
Stroking	Meissner corpuscle		
	Hair follicle receptor		
Texture	Merkel's disk		
Vibration	Pacinian corpuscle		
Skin stretch	Ruffini end organ		
Itch	Free nerve endings		
Pressure	Merkel disk	Mechanoreceptors	Compression of receptors
Proprioception	Pacinian corpuscle	Mechanoreceptors	Compression of receptors
Temperature	Free nerve endings	Thermoreceptors	Temperature around nerve endings
	Cold receptors		
	Warm receptors		
Pain	Free nerve endings	Nociceptors	Irritation of nerve endings (e.g., mechanical, chemical, or thermal)
Visceral			
Pain	Free nerve endings	Nociceptors	Irritation of nerve endings
Pressure	Pacinian corpuscle	Mechanoreceptors	Compression of receptors
Special			
Smell	Specialized	Chemoreceptors	Binding of molecules to membrane receptors
Taste	Specialized	Chemoreceptors	Binding of molecules to membrane receptors
Sight	Specialized	Photoreceptors	Chemical change in receptors initiated by light
Hearing	Specialized	Mechanoreceptors	Bending of microvilli on receptor cells
Balance	Specialized	Mechanoreceptors	Bending of microvilli on receptor cells

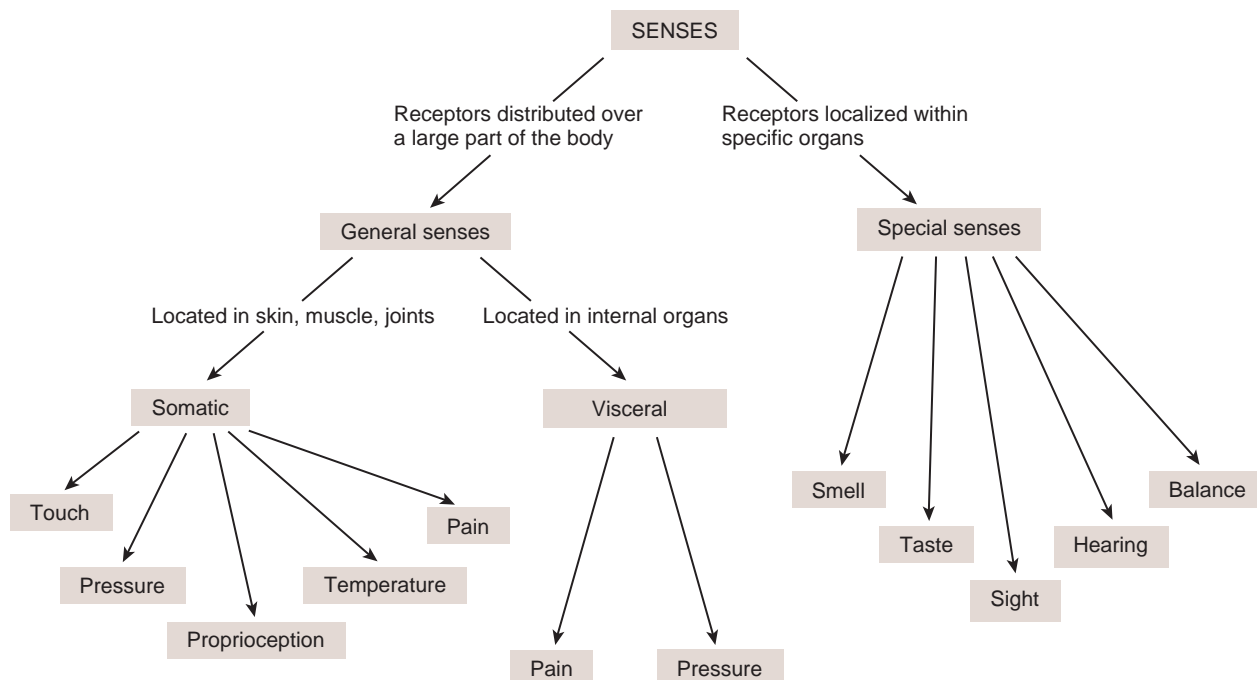

FIGURE 14.1 Classification of Senses

TABLE 14.2 Sensory Receptors

Type of Receptor	Structure	Function
Free nerve ending	Branching, no capsule	Pain, itch, tickle, temperature, joint movement, and proprioception
Merkel disk	Flattened expansions at the end of axons; each expansion associated with a Merkel cell	Light touch and superficial pressure
Hair follicle receptor	Wrapped around hair follicles or extending along the hair axis, each axon supplies several hairs, and each hair receives branches from several neurons, resulting in considerable overlap.	Light touch; responds to very slight bending of the hair
Pacinian corpuscle	Onion-shaped capsule of several cell layers with a single central nerve process	Deep cutaneous pressure, vibration, and proprioception
Meissner corpuscle	Several branches of a single axon associated with wedge-shaped epitheloid cells and surrounded by a connective tissue capsule	Two-point discrimination
Ruffini end organ	Branching axon with numerous small, terminal knobs surrounded by a connective tissue capsule	Continuous touch or pressure; responds to depression or stretch of the skin
Muscle spindle	Three to 10 striated muscle fibers enclosed by a loose connective tissue capsule, striated only at the ends, with sensory nerve endings in the center	Proprioception associated with detection of muscle stretch; important for control of muscle tone
Golgi tendon organ	Surrounds a bundle of tendon fascicles and is enclosed by a delicate connective tissue capsule; nerve terminations are branched with small swellings applied to individual tendon fascicles	Proprioception associated with the stretch of a tendon; important in the control of muscle contraction

**FIGURE 14.2** Sensory Nerve Endings in the Skin

production as the skin is cooled. The second type, **warm receptors**, increases its rate of action potential production as skin temperature increases. Both cold and warm receptors respond most strongly to changes in temperature. Cold receptors are 10 to 15 times more numerous in any given area of skin than warm receptors. The third type is a pain receptor, which is stimulated by extreme cold or heat. At very cold temperatures (0° – 12°C), only pain receptors are stimulated. The pain sensation ends as the temperature increases above 15°C . Between 12° and 35°C , cold fibers are stimulated. Nerve fibers from warm receptors are stimulated between 25° and 47°C . “Comfortable” temperatures, between 25° and 35°C , therefore stimulate both warm and cold receptors. Temperatures above 47°C stimulate cold and pain receptors but do not stimulate warm receptors.

PREDICT 1

How might a very cold object placed in the hand be misperceived as being hot?

Merkel (mer'kĕl), or **tactile disks** are more complex than free nerve endings (see figure 14.2) and consist of axonal branches that end as flattened expansions, each associated with a specialized epithelial cell. They are distributed throughout the basal layers of the epidermis just superficial to the basement membrane and are associated with dome-shaped mounds of thickened epidermis in hairy skin. Merkel disks are involved with the sensations of light touch and superficial pressure. These receptors can detect a skin displacement of less than 1 mm (1/25 inch).

Hair follicle receptors, or **hair end organs**, respond to very slight bending of the hair and are involved in light touch (see figure 14.2). These receptors are extremely sensitive and require very little stimulation to elicit a response. The sensation, however, is not

very well localized. The dendritic tree at the distal end of a sensory axon has several hair follicle receptors. The field of hairs innervated by these receptors overlaps with the fields of hair follicle receptors of adjacent axons. The considerable overlap that exists in the endings of sensory neurons helps explain why light touch is not highly localized, yet, because of converging signals within the CNS, it is very sensitive.

Pacinian (pa-sin'ĕ-an, pa-chin'ĕ-an), or **lamellated corpuscles** are complex receptors that resemble an onion (see figure 14.2). A single dendrite extends to the center of each lamellated corpuscle. The corpuscles are located within the deep dermis or hypodermis, where they are responsible for deep cutaneous pressure and vibration. Pacinian corpuscles associated with the joints help relay **proprioceptive** (prō-prĕ-ō-sep'tiv; perception of position) information about joint positions.

Meissner (mīs'ner), or **tactile corpuscles** are distributed throughout the dermal papillae (see figure 14.2 and chapter 5) and are involved in two-point discrimination. **Two-point discrimination** (fine touch) is the ability to detect simultaneous stimulation at two points on the skin. The distance between two points that a person can detect as separate points of stimulation differs for various regions of the body. This sensation is important in evaluating the texture of objects. Meissner corpuscles are numerous and close together in the tongue and fingertips but are less numerous and more widely separated in other areas, such as the back (figure 14.3).

Ruffini (rū-fĕ'nĕ) **end organs** are located in the dermis of the skin (see figure 14.2), primarily in the fingers. They respond to pressure on the skin directly superficial to the receptor and to stretch of adjacent skin. These receptors are important in responding to continuous touch or pressure.

Muscle spindles (figure 14.4) consist of 3–10 specialized skeletal muscle fibers. They are located in skeletal muscles and provide information about the length of the muscle (see “Stretch

FIGURE 14.3 Two-Point Discrimination

Two-point discrimination can be demonstrated by touching a person's skin with the two points of a compass. When the two points are closer together than the receptor field, the individual perceives only one point. When the two points of the compass are opened wider, the person becomes aware of two points.

FIGURE 14.4 Muscle Spindle

Reflex,” p. 417). Muscle spindles are important to the control and tone of postural muscles. Brain centers act through descending tracts to either increase or decrease action potentials in gamma motor neurons. Stimulation of the gamma motor system, caused by stretch of the muscle, activates the stretch reflex, which in turn increases the tone of the muscles involved.

Golgi tendon organs are proprioceptive receptors associated with the fibers of a tendon near the junction between the muscle and tendon (figure 14.5). They are activated by an increase in tendon tension, caused either by contraction of the muscle or by passive stretch of the tendon.

FIGURE 14.5 Golgi Tendon Organ

- 1** In general, into what three groups can sensory receptors be classified?
- 2** List the eight major types of sensory receptors, indicate where they are located, and state the functions they perform.

Responses of Sensory Receptors

Interaction of a stimulus with a sensory receptor produces a graded potential called a **receptor potential**. Some sensory receptor cells, called **primary receptors**, have axons that conduct action potentials in response to the receptor potential (figure 14.6a). When

PROCESS FIGURE 14.6 Comparison of Primary and Secondary Receptors

(a) A primary receptor has an axon that conducts action potentials in response to the receptor potential. (b) A secondary receptor has no axon, but the receptor potential results in the release of a neurotransmitter, which in turn stimulates a postsynaptic neuron.

the ends of these neurons are stimulated, a receptor potential is produced. If it reaches threshold, an action potential is produced and is propagated toward the CNS. Most sensory neurons, including all those in table 14.2, belong to this category. Other receptor cells, called **secondary receptors**, have no axons or have short, axonlike projections and the receptor potentials produced in those cells do not result in action potentials (figure 14.6b). Instead, the receptor potentials cause the release of neurotransmitter molecules from the receptor cell that bind to receptors on the membrane of a neuron. This causes a receptor potential in the neuron, which produces an action potential if threshold is reached. The receptor cells of the special senses of taste, hearing, and balance belong to this category.

Some sensations have the quality of **accommodation**, or **adaptation**, a decreased sensitivity to a continued stimulus. After exposure to a stimulus for a time, the response of the receptors or the sensory pathways to a certain stimulus strength lessens from that which occurs when the stimulus was first applied. The local graded depolarization that produces a receptor potential accommodates, or returns to, its resting level even though the stimulus is still applied. For example, when a person first gets dressed, tactile receptors and pathways relay information to the brain that create an awareness that the clothes are touching the skin. After a time, the action potentials from the skin decrease, and the clothes are ignored.

Another way that sensations change through time occurs in proprioception. Proprioception provides information about the precise position and the rate of movement of various body parts, the weight of an object being held in the hand, and the range of movement of a joint. This information is involved in activities such as walking, climbing stairs, shooting a basketball, driving a car,

eating, and writing. Receptors for this system are located around joints and in muscles. Two types of proprioceptors are involved in providing positional information: tonic receptors and phasic receptors. **Tonic receptors**, or **slowly adapting receptors**, generate action potentials as long as a stimulus is applied and accommodate very slowly. Information from slowly adapting receptors allows a person to know, for example, where the little finger is at all times without having to look for it. **Phasic receptors**, or **rapidly adapting receptors**, by contrast, accommodate rapidly and are most sensitive to changes in stimuli. For example, information from rapidly adapting receptors allows a person to know where the little finger is as it moves; thus, we can control its movement through space and predict where it will be in the next moment.

We are usually not conscious of tonic or phasic input because most of this peripheral input is ignored by higher brain centers most of the time. Through selective awareness, however, we can call up the information when we wish. For example, where is the thumb of your right hand at this moment? Were you aware of its position a few seconds ago?

3 *What are primary and secondary receptors? What effect does a receptor potential have on them?*

4 *Define adaptation. Describe tonic and phasic receptors.*

Sensory Tracts

The spinal cord and brainstem contain a number of sensory pathways that transmit action potentials from the periphery to various parts of the brain (table 14.3). Each pathway is involved with specific modalities (the type of information transmitted). The

TABLE 14.3 Ascending Spinal Pathways

Pathway	Modality (Information Transmitted)	Origin	Primary Cell Body	Secondary Cell Body
Anterolateral				
Spinothalamic	Pain, temperature, light touch, pressure, tickle, and itch	Cutaneous receptors	Dorsal root ganglion	Posterior horn of spinal cord
Spinoreticular	Pain	Cutaneous receptors	Dorsal root ganglion	Posterior horn of spinal cord
Spinomesencephalic (including spinotectal)	Pain and touch	Cutaneous receptors	Dorsal root ganglion	Posterior horn of spinal cord
Dorsal-column/medial-lemniscal system	Proprioception, two-point discrimination, pressure, and vibration	Joints, tendons, muscles	Dorsal root ganglion	Medulla oblongata
Spinocerebellar				
Posterior	Proprioception	Joints and tendons	Dorsal root ganglion	Posterior horn of spinal cord
Anterior	Proprioception	Joints and tendons	Dorsal root ganglion	Posterior horn of spinal cord
Spinoolivary	Proprioception relating to balance	Joints and tendons	Dorsal root ganglion	Posterior horn of spinal cord

neurons that make up each pathway are associated with specific types of sensory receptors. For example, thermoreceptors located in the skin generate action potentials that are propagated along the sensory pathway for pain and temperature, whereas Golgi tendon organs located in tendons generate action potentials that are propagated along the sensory pathway involved with proprioception.

The names of many ascending pathways, or tracts, in the CNS indicate their origin and termination (figure 14.7). Others indicate their location in the spinal cord. Each pathway usually is given a composite name in which the first half of the word indicates its origin and the second half indicates its termination. Ascending pathways therefore usually begin with the prefix *spino-*, indicating that they originate in the spinal cord. For example, a spinocerebellar (*spi'nō-ser-e-bel'ar*) tract is one that originates in the spinal cord and terminates in the cerebellum. An example of location nomenclature is the dorsal-column/medial-lemniscal system, whose name is a combination of the pathway names in the spinal cord and brainstem. The specific function of each ascending tract, however, is not suggested by its name.

The two major ascending systems of tracts involved in the conscious perception of external stimuli are the anterolateral system and the dorsal-column/medial-lemniscal system (see table 14.3). Those pathways carrying sensory input that we are not consciously aware of include the spinocerebellar, spinoolivary, spinomesencephalic, and spinoreticular tracts, the last two of which are part of the anterolateral system.

Anterolateral System

The **anterolateral system** is one of the two major systems that convey cutaneous sensory information to the brain. Historically,

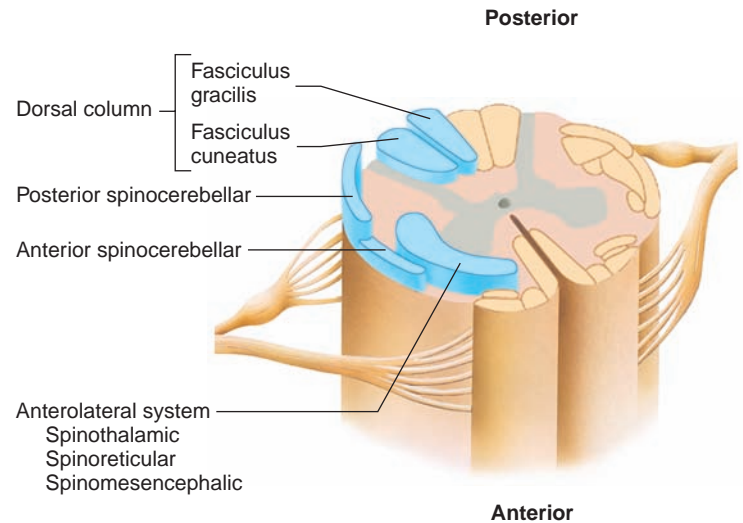

FIGURE 14.7 Cross Section of the Spinal Cord at the Cervical Level Depicting the Ascending Pathways

Ascending pathways are labeled on the left side of the figure only (blue), although they exist on both sides.

the anterolateral system was divided into anterior and lateral spinothalamic tracts. It is now known that dividing the anterolateral system into anterior and lateral spinothalamic tracts was artificial and not clinically relevant. The anterolateral system includes the spinothalamic, spinoreticular, and spinomesencephalic tracts. There is, however, considerable overlap among these three tracts

Crossover	Tertiary Cell Body	Termination	Side of Body Where Fibers Terminate
Level at which primary neuron enters spinal cord for pain and temperature or 8 to 10 segments from where primary neuron enters spinal cord for light touch	Thalamus	Cerebral cortex	Contralateral
Reticular formation	Reticular formation	Reticular formation and thalamus	Contralateral
At point of origin	Superior colliculus	Mesencephalon and superior colliculus	Contralateral
Medulla oblongata	Thalamus	Cerebral cortex and cerebellum	Contralateral
Uncrossed	Cerebellum	Cerebellum	Ipsilateral
Some uncrossed; some cross at point of entry; recross at cerebellum	Cerebellum	Cerebellum	Ipsilateral
Crossed at point of entry; recross to reach cerebellum	Accessory olivary nucleus	Accessory olivary nucleus, then cerebellum	Ipsilateral

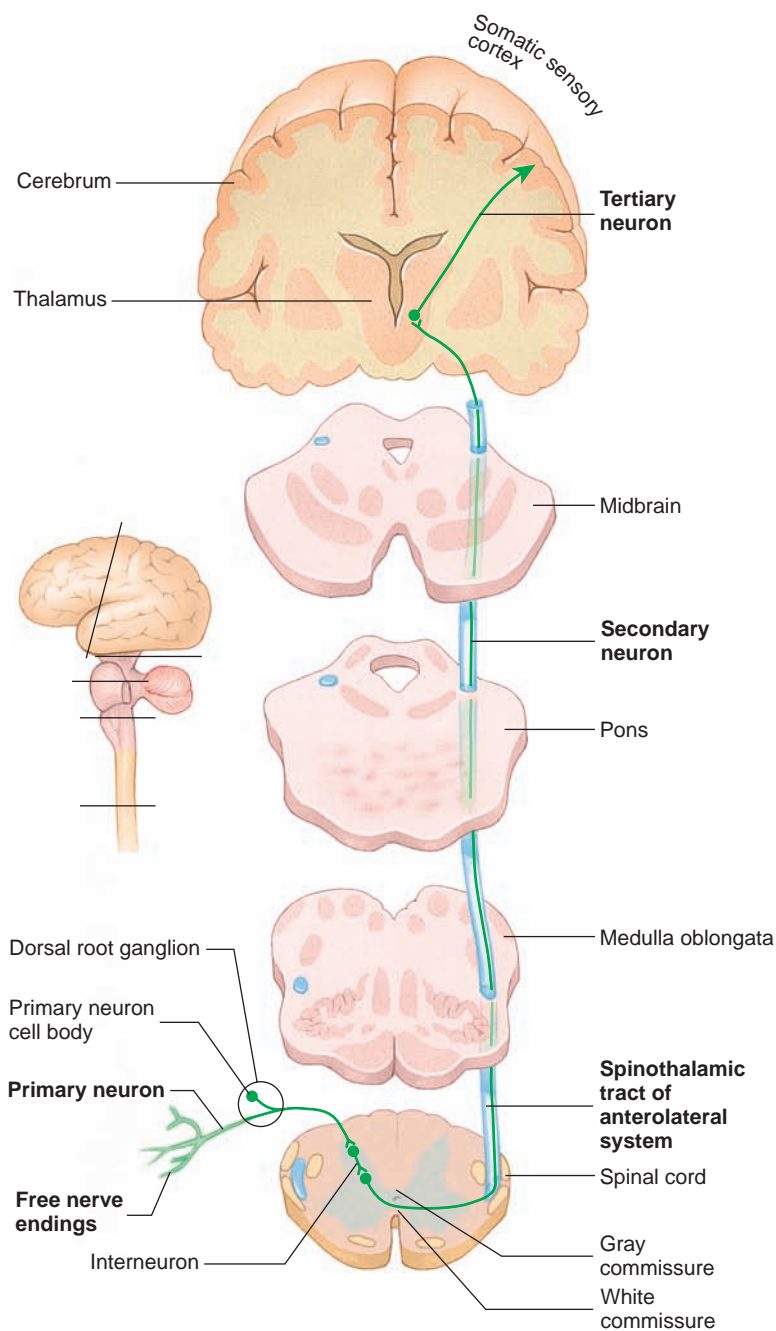

FIGURE 14.8 Spinothalamic Tract of the Anterolateral System

Some axons of the spinothalamic tract in the anterolateral system transmit action potentials for pain and temperature. Lines on the inset indicate levels of section.

within the anterolateral system. The **spinothalamic tract** carries pain and temperature information, as well as light touch and pressure, tickle and itch sensations (figure 14.8).

Three neurons in sequence—the primary, secondary, and tertiary—are involved in the spinothalamic tract from the peripheral receptor to the cerebral cortex. The **primary neuron** cell bodies of the spinothalamic tract are in the dorsal root ganglia. The primary neurons relay sensory input from the periphery

to the posterior horn of the spinal cord, where they synapse with interneurons. The interneurons, which are not specifically named in the three-neuron sequence, synapse with secondary neurons. Axons from the **secondary neurons** cross to the **contralateral**, or opposite side, of the spinal cord through the anterior portion of the gray and white commissures and enter the spinothalamic tract, where they ascend to the thalamus. The secondary neurons synapse with cell bodies of tertiary neurons in the thalamus. **Tertiary neurons** from the thalamus project to the somatic sensory cortex.

Some neurons in the spinoreticular tracts do not cross over but ascend on the **ipsilateral**, or same side, of the spinal cord on which they enter.

PREDICT 2

Describe the clinical results of a lesion on one side of the spinal cord that interrupts the spinothalamic part of the anterolateral system.

Syringomyelia

Syringomyelia (sī-rīng'gō-mī-ē'lē-ä) is a degenerative cavitation of the central canal of the spinal cord, often caused by a cord tumor. Symptoms include neuralgia (pain along the course of the nerve), paresthesia (abnormal sensations, burning, tingling, increased sensitivity to pain), specific loss of pain and temperature sensation, and paresis (partial paralysis). This defect is unusual in that it occurs in a distinct band that includes both sides of the body because commissural tracts are destroyed.

The defect causing syringomyelia occurs where the fibers giving rise to the anterolateral system cross over in the center of the spinal cord. As a result of damage to crossing fibers from both sides, there is loss of pain and temperature on both sides of the body in a segment at the level of the cord damage. The loss of function is only at that level. There is no loss of function below the level of the damage.

Dorsal-Column/Medial-Lemniscal System

The **dorsal-column/medial-lemniscal** (lem-nis'käl) system carries the sensations of two-point discrimination, proprioception, pressure, and vibration (figure 14.9). This system is named for the dorsal column of the spinal cord and the medial lemniscus, which is the continuation of the dorsal column in the brainstem. The term *lemniscus* means ribbon and refers to the thin, ribbonlike appearance of the pathway as it passes through the brainstem.

Primary neurons of the dorsal-column/medial-lemniscal system are located in the dorsal root ganglia. They are the largest cell bodies in the dorsal root ganglia, especially those for two-point discrimination. Many axons of the primary neurons of the dorsal-column/medial-lemniscal system enter the spinal cord and ascend the entire length of the spinal cord, without crossing to its opposite side, and synapse with secondary neurons located in the medulla oblongata. Others synapse in the thoracic portion of the spinal cord.

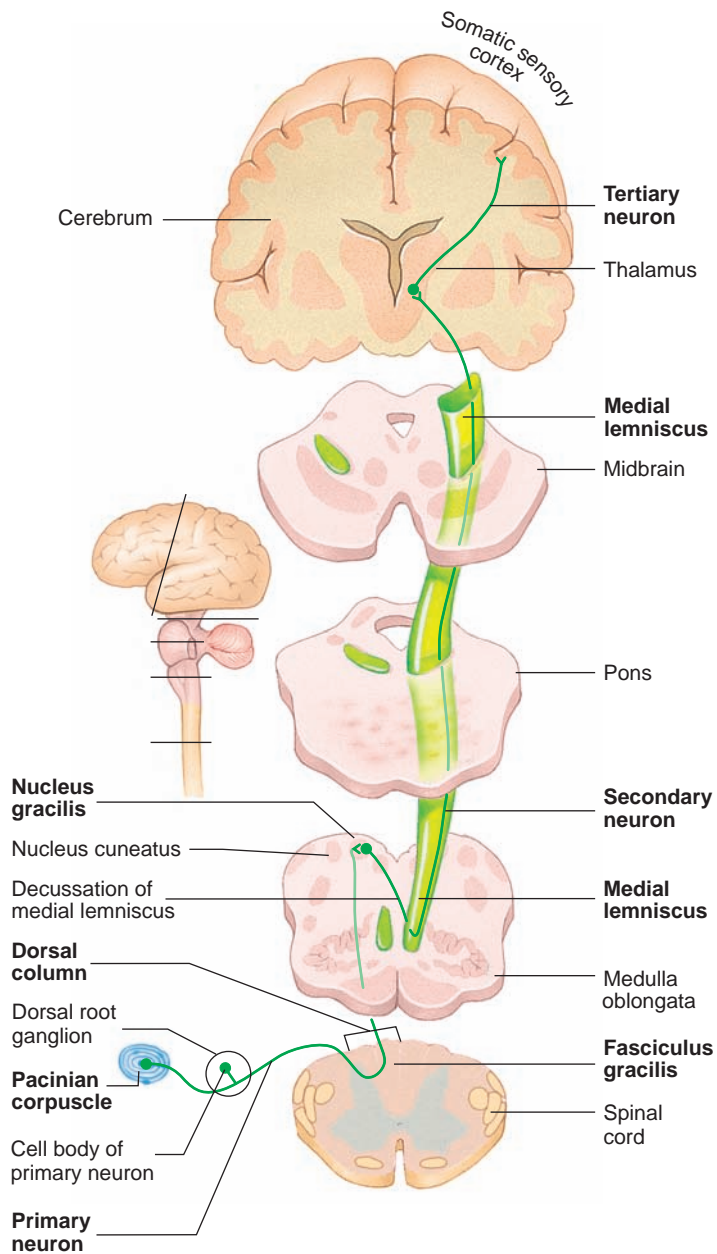

FIGURE 14.9 Dorsal-Column/Medial-Lemniscal System

The fasciculus gracilis and fasciculus cuneatus (not illustrated) convey proprioception, pressure, vibration, and two-point discrimination. Lines on the inset indicate levels of section.

In the spinal cord, the dorsal-column/medial-lemniscal system is divided into two tracts (see figure 14.7) based on the source of the stimulus. The **fasciculus gracilis** (gras'i-lis; thin) conveys sensations from nerve endings below the midthoracic level, and the **fasciculus cuneatus** (kū'nē-ā'tūs; wedge-shaped) conveys impulses from nerve endings above the midthorax. The fasciculus gracilis terminates by synapsing with secondary neurons in the **nucleus gracilis** or with neurons of the posterior spinocerebellar tracts. The fasciculus cuneatus primarily terminates by synapsing with secondary neurons in the **nucleus**

cuneatus. Both the nucleus gracilis and the nucleus cuneatus are in the medulla oblongata. Secondary neurons exit the nucleus gracilis and the nucleus cuneatus, cross to the opposite side of the medulla through the decussations of the medial lemniscus, and ascend through the medial lemniscus to terminate in the thalamus. Tertiary neurons from the thalamus project to the primary somatic sensory cortex (see page 486).

PREDICT 3

Two people, Bill and Mary, were involved in an accident and each experienced a loss of proprioception, fine touch, and vibration on the left side of the body below the waist. It was determined that Bill had damage to his spinal cord as a result of the accident and that Mary had damage to her brainstem. Explain which side of the spinal cord was damaged in Bill and which side of the brainstem was damaged in Mary.

Trigeminothalamic Tract

As the fibers of the spinothalamic tracts pass through the brainstem, they are joined by fibers of the **trigeminothalamic tract**. The trigeminothalamic tract is made up primarily of afferent fibers from the trigeminal nerve, joined by a few tactile afferent fibers from the ear and tongue carried by cranial nerves VII, IX, and sometimes X. This tract carries the same sensory information as the spinothalamic tracts and dorsal-column/medial-lemniscal system but from the face, nasal cavity, and oral cavity, including the teeth. The trigeminothalamic tract is similar to the spinothalamic tracts and dorsal-column/medial-lemniscal system in that primary neurons from one side of the face synapse with secondary neurons, which cross to the opposite side of the brainstem. The secondary neurons synapse with tertiary neurons in the thalamus. Tertiary neurons from the thalamus project to the somatic sensory cortex.

Spinocerebellar System and Other Tracts

The spinocerebellar tracts (see figure 14.7) carry proprioceptive information to the cerebellum so that information concerning actual movements can be monitored and compared with cerebral information representing intended movements.

Two spinocerebellar tracts extend through the spinal cord: (1) the **posterior spinocerebellar tract** (figure 14.10), which originates in the thoracic and upper lumbar regions and contains uncrossed nerve fibers that enter the cerebellum through the inferior cerebellar peduncles, and (2) the **anterior spinocerebellar tract**, which carries information from the lower trunk and lower limbs and contains both crossed and uncrossed nerve fibers that enter the cerebellum through the superior cerebellar peduncle. The crossed fibers recross in the cerebellum. Both spinocerebellar tracts transmit proprioceptive information to the cerebellum from the same side of the body as the cerebellar hemisphere to which they project. Why the anterior spinocerebellar tract crosses twice to accomplish this feat is unknown. Much of the proprioceptive information carried from the lower limbs by the fasciculus gracilis of the dorsal-column/medial-lemniscal

FIGURE 14.10 Posterior Spinocerebellar Tract

This tract transmits proprioceptive information from the thorax, upper limbs, and upper lumbar region to the cerebellum. Lines on the inset indicate levels of section.

system is transferred by synapses in the inferior thorax to the spinocerebellar system and enters the cerebellum as unconscious proprioceptive information. The spinocerebellar tracts convey very little information from the upper limbs to the cerebellum. Proprioception from the upper limbs is projected to the thalamus. This input enters the cerebellum through the inferior peduncle from the cuneate nucleus of the dorsal-column/medial-lemniscal system. The dorsal-column/medial-lemniscal system, therefore, is

involved not only in conscious awareness of proprioception but also unconscious neuromuscular functions.

PREDICT 4

Most of the neurons from the fasciculus gracilis synapse in the inferior thorax and enter the spinocerebellar system, whereas most of the neurons from the fasciculus cuneatus synapse in the nucleus cuneatus and then continue to the thalamus and cerebrum. It can therefore be deduced that most of the proprioception from the lower limbs is unconscious and most of the proprioception from the upper limbs is conscious. Explain why this difference in the two sets of limbs is of value.

The **spinoolivary tracts** project to the accessory olivary nucleus and to the cerebellum, where action potentials carried by these tracts contribute to the coordination of movement associated primarily with balance. The **spinothalamic tracts** end in the superior colliculi of the midbrain and transmit action potentials involved in reflexes that turn the head and eyes toward a point of cutaneous stimulation.

Descending Pathways Modifying Sensation

The corticospinal (see p. 493) and other descending tracts send collateral branches to the thalamus, reticular formation, trigeminal nuclei, and spinal cord. Neuromodulators, such as endorphins and enkephalin, released from axons originating in these CNS regions decrease the frequency of action potentials in sensory tracts (see the discussion of presynaptic inhibition in chapter 11). Through this route, the cerebral cortex or other brain regions may reduce the conscious perception of sensations.

- 5 **What are the functions of the anterolateral and dorsal-column/medial-lemniscal systems? Describe where the neurons of these systems cross over and synapse.**
- 6 **What kind of information is carried in the spinocerebellar tracts? Where do the anterior and posterior spinocerebellar tracts originate? Do these tracts terminate on the same or opposite side of the body from where they originate?**
- 7 **What are the functions of the spinoolivary and spinomesencephalic tracts?**
- 8 **How do descending pathways modulate sensation?**

Sensory Areas of the Cerebral Cortex

Figure 14.11 depicts a lateral view of the left cerebral cortex with some of its functional areas labeled. Sensory pathways project to specific regions of the cerebral cortex, called **primary sensory areas**, where these sensations are perceived.

Most of the postcentral gyrus is called the **primary somatic sensory cortex**, or **general sensory area**. The terms *area* and *cortex* are often used interchangeably for the same functional region of the cerebral cortex. Fibers carrying general sensory input, such as pain, pressure, and temperature, synapse in the thalamus, and thalamic neurons relay the information to the primary somatic sensory cortex.

FIGURE 14.11 Functional Regions of the Lateral Side of the Left Cerebral Cortex

The somatic sensory cortex is organized topographically relative to the general plan of the body (figure 14.12). Sensory impulses conducting input from the feet project to the most superior portion of the somatic sensory cortex, and sensory impulses from the face project to the most inferior portion. The pattern of the somatic sensory cortex in each hemisphere is arranged in the form of an upside-down half homunculus (hō-mūngk'ū-lūs; little human) representing the opposite side of the body, with the feet located superiorly and the head located inferiorly. The size of various regions of the somatic sensory cortex is related to the number of sensory receptors in that area of the body. The density of sensory receptors is much greater in the face than in the legs; therefore, a greater area of the somatic sensory cortex contains sensory neurons associated with the face, and the homunculus has a disproportionately large face.

There are other primary sensory areas of the cerebral cortex (see figure 14.11). The **taste area**, where taste sensations are consciously perceived in the cortex, is located at the inferior end of the postcentral gyrus. The **olfactory cortex** (not shown in figure 14.11) is on the inferior surface of the frontal lobe and is where both conscious and unconscious responses to odor are initiated (see chapter 15). The **primary auditory cortex**, where auditory stimuli are processed by the brain, is located in the superior part of the temporal lobe. The **visual cortex**, where portions of visual images are processed, is located in the occipital lobe. In the visual cortex, color, shape, and movement are processed separately rather than as a complete “color motion picture.” These sensory areas are discussed more fully in chapter 15.

The primary sensory areas of the cerebral cortex must be intact for conscious perception, localization, and identification of a stimulus. Cutaneous sensations, although integrated within the cerebrum, are perceived as though they were on the surface of the body. This is called **projection** and indicates that the brain refers a cutaneous sensation to the superficial site at which the stimulus interacts with the sensory receptors.

PREDICT 5

Using the visual association areas as an example, explain the general functions of the association areas around the other primary cortical areas (see figure 14.11).

Sensory Processing

Cortical areas immediately adjacent to the primary sensory centers, called **association areas**, are involved in the process of recognition. The **somatic sensory association area** is posterior to the primary somatic sensory cortex, and the **visual association area** is anterior to the visual cortex (see figure 14.11). Sensory action potentials originating in the retina of the eye reach the visual cortex, where the image is “perceived.” Action potentials then pass from the visual cortex to the visual association area, where the present visual information is compared with past visual experience (“Have I seen this before?”). On the basis of this comparison, the visual association area “decides” whether or not the visual input is recognized and passes judgment concerning the significance of the input. For

CLINICAL FOCUS

Pain

Pain is a sensation characterized by a group of unpleasant and complex perceptual and emotional experiences that trigger autonomic, psychologic, and somatic motor responses. Pain sensation has two components: (1) rapidly conducted action potentials carried by large-diameter, myelinated axons, resulting in sharp, well-localized, pricking, or cutting pain, followed by (2) more slowly propagated action potentials, carried by smaller, less heavily myelinated axons, resulting in diffuse burning or aching pain. Research indicates that pain receptors have very uniform sensitivity, which does not change dramatically from one instant to another. Variations in pain sensation result from the mechanisms by which pain receptors are stimulated, differences in the integration of action potentials from the pain receptors, and complex interactions in the cerebral cortex, cingulate gyrus, and thalamus, where the emotional component of pain is registered. Neurons in the cerebral cortex respond to pain stimuli selectively based on prior experience and context. Stress, for example, can reduce pain perception.

Although the dorsal-column/medial-lemniscal system contains no pain fibers, tactile and mechanoreceptors are often activated by the same stimuli that affect pain receptors. Action potentials from tactile receptors provide information that allows the pain sensation to be localized. Superficial pain is highly localized, in part, because of the simultaneous stimulation of pain receptors and mechanoreceptors in the skin. Deep or visceral pain is not highly localized (diffuse) because of fewer mechanoreceptors in the deeper structures, and it is normally perceived as a diffuse pain.

Dorsal-column/medial-lemniscal system neurons are involved in what is called the **gate-control theory** of pain control. Primary neurons of the dorsal-column/medial-lemniscal system send out collateral branches that synapse with interneurons in the posterior horn of the spinal cord. These interneurons have an inhibitory effect on secondary neurons of the spinothalamic tract. Thus, pain action potentials traveling through the spinothalamic tract can be suppressed by action potentials that origi-

nate in neurons of the dorsal-column/medial-lemniscal system. The arrangement may act as a “gate” for pain action potentials transmitted in the spinothalamic tract. Increased activity in the dorsal-column/medial-lemniscal system tends to close the gate, thereby reducing pain action potentials transmitted in the spinothalamic tract. Descending pathways from the cerebral cortex or other brain regions can also regulate this “gate.”

The gate-control theory may explain the physiologic basis for the following methods that have been used to reduce the intensity of chronic pain: electric stimulation of the dorsal-column/medial-lemniscal neurons, transcutaneous electric stimulation (applying a weak electric stimulus to the skin), acupuncture, massage, and exercise. The frequency of action potentials that are transmitted in the dorsal-column/medial-lemniscal system is increased when the skin is rubbed vigorously and when the limbs are moved and may explain why vigorously rubbing a large area around a source of pricking pain tends to reduce the intensity of the painful sensation. Exercise normally decreases the sensation of pain, and exercise programs are important components in the management of chronic pain not associated with illness. Action potentials initiated by acupuncture procedures may act through a gating mechanism in which inhibition of action potentials in neurons that transmit pain action potentials upward in the spinal cord is influenced by activity in sensory cells that send collateral branches to the posterior horn.

Analgesics act in much the same way as gate control. Some analgesics block the transmission of nociception in the spinal cord from primary neurons to neurons of the ascending pathways. Other analgesics function at the level of the cerebral cortex to modulate pain.

REFERRED PAIN

Referred pain is a painful sensation in a region of the body that is not the source of the pain stimulus. Most commonly, referred pain is sensed in the skin or other superficial structures when internal organs are damaged or inflamed.

This sensation usually occurs because both the area of skin to which the pain is referred and the visceral area that is damaged are innervated by neurons that project to the same area of the cerebral cortex. The brain cannot distinguish between the two sources of painful stimuli, and the painful sensation is referred to the most superficial structures innervated by the converging neurons. This referral may occur because the number of receptors is much greater in superficial structures than in deep structures and the brain is more “accustomed” to dealing with superficial stimuli.

Referred pain is clinically useful in diagnosing the actual cause of a painful stimulus. Heart attack victims often feel cutaneous pain radiating from the left shoulder down the arm. Other examples of referred pain are shown in figure A.

PHANTOM PAIN

Phantom pain occurs in people who have had appendages amputated or a structure such as a tooth removed. Many of these people perceive pain, which can be intense, or other sensations, in the amputated structure as if it were still in place. If a neuron pathway that transmits action potentials is stimulated at any point along that pathway, action potentials are initiated and propagated toward the CNS. Integration results in the perception of pain that is projected to the site of the sensory receptors, even if those sensory receptors are no longer present. A similar phenomenon can be easily demonstrated by bumping the ulnar nerve as it crosses the elbow (the funny bone). A sensation of pain is often felt in the fourth and fifth digits, even though the neurons were stimulated at the elbow.

A factor that may be important in phantom pain is the lack of touch, pressure, and proprioceptive impulses from the amputated limb. Those action potentials suppress the transmission of pain action potentials in the pain pathways, as explained by the gate-control theory of pain. When a limb is amputated, the inhibitory effect of sensory information is removed. As a consequence, the intensity of phantom pain may be increased. Another factor in phantom

FIGURE A Areas of Referred Pain on the Body Surface

Pain from the indicated internal organs is referred to the surface areas shown.

pain may be that the cerebral cortex retains an image of the amputated body part.

CHRONIC PAIN

Chronic pain is long-lasting. Some chronic pain has a known cause, such as tissue damage, as in the case of arthritis. Other chronic pain cannot be associated with tissue damage and has no known cause.

Pain is important in warning us of potentially injurious conditions because pain receptors are stimulated when tissues are injured. Pain itself, however, can become a problem. Chronic pain, such as migraine headaches, localized facial pain, or back pain, can be very debilitating, and pain loses its value of providing information about the condition of

the body. People suffering from chronic pain often feel helpless and hopeless, and they may become dependent on drugs. The pain can interfere with vocational pursuits, and many victims are unemployed or even housebound and socially isolated. They are easily frustrated or angered, and they suffer symptoms of major depression. These qualities are associated with what is called **chronic pain syndrome**. Over 2 million people in the United States at any given time suffer chronic pain sufficient to impair activity.

Chronic pain may originate with acute pain associated with an injury or may develop for no apparent reason. How sensory signals are processed in the thalamus and cerebrum may determine if the input is evaluated as only a discomfort, a minor pain, or a severe pain and

how much distress is associated with the sensation. The brain actively regulates the amount of pain information that gets through to the level of perception, thereby suppressing much of the input. If this dampening system becomes less functional, pain perception may increase. Other nervous system factors, such as a loss of some sensory modalities from an area, or habituation of pain transmission, which may remain even after the stimulus is removed, may actually intensify otherwise normal pain sensations. Treatment often requires a multidisciplinary approach, including such interventions as surgery or psychotherapy. Some sufferers respond well to drug therapy, but some drugs, such as opiates, have a diminishing effect and may become addictive.

SENSITIZATION IN CHRONIC PAIN

Tissue damage within an area of injury, such as the skin, can cause an increase in the sensitivity of nerve endings in the area of damage, a condition called **peripheral sensitization**. One class of pain receptors is not activated by traditional noxious stimuli but is recruited only when tissues become inflamed. These receptors, once activated, add to the total barrage of sensory signals to the brain and intensify the sensation of pain.

The CNS may also respond to tissue damage by decreasing its threshold and increasing its sensitivity to pain. This condition is called **central sensitization**. Central sensitization apparently results from a specific subset of receptors that is only recruited during repetitive neuron firing, such as when intense pain sensations are experienced. These receptors maintain a hyperexcitable state in the CNS cells. This chronic, hyperexcitable state can result in persistent, chronic pain states.

This information concerning peripheral and central sensitization and the knowledge that sensitization involves neuronal and chemical receptors not normally involved in sensation may lead to the discovery of new drugs for treating chronic pain. Rather than searching for new analgesics, which may decrease a broad range of sensations, an opportunity is now available to develop a new class of drugs, the “antihyperanalgesics,” which may block sensitization without diminishing other sensations, including normal pain.

FIGURE 14.12 Topography of the Somatic Sensory Cortex

Cerebral cortex seen in coronal section on the left side of the brain. The figure of the body (homunculus) depicts the nerve distributions; the size of each body region shown indicates relative innervation. The cortex occurs on both sides of the brain but appears on only one side in this illustration. The inset shows the somatic sensory region of the left hemisphere (green).

example, we generally pay less attention to people in a crowd we have never seen before than to someone we know.

The visual association area, like other association areas of the cortex, has reciprocal connections with other parts of the cortex that influence decisions. For example, the visual association area has input from the frontal lobe, where emotional value is placed on the visual input. Because of these numerous connections, visual information is judged several times as it passes beyond the visual association area. This may be one of the reasons that, when two people view the same painting, their individual perceptions of it can be vastly different.

PREDICT 6

A man has constipation, which causes distention and painful cramping in his colon. What kind of pain does he experience (local or diffuse) and where is it perceived? Explain.

- 9 Describe in the cerebral cortex the locations and functions of the primary sensory areas and their association areas.
- 10 Describe the topographic organization of the general body plan in the primary somatic sensory cortex. Why are some areas of the body represented as larger than other areas?
- 11 What are the related functions of the primary motor area, the premotor area, and the prefrontal area of the cerebral cortex?

CONTROL OF SKELETAL MUSCLES

The motor system of the brain and spinal cord is responsible for maintaining the body's posture and balance; for moving the trunk, head, limbs, and eyes; and for communicating through facial expressions and speech. Reflexes mediated through the spinal cord (see chapter 12) and brainstem (see chapter 13) are responsible for some body movements. They occur without conscious thought. **Voluntary movements**, on the other hand, are movements consciously activated to achieve a specific goal, such as walking or typing. Although consciously activated, the details of most voluntary movements occur automatically. After walking begins, it is not necessary to think about the moment-to-moment control of every muscle because neural circuits automatically control the limbs. After learning how to do complex tasks, such as typing, people can perform them relatively automatically.

Voluntary movements depend on upper and lower motor neurons. **Upper motor neurons** directly or through interneurons connect to lower motor neurons. The cell bodies of upper motor neurons are in the cerebral cortex. **Lower motor neurons** have axons that leave the central nervous system and extend through peripheral nerves to supply skeletal muscles. The cell bodies of lower motor neurons are located in the anterior horns of the spinal cord gray matter and in cranial nerve nuclei of the brainstem.

Voluntary movements depend on the following:

1. The initiation of most voluntary movement begins in the premotor areas of the cerebral cortex and involves stimulation of upper motor neurons (see "Motor Areas of the Cerebral Cortex," p. 491).
2. The axons of the upper motor neurons form the descending tracts. They stimulate lower motor neurons, which stimulate skeletal muscles to contract (see "Motor Tracts," p. 491).
3. The cerebral cortex interacts with the basal nuclei and cerebellum in the planning, coordination, and execution of movements (see "Modifying and Refining Motor Activities," p. 496).

- 12 Distinguish between upper and lower motor neurons.

FIGURE 14.13 Topography of the Primary Motor Cortex

Cerebral cortex seen in coronal section on the left side of the brain. The figure of the body (homunculus) depicts the nerve distributions; the size of each body region shown indicates relative innervation. The cortex occurs on both sides of the brain but appears on only one side in this illustration. The inset shows the motor region of the left hemisphere (pink).

Motor Areas of the Cerebral Cortex

The **precentral gyrus** is also called the **primary motor cortex** or **primary motor area** (see figure 14.11). Action potentials initiated in this region control many voluntary movements, especially the fine motor movements of the hands. Upper motor neurons are not confined to the precentral gyrus—only about 30% of them are located there. Another 30% are in the premotor area, and the rest are in the somatic sensory cortex.

The cortical functions of the precentral gyrus are arranged topographically according to the general plan of the body—similar to the topographic arrangement of the postcentral gyrus (figure 14.13). The

neuron cell bodies controlling motor functions of the feet are in the most superior and medial portions of the precentral gyrus, whereas those for the face are in the inferior region. Muscle groups with many motor units are represented by relatively large areas of the precentral gyrus. For example, muscles performing precise movements, such as those controlling the hands and face, have many motor units, each of which has a small number of muscle fibers. Multiple-motor unit summation (see chapter 9) can precisely control the force of contraction of these muscles because only a few muscle fibers at a time are recruited. Muscle groups with few motor units are represented by relatively small areas of the precentral gyrus, even if the muscles innervated are quite large. Muscles such as those controlling movements of the thigh and leg have proportionately fewer motor units than hand muscles but have many more and much larger muscle fibers per motor unit. They are less precisely controlled because the activation of a motor unit stimulates the contraction of many large muscle fibers.

The **premotor area**, located anterior to the primary motor cortex (see figure 14.11), is the staging area in which motor functions are organized before they are initiated in the motor cortex. For example, if a person decides to take a step, the neurons of the premotor area are stimulated first. The determination is made in the premotor area as to which muscles must contract, in what order, and to what degree. Action potentials are then passed to the upper motor neurons in the motor cortex, which actually initiate the planned movements.

Apraxia

The premotor area must be intact for a person to carry out complex, skilled, or learned movements, especially ones related to manual dexterity—for example, a surgeon's use of a scalpel or a student's use of a pencil. Impairment in the performance of learned movements, called **apraxia** (ă-prak'sē-ă), can result from a lesion in the premotor area. Apraxia is characterized by hesitancy and reduced dexterity in performing these movements.

The motivation and foresight to plan and initiate movements occur in the next most anterior portion of the brain, the **prefrontal area**, an association area that is well developed only in primates and especially in humans. It is involved in the motivation and regulation of emotional behavior and mood. The large size of this area of the brain in humans may account for their relatively well-developed forethought and motivation and for the emotional complexity of humans.

13 *Where are the primary motor, premotor, and prefrontal areas of the cerebral cortex located?*

14 *Why are some areas of the body represented as larger than other areas on the topographic map of the body on the primary motor areas?*

Motor Tracts

Motor tracts are descending pathways containing axons that carry action potentials from regions of the cerebrum or cerebellum to the brainstem or spinal cord. The names of descending tracts

are based on their origin and termination (figure 14.14 and table 14.4). Much like the names of ascending tracts, the prefix indicates its origin and the suffix indicates its destination. For example, the corticospinal tract is a motor tract that originates in the cerebral cortex and terminates in the spinal cord.

Amyotrophic Lateral Sclerosis
Amyotrophic (ă-mī-ō-trō'fik) **lateral sclerosis (ALS)**, also called Lou Gehrig's disease, usually affects people between the ages of 40 and 70. About 10% of the cases of ALS are inherited. It begins with weakness and clumsiness and progresses within 2–5 years to loss of muscle control. The disease selectively destroys both upper and lower motor neurons. The inherited form of ALS apparently results from a mutation in DNA coding for the enzyme **superoxide dismutase (SOD)** and is located on chromosome 21. SOD is involved in eliminating a free radical, known as superoxide, from the body. Free radicals are molecules that readily accept electrons, which makes them highly reactive. They can strip electrons from proteins, lipids, or nucleic acids, thereby destroying their functions and resulting in cell dysfunction or death. Free-radical damage has been implicated in ALS, arteriosclerosis, arthritis, cancer, and aging. Superoxide is one of the most important and toxic free radicals. It forms as the result of oxygen reacting with other free radicals. Although oxygen is critical for aerobic metabolism, it is also dangerous to tissues. SOD catalyzes the conversion of superoxide to hydrogen peroxide, which is then converted by catalase to oxygen and water. Apparently, if SOD is defective, superoxide is not degraded and can destroy cells. Motor neurons appear to be particularly sensitive to superoxide attack.

The descending motor fibers are divided into two groups: direct pathways and indirect pathways (figure 14.15). The **direct**

FIGURE 14.14 Cross Section of the Spinal Cord at the Cervical Level Depicting the Descending Pathways

Descending pathways are labeled on the left side of the figure only (*pink*), though they exist on both sides.

pathways, also called the **pyramidal** (pi-ram'i-dal) **system**, are involved in the maintenance of muscle tone and in controlling the speed and precision of skilled movements, primarily fine movements involved in dexterity. Most of the **indirect pathways**, sometimes called the **extrapyramidal system**, are involved in less precise control of motor functions, especially those associated with overall body coordination and cerebellar function, such as posture. Many of the indirect pathways are phylogenetically older

TABLE 14.4 Descending Spinal Pathways

Pathway	Functions Controlled	Examples of Movements Controlled	Origin
Direct	Conscious skilled movements		
Corticospinal tract	Movements below the head, especially of the hands		
Lateral	Movements of the neck, trunk, and limbs	Push-ups, moving with a hula hoop	Cerebral cortex
Anterior	Movements of the neck and upper limb extremities	Typing	Cerebral cortex
Corticobulbar tract	Movements of the head and face	Facial expression, chewing	Cerebral cortex
Indirect	Unconscious movements		
Rubrospinal	Movement coordination	Positioning of digits and palm of the hand when reaching out to grasp	Red nucleus
Vestibulospinal	Maintenance of upright posture, balance	Extension of upper limbs when falling	Vestibular nucleus
Reticulospinal	Posture adjustment, walking	Maintenance of posture when standing on one foot	Reticular formation
Tectospinal	Movements of head and neck in response to visual and auditory reflexes	Movement of head and neck away from a sudden flash of light	Superior colliculus

and control more “primitive” movements of the trunk and proximal portions of the limbs. The direct pathways, which exist only in mammals, may be thought of as overlying the indirect pathways and are more involved in finely controlled movements of the face and distal portions of the limbs. Some indirect pathways, such as those from the basal nuclei and cerebellum, help in fine control of the direct pathways.

Direct Pathways

Direct pathways are so-named because upper motor neurons in the cerebral cortex, whose axons form these pathways, synapse directly with lower motor neurons in the brainstem or spinal cord. They are also called the pyramidal system because the fibers of these pathways form the medullary **pyramids**. The direct pathways include groups of nerve fibers arrayed into two tracts: the **corticospinal tract**, which is involved in direct cortical control of movements below the head, and the **corticobulbar tract**, which is involved in direct cortical control of movements in the head and neck.

The corticospinal tract consists of axons of upper motor neurons located in the primary motor and premotor areas of the frontal lobes and the somatic sensory parts of the parietal lobes. They descend through the **internal capsules** and the cerebral peduncles of the midbrain to the pyramids of the medulla oblongata. At the inferior end of the medulla 75%–85% of the corticospinal fibers cross to the opposite side of the CNS through the **pyramidal decussation**, which is visible on the anterior surface of the inferior medulla. The crossed fibers descend in the **lateral corticospinal tracts** of the spinal cord (figure 14.16). The remaining 15%–25% descend uncrossed in the **anterior corticospinal tracts** and decussate near the level where they synapse with lower motor neurons. The anterior corticospinal tracts supply the neck and

upper limbs, and the lateral corticospinal tracts supply all levels of the body (see table 14.4).

Most of the corticospinal fibers synapse with interneurons in the lateral portions of the spinal cord central gray matter. The interneurons, in turn, synapse with the lower motor neurons of the anterior horn that innervate primarily distal limb muscles.

Damage to the corticospinal tracts results in reduced muscle tone, clumsiness, and weakness but not in complete paralysis, even if the damage is bilateral. Experiments with monkeys have demonstrated that bilateral sectioning of the medullary pyramids results in (1) loss of contact-related activities, such as tactile placing of the foot and grasping, (2) defective fine movements, and (3) hypotonia (reduced tone). These and other experimental data support the conclusion that the corticospinal system is superimposed over the older, indirect pathways and that it has many parallel functions. The main function of the direct pathways is to add speed and agility to conscious movements, especially of the hands, and to provide a high degree of fine motor control, such as in movements of individual fingers. Spinal cord lesions that affect both the direct and indirect pathways result in complete paralysis.

The corticobulbar tracts are analogous to the corticospinal tracts. The former innervate the head, and the latter innervate the rest of the body. Cells that contribute to the corticobulbar tracts are in regions of the cortex similar to those of the corticospinal tracts, except that they are more laterally and inferiorly located. Corticobulbar tracts follow the same basic route as the corticospinal system down to the level of the brainstem. At that point, most corticobulbar fibers terminate in the reticular formation near the **cranial nerve nuclei**. Interneurons from the reticular formation then enter the cranial nerve nuclei, where they synapse with lower motor neurons. These nuclei give rise to the nerves that control

Crossover	Termination	Side of Body Where Fibers Terminate
Inferior end of medulla oblongata	Anterior horn of spinal cord	Contralateral
Level of lower motor neuron	Anterior horn of spinal cord	Contralateral
Varies for the different cranial nerves	Cranial nerve nuclei in brainstem (lower motor neuron)	Contralateral
Midbrain	Anterior horn of spinal cord	Contralateral
Uncrossed	Anterior horn of spinal cord	Ipsilateral
Some uncrossed; some cross at termination	Anterior horn of spinal cord	Ipsilateral or contralateral
Midbrain	Cranial nerve nucleus in medulla oblongata and anterior horn of upper levels of spinal cord (lower motor neurons that turn head and neck)	Contralateral

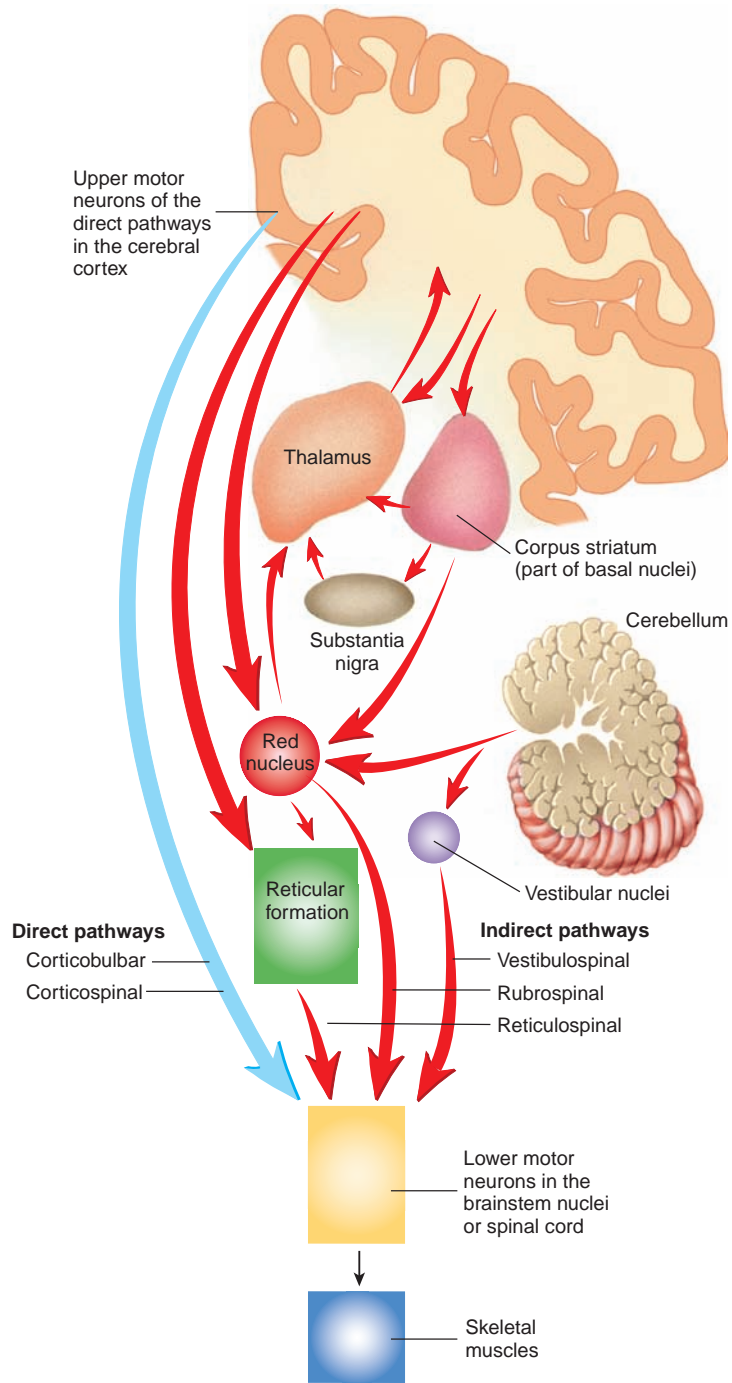

FIGURE 14.15 Descending Pathways

The direct pathways (corticobulbar and corticospinal) are indicated by the blue arrow. The indirect pathways and their interconnections are indicated by the red arrows.

eye and tongue movements, mastication, facial expression, and palatine, pharyngeal, and laryngeal movements.

Brown-Séquard Syndrome

A lesion of the spinal cord that destroys half the cord at a specific level (hemisection) results in a very specific syndrome, called the **Brown-Séquard syndrome**. The syndrome includes contralateral loss of pain and temperature because fibers entering the anterolateral system cross over where they enter the spinal cord, as well as ipsilateral loss of proprioception, two-point discrimination, and most upper motor control because the dorsal-column/medial-lemniscal system ascends ipsilaterally and the lateral corticospinal tract descends ipsilaterally.

- 15** What two tracts form the direct pathways? What area of the body is supplied by each tract? Describe the location of the neurons in each tract, where they cross over, and where they synapse.

Indirect Pathways

The indirect pathways (figure 14.17) originate in neurons of the cerebrum and cerebellum whose axons synapse in some intermediate nucleus rather than directly with lower motor neurons. Axons from the neurons in those nuclei form the indirect pathways. They do not pass through the pyramids or through the corticobulbar tracts and, therefore, are sometimes called extrapyramidal. The major tracts are the rubrospinal, vestibulospinal, and reticulospinal tracts. Many interconnections and feedback loops are present in this system.

Neurons of the **rubrospinal tract** begin in the red nucleus, which is located at the boundary between the diencephalon and midbrain. The tract decussates in the midbrain and descends in the lateral column of the spinal cord. The red nucleus receives input from both the motor cortex and the cerebellum. Lesions in the red nucleus result in intention, or action, tremors similar to those seen in cerebellar lesions (see the Clinical Focus “Dyskinesias,” p. 496). The function of the red nucleus, therefore, is related closely to cerebellar function. The rubrospinal tract is the one indirect tract that is very closely related to the direct, corticospinal tract. It terminates in the lateral portion of the spinal cord central gray matter with the corticospinal tract, and it transmits action potentials involved in the comparator function of the cerebellum (see p. 497). It plays a major role in regulating fine motor control of muscles in the distal part of the upper limbs. Damage to the rubrospinal tract impairs forearm and hand movements but does not greatly affect general body movements.

The **vestibulospinal tracts** (see figure 14.14) originate in the vestibular nuclei, descend in the anterior column, and synapse with interneurons and lower motor neurons in the ventromedial portion of the spinal cord central gray matter. Their fibers preferentially influence neurons innervating extensor muscles in the trunk and proximal portion of the lower limbs and are involved primarily in the maintenance of upright posture. The vestibular nuclei receive major input from the vestibular nerve (see chapter 15) and the cerebellum.

FIGURE 14.17 Indirect Pathways

Examples of indirect pathways are rubrospinal and reticulospinal tracts. Lines on the inset indicate levels of section.

Neuron cell bodies of the **reticulospinal tract** (see figure 14.14) are in the reticular formation of the pons and medulla oblongata. Their axons descend in the anterior portion of the lateral column and synapse with interneurons and lower motor neurons in the ventromedial portion of the spinal cord central gray matter. This

CLINICAL FOCUS

Dyskinesias

Dyskinesias (dis-ki-nē'zē-ās) are a group of disorders often involving the basal nuclei in which unwanted, superfluous movements occur. Defects in the basal nuclei may result in brisk, jerky, purposeless movements that resemble fragments of voluntary movements. **Sydenham chorea** (kōr-ē'ā; also called St. Vitus dance) is a disease usually associated with a toxic or an infectious disorder that apparently causes temporary dysfunction of the corpus striatum. It usually affects children. **Huntington chorea** is a dominant hereditary disorder that begins in middle life, causing mental deterioration and progressive degeneration of the corpus striatum in affected individuals.

Cerebral palsy (pawl'zē) is a general term referring to defects in motor functions or coordination resulting from several types of brain damage, which may be caused by abnormal brain development or birth-related injury. Some symptoms of cerebral palsy, such as increased muscle tension, are related to basal nuclei dysfunction. **Athetosis** (ath-ē-tō'sis), often one of the features of cerebral palsy, is characterized by slow, sinuous, aimless movements. When the face, neck, and tongue muscles are involved, grimacing, protrusion, and writhing of the tongue and difficulty in speaking and swallowing are characteristics.

Damage to the subthalamic nucleus can result in **hemiballismus** (hem-ē-bal-iz'mūs),

an uncontrolled, purposeless, and forceful throwing or flailing of the arm. Forceful twitching of the face and neck may also result from subthalamic nuclear damage.

Parkinson disease—characterized by muscular rigidity; loss of facial expression; tremor; a slow, shuffling gait; and general lack of movement—is caused by a dysfunction in the substantia nigra. The disease usually occurs after age 55 and is not contagious or inherited. A resting tremor, called “pill-rolling,” is characteristic of Parkinson disease; it consists of circular movement of the opposed thumb and index fingertips. The increased muscular rigidity in Parkinson disease results from defective inhibition of some of the basal nuclei by the substantia nigra. In this disease, dopamine, an inhibitory neurotransmitter produced by the substantia nigra is deficient. The melanin-containing cells of the substantia nigra degenerate, resulting in a loss of pigment.

Parkinson disease can be treated with levodopa (lē-vō-dō'pā, L-dopa), a precursor to dopamine, or more effectively with Sinemet, a combination of L-dopa and carbidopa (kar-bi-dō'pā). Carbidopa is a decarboxylase inhibitor, which prevents the breakdown of L-dopa before it can reach the brain. Because of the long-term side effects, including dyskinesias, associated with levodopa, other dopamine agonists, such as ropinirole and pramipexole,

are being examined. A protein called **glial cell line-derived neurotrophic factor (GDNF)** has been discovered that selectively promotes the survival of dopamine-secreting neurons. Chronic stimulation of the globus pallidus (part of the lentiform nucleus) with an electrical pulse generator has shown some success. Treatment of the disorder by transplanting fetal tissues, or stem cells from adult tissues, capable of producing dopamine is also under investigation.

Cerebellar lesions result in a spectrum of characteristic functional disorders. Movements tend to be **ataxic** (jerky) and **dysmetric** (overshooting—for example, pointing past or deviating from a mark that one tries to touch with the finger). Alternating movements, such as supination and pronation of the hand, are performed in a clumsy manner. **Nystagmus** (nis-tag'mūs), which is a constant motion of the eyes, may also occur. A cerebellar tremor is an intention tremor (i.e., the more carefully one tries to control a given movement, the greater the tremor becomes). For example, when a person with a cerebellar tremor attempts to drink a glass of water, the closer the glass comes to the mouth the shakier the movement becomes. This type of tremor is in direct contrast to basal nuclei tremors, in which the resting tremor largely or completely disappears during purposeful movement.

tract maintains posture through the action of trunk and proximal upper and lower limb muscles during certain movements. For example, when a person who is standing lifts one foot off the ground, the weight of the body is shifted to the other limb. The reticulospinal tract apparently enhances the functions of the alpha motor neurons in the crossed extensor reflex during this type of movement so that balance is maintained.

Another major portion of the indirect pathways involves the basal nuclei (see figure 14.15). The basal nuclei have a number of connections with each other, as well as with the thalamus and cerebrum. The basal nuclei also interact with other indirect pathways, such as the rubrospinal tract, by which they modulate motor functions.

16 *Name the structures and the tracts that form the indirect pathways. What functions do they control? Contrast them with the functions of the direct pathways.*

Modifying and Refining Motor Activities

Basal Nuclei

The **basal nuclei** (see figure 13.10) are important in planning, organizing, and coordinating motor movements and posture. Complex neural circuits link the basal nuclei with each other, with the thalamus, and with the cerebral cortex. These connections form several feedback loops, some of which are stimulatory and others inhibitory. The stimulatory circuits facilitate muscle activity, especially at the beginning of a voluntary movement, such as rising from a sitting position or beginning to walk. The inhibitory circuits facilitate the actions of the stimulatory circuits by inhibiting muscle activity in antagonist muscles. Inhibitory circuits also decrease muscle tone when the body, limbs, and head are at rest (eliminating “unwanted” movement). Disorders of the basal nuclei result in difficulty in rising from a sitting position and difficulty

in initiating walking. People with basal nuclei disorders exhibit increased muscle tone and exaggerated, uncontrolled movements when they are at rest. A specific feature of some basal nuclei disorders is a “resting tremor,” a slight shaking of the hands when a person is not performing a task. Parkinson disease and cerebral palsy are basal nuclei disorders.

Cerebellum

The **cerebellum** (see figure 13.6) consists of three functional parts: the vestibulocerebellum, or flocculonodular lobe; the spinocerebellum; and the cerebrocerebellum. The vestibulocerebellum receives direct input from the vestibular structures, especially the semicircular canals (see chapter 15), and sends axons to the vestibular nuclei of the brainstem. It helps maintain muscle tone in postural muscles. It also helps control balance, especially during movements, and it helps coordinate eye movement.

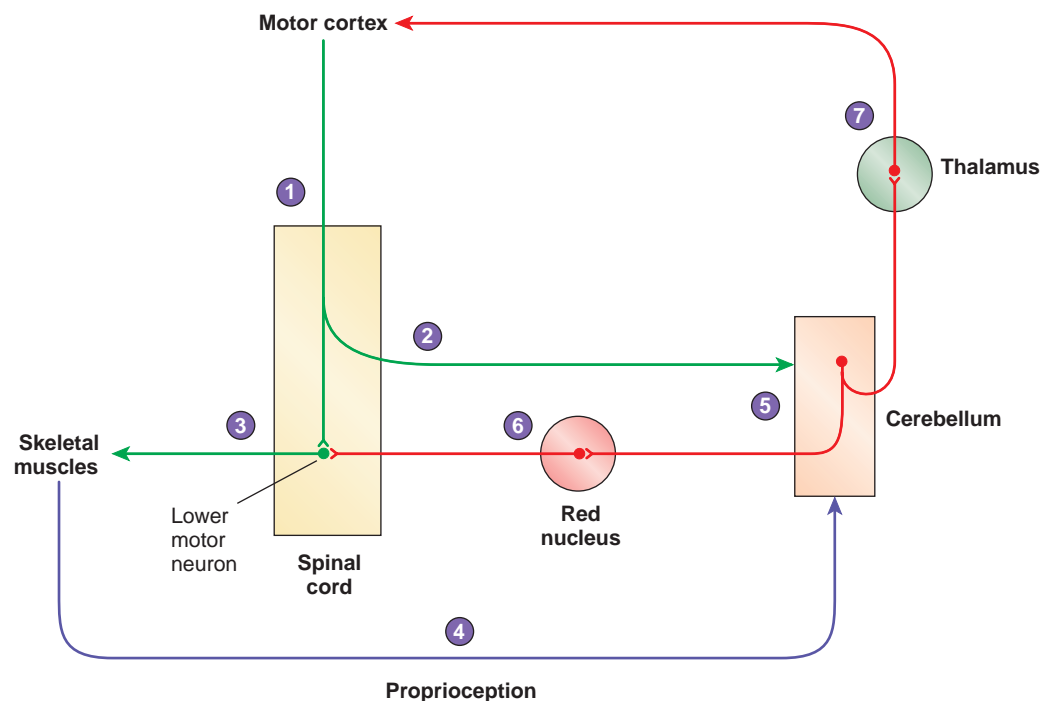

The **vermis** and medial portion of the **lateral hemisphere**, referred to jointly as the **spinocerebellum**, helps accomplish fine motor coordination of simple movements by means of its **comparator** function. Action potentials from the motor cortex descend into the spinal cord to initiate voluntary movements. At the same time, action potentials are carried from the motor cortex to the cerebellum to give the cerebellar neurons information representing the intended movement (figure 14.18). Simultaneously, action potentials from proprioceptive neurons ascend through the spinocerebellar tracts to the cerebellum. Proprioceptive neurons innervate the joints and tendons of the structure being moved, such as the elbow or knee, and provide information about the position of the body or body parts. These action potentials give the cerebellar neurons information from the periphery about

the actual movements. The cerebellum compares the action potentials from the motor cortex with those from the moving structures. That is, it compares the intended movement with the actual movement. If a difference is detected, the cerebellum sends action potentials through the thalamus to the motor cortex and to the spinal cord to correct the discrepancy. The result is smooth and coordinated movements.

The comparator function coordinates simple movements, such as touching your nose. Rapid, complex movements, however, require much greater coordination and training. The **cerebrocerebellum** consists of the lateral two-thirds of the lateral hemispheres. It communicates with the motor, premotor, and prefrontal portions of the cerebral cortex to help in planning and practicing rapid, complex motor actions. The connections from the cerebellum to the cerebral peduncles constitute a large portion of the axons in the cerebral peduncles. Because of the cerebrocerebellum, with training, a person can learn highly skilled and rapid movements that are accomplished more rapidly than can be accounted for by the comparator function of the cerebellum. In these cases, the cerebellum participates with the cerebrum in learning highly specialized movements, such as playing the piano or swinging a baseball bat. The cerebrocerebellum is also involved in cognitive functions, such as rhythm, conceptualization of time intervals, some word associations, and solutions to pegboard puzzles—tasks once thought to occur only in the cerebrum.

- 17 **What are the functions of the basal nuclei?**
- 18 **Explain the comparator activities of the spinocerebellum.**
- 19 **Describe the role of the cerebrocerebellum in rapid and skilled motor movements, such as playing the piano.**

1. The motor cortex sends action potentials to lower motor neurons in the spinal cord.
2. Action potentials from the motor cortex inform the cerebellum of the intended movement.
3. Lower motor neurons in the spinal cord send action potentials to skeletal muscles, causing them to contract.
4. Proprioceptive signals from the skeletal muscles and joints to the cerebellum convey information concerning the status of the muscles and the structure being moved during contraction.
5. The cerebellum compares the information from the motor cortex to the proprioceptive information from the skeletal muscles and joints.
6. Action potentials from the cerebellum to the spinal cord modify the stimulation from the motor cortex to the lower motor neurons.
7. Action potentials from the cerebellum are sent to the motor cortex, which modify its motor activity.

PROCESS FIGURE 14.18 Cerebellar Comparator Function

Cerebellar Dysfunction

Cerebellar dysfunction results in (1) decreased muscle tone, (2) balance impairment, (3) a tendency to overshoot when reaching for or touching an object, and (4) an intention tremor, which is a shaking in the hands that occurs only while attempting to perform a task. Although the cerebellum and basal nuclei both control motor functions, they have opposite effects, and they exhibit opposite symptoms when injured. For example, cerebellar dysfunction results in decreased muscle tone and an intention tremor, whereas basal nuclear dysfunction often results in increased muscle tone and a resting tremor.

BRAINSTEM FUNCTIONS

The major ascending and descending pathways project through the brainstem. In addition, the brainstem contains nuclei of cranial nerves III–X and XII (see table 13.4 and figure 13.2), and nuclei of the reticular formation. Only collateral branches of cranial nerve II (optic nerve) project to brainstem nuclei. Cranial nerves I (olfactory nerve) and XI (spinal accessory nerve) do not have projections to or nuclei in the brainstem.

Sensory Input Projecting Through the Brainstem

The brainstem receives sensory input from collateral branches of ascending spinal cord pathways and from the axons of cranial nerves II (vision), V (tactile sensation from the face, nasal cavity, and oral cavity), VII (taste), VIII (hearing and balance), IX (taste and tactile sensation in the throat), and X (taste, tactile sensation in the larynx, and visceral sensation in the thorax and abdomen). Cranial nerves V, VII, VIII, IX, and X have sensory nuclei in the brainstem. Many of these nuclei are involved in the special senses (see chapter 15). The brainstem nuclei associated with cranial nerve II are involved in visual reflexes.

As noted earlier, fibers of the spinothalamic tracts passing through the brainstem are joined by fibers of the trigeminothalamic tract (see p. 485). This tract carries tactile sensations, such as pain and temperature, two-point discrimination, and light touch from the face, nasal cavity and oral cavity, including the teeth.

RAS Functions of the Brainstem

Collateral branches of trigeminothalamic tract neurons project to the reticular formation, where they stimulate wakefulness and consciousness. This part of the reticular formation and its connections constitute the **reticular activation system (RAS)**, which is involved in the sleep–wake cycle.

Collateral branches of cranial nerves II (optic), V (trigeminal), and VIII (vestibulocochlear); ascending tactile sensory pathways; and descending neurons from the cerebrum also project to the RAS. Visual and acoustic stimuli, as well as mental activities, stimulate the RAS to help maintain alertness and attention. Ringing alarm clocks, sudden flashes of bright lights, and cold water being splashed on the face can all arouse consciousness (figure 14.19). The removal of auditory, visual, and other stimuli may lead to drowsiness or sleep. For example, consider what happens to students

during a monotonous lecture in a dark lecture hall. Damage to RAS cells of the reticular formation can result in coma.

PREDICT 7

Luke tried to go to sleep, but a dripping bathroom faucet kept him awake. Explain.

Drugs and the Reticular Activating System

Certain drugs can either stimulate or depress the RAS. General anesthetics suppress this system, and many tranquilizers depress it. On the other hand, ammonia (smelling salts) and other irritants stimulate trigeminal nerve endings in the nose. As a result, action potentials are sent to the reticular formation and the cerebral cortex to arouse an unconscious patient.

Motor Output and Reflexes Projecting Through the Brainstem

Descending pathways in the brainstem pass to the spinal cord, pass into the cerebellum, or synapse with cranial nerve motor nuclei and other nuclei in the brainstem. Some of the descending pathways originate in the cerebral cortex and pass directly through the brainstem (direct spinal pathways). Many direct descending pathways synapse in cranial nerve motor nuclei to initiate movements within the head, such as eye movements. Others synapse with brainstem nuclei, which in turn send descending fibers into the spinal cord (indirect pathways). Descending fibers from the reticular formation constitute one of the body's most important motor pathways. Fibers from the reticular formation are critical in controlling many functions, such as respiratory movements and cardiac rhythms. Cranial nerves III, IV, V, VI, VII, IX, X, and XII all have motor nuclei in the brainstem. Functionally, the motor output projecting through the brainstem can be classified into two categories, somatic motor and parasympathetic.

Somatic Motor Output and Reflexes

Cranial nerves III (oculomotor), IV (trochlear), and VI (abducent) control the eye muscles. The eyes can be controlled by the cerebrum to move and look toward an object. Action potentials reaching the superior colliculi from the cerebrum are involved in the visual tracking of moving objects. Visual tracking with both eyes to the right involves the lateral rectus muscle and abducent nerve of the right eye and the medial rectus muscle and oculomotor nerve of the left eye. Coordination of these two nerves and muscles requires nuclei of the reticular formation. The eye muscles along with the muscles of the neck (mainly the trapezius and sternocleidomastoid, innervated by cranial nerve IX) can also be involved in reflexes that are initiated in the superior colliculi in response to visual and auditory stimuli. Collateral branches from the optic tract (II) synapse in the superior colliculi of the midbrain (see figure 13.7). Axons from the superior colliculi project to cranial nerve nuclei III, IV, and VI and to the upper cervical part of the spinal cord (motor neurons of XI), where they stimulate the motor neurons involved in turning the eyes and

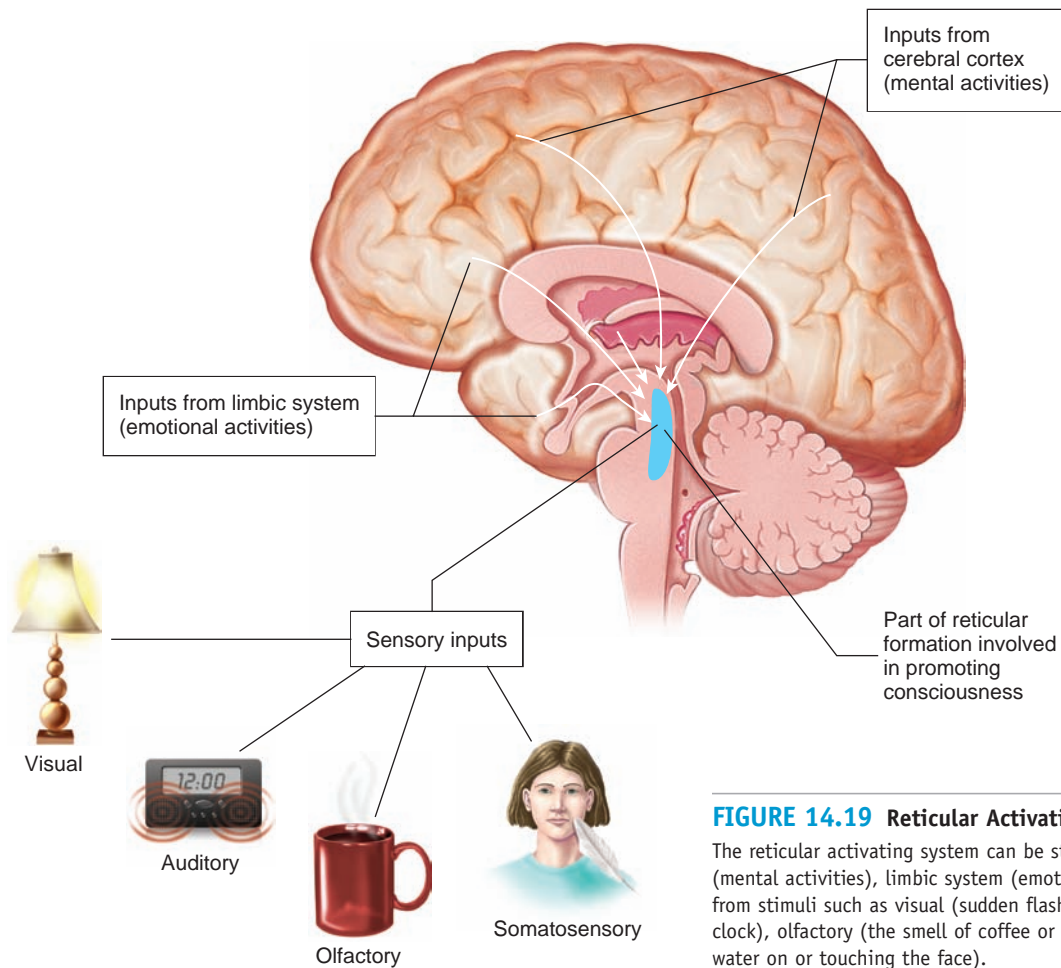

FIGURE 14.19 Reticular Activating System

The reticular activating system can be stimulated by inputs from the cerebral cortex (mental activities), limbic system (emotional activities), and a variety of sensory inputs from stimuli such as visual (sudden flashes of light), auditory (the ringing of an alarm clock), olfactory (the smell of coffee or burning), and somatosensory (splashing cold water on or touching the face).

head toward a visual stimulus. Similarly, the superior colliculi also receive input from auditory pathways, which can initiate a reflex that turns the eyes and head toward a sudden noise. Axons in the spinomesencephalic pathway of the spinal cord (see table 14.3) also project to the superior colliculi. Input from this pathway initiates a reflex that turns the eyes and head toward a tactile stimulus on the body.

Motor fibers from cranial nerve V (trigeminal) innervate the muscles of mastication and control chewing; however, once the chewing cycle is initiated, the reticular formation regulates the cycle. Even though the initiation of chewing can be under conscious control, the presence of food in the mouth initiates a reflex between the sensory nuclei and the motor nucleus of cranial nerve V, thereby starting the chewing cycle. Other reflexes in the trigeminal nerve system detect how hard or soft an item is in the mouth and adjusts the bite accordingly. Reflexes between the trigeminal sensory nuclei and the motor nucleus of cranial nerve XII (hypoglossal) control the tongue to help place the food between the teeth for chewing, while keeping the tongue out of harm's way.

Cranial nerve VII (facial), which innervates the muscles of facial expression, is controlled by the cerebrum and is very important in communication.

Somatic motor fibers from cranial nerves IX (glossopharyngeal) and X (vagus) supply muscles of the pharynx and larynx associated with swallowing and speech. Swallowing, once initiated under conscious control, continues as a reflex. The pharyngeal muscles of swallowing are largely innervated by the vagus nerve and, to a smaller extent, by the glossopharyngeal nerve.

Unlike swallowing, which is largely a reflex, speech is highly controlled by the cerebrum. The vagus nerve innervates the muscles of the larynx responsible for voice production and controls the pharyngeal and most palatine muscles responsible for the movement of the soft palate during speech. The complex movements of the tongue during speech are controlled by the hypoglossal nerve (XII), which innervates nearly all the muscles of the tongue.

Parasympathetic Output and Reflexes

The constriction of the pupil involves parasympathetic stimulation through the oculomotor (III) nerve. The visual reflexes resulting in pupil constriction are coordinated through nuclei in the reticular formation. These reflexes are also coordinated by a nuclear region in the diencephalon called the pretectal area (in front of the tectum, the roof of the midbrain).

The Brain's Canary

Function of the pretectal area is critical for normal pupillary constriction in response to light. This area of the brain can be thought of as the “brain’s canary.” For many years, miners carried caged canaries with them into deep mine shafts to detect poisonous gas. An unconscious or dead canary warned the miners of methane gas before enough had accumulated to kill them. Like a canary, the pretectal area is more sensitive to brain damage, or symptoms of the damage are more easily observed in functions coordinated by the pretectal area, than many other parts of the brain. Fixed, dilated pupils in a patient are a sign that the pretectal area is not functioning normally and that the patient may have experienced damage to the brain.

Tactile sensory input from the nasal cavity via the trigeminal (V) nerve can initiate a sneeze reflex. Tactile sensory input from the oral cavity via the trigeminal (V) nerve informs the cerebrum of the presence of food or another object in the mouth. The presence of an object in the mouth—even a nonfood item, such as a marble—stimulates a reflex between the trigeminal sensory nuclei and the motor nuclei of VII (facial) and IX (glossopharyngeal), which innervate the salivary glands to stimulate salivation.

Sensory input from the glossopharyngeal nerve (IX) conveys tactile information from the back of the tongue, the soft palate, and the throat (pharynx) to the brainstem. Mechanical stimulation of these areas can initiate a gag reflex, whereas other stimulation of the throat can initiate a cough reflex. Sensory input from the vagus nerve (X) conveys tactile information from the larynx (voice box) and thoracic and abdominal viscera. Tactile input from the larynx can also initiate a cough reflex. In addition, the vagus nerve (X) is involved in many complex reflexes associated with vital functions such as heart rate, respiration, and digestion. Many of these involve the reticular formation and are discussed in later chapters.

Vital Functions Controlled in the Brainstem

Because many vital functions, such as heart rate, blood pressure, and respiration are regulated by nuclei in the brainstem, many medical emergency evaluations are of brainstem function. When a person is involved in a serious accident or is extremely ill, these vital functions may be affected. Such signs of brainstem damage can be assessed by medical personnel.

- 23** *What are some of the vital functions that are regulated in the brainstem?*

PREDICT 8

Some types of epilepsy are treated by placing an electronic device inside the neck to stimulate the vagus nerve. Minor injury to the vagus nerve during implantation of the device can lead to hoarseness. Why is this so? Can you predict two other consequences of minor injury to the vagus nerve?

OTHER BRAIN FUNCTIONS

The human brain is capable of many functions besides awareness of sensory input and the control of skeletal muscles. Speech, mathematical and artistic abilities, sleep, memory, emotions, and judgment are functions of the brain.

Speech

In most people, the speech area is in the left cerebral cortex. Two major cortical areas are involved in speech: **Wernicke’s area** (sensory speech area), a portion of the parietal lobe, and **Broca’s area** (motor speech area) in the inferior part of the frontal lobe (see figure 14.11). Wernicke’s area is necessary for understanding and formulating coherent speech. Broca’s area initiates the complex series of movements necessary for speech. The two areas are connected by a bundle of neurons known as the **arcuate fasciculus** (figure 14.20a).

For someone to speak a word that he or she sees, such as when reading out loud, the following sequence of events must take place. Action potentials from the eyes reach the primary visual cortex, where the word is seen. The word is then recognized in the visual association area and understood in parts of Wernicke’s area. Then action potentials representing the word are conducted through association fibers that connect Wernicke’s and Broca’s areas. In Broca’s area, the word is formulated as it will be spoken. Action potentials are then propagated to the premotor area, where the movements are programmed, and finally to the primary motor cortex, where the proper movements are triggered (figure 14.20b).

To repeat a word that has been heard is similar. The information passes from the ears to the primary auditory cortex and then passes to the auditory association area, where the word is recognized, and continues to Wernicke’s area, where the word is understood and formulated as it will be spoken. From Wernicke’s area, it follows the same route as followed for speaking words that are seen.

Aphasia

Aphasia (ă-fā’zē-ă), absent or defective speech or language comprehension, results from a lesion in the language areas of the cortex. The several types of aphasia depend on the site of the lesion. **Receptive aphasia** (Wernicke’s aphasia), which includes defective auditory and visual comprehension of language, defective naming of objects, and repetition of spoken sentences, is caused by a lesion in Wernicke’s area. Both **jargon aphasia**, in which a person may speak fluently but unintelligibly, and **conduction aphasia**, in which a person has poor repetition but relatively good comprehension, can result from a lesion in the tracts between Wernicke’s and Broca’s areas. **Anomic** (ă-nō’mik) **aphasia**, caused by the isolation of Wernicke’s area from the parietal or temporal association areas, is characterized by fluent but circular speech resulting from poor word-finding ability. **Expressive aphasia** (Broca’s aphasia), caused by a lesion in Broca’s area, is characterized by hesitant and distorted speech.

- 24** *List the sequence of events that must occur for a person to repeat a word that he or she hears.*

FIGURE 14.20 Demonstration of Cortical Activities During Speech

(a) The arcuate fasciculus connects the two key areas involved in speech. (b) The figures show the pathway for reading and naming something that is seen, such as reading aloud. PET scans show the areas of the brain that are most active during various phases of speech. *Red* indicates the most active areas; *blue* indicates the least active areas.

PREDICT 9

Propose the sequence needed for a blindfolded person to name an object placed in the right hand.

Right and Left Cerebral Cortex

The cortex of the right cerebral hemisphere controls muscular activity in and receives sensory input from the left half of the body. The left cerebral hemisphere controls muscles in and receives sensory input from the right half of the body. Sensory information received by the cortex of one hemisphere is shared with the other through connections between the two hemispheres called **commissures** (kom'i-shürz; a joining together). The largest of these commissures is the **corpus callosum** (kōr'pūs kā-lō'sūm; callous body), which is a broad band of tracts at the base of the longitudinal fissure (see figure 13.1).

Language and perhaps other functions, such as artistic activities, are not shared equally between the left and right cerebral hemispheres. The left hemisphere is more involved in such skills as mathematics and speech. The right hemisphere is involved in activities such as spatial perception, the recognition of faces, and musical ability.

25 Name the largest pathway that connects the right and left cerebral hemispheres.

26 What are the functions localized in the left cerebral hemisphere? In the right cerebral hemisphere?

Hemisphere Dominance and Amorphosynthesis

Dominance of one cerebral hemisphere over the other, for most functions, is probably not very important in most people because the two hemispheres are in constant communication through the corpus callosum, literally allowing the right hand to know what the left hand is doing. Surgical cutting of the corpus callosum has been successful in treating a limited number of epilepsy cases. Under certain conditions, however, interesting functional defects develop in people who have had their corpus callosum severed. For example, if a patient with a severed corpus callosum is asked to reach behind a screen to touch one of several items with one hand without being able to see it and then is asked to point out the same object with the other hand, the person cannot do it. Tactile information from the left hand enters the right somatic sensory cortex, but that information is not transferred to the left hemisphere, which controls the right hand. As a result, the left hemisphere cannot direct the right hand to the correct object.

A person suffering a stroke in the right parietal lobe may lose the ability to recognize faces while retaining essentially all other brain functions. A more severe lesion can cause a person to lose the ability to identify simple objects. This defect is called **amorphosynthesis** (ă-mōr'fō-sin'thē-sis). Some people with a similar lesion in the right cerebral hemisphere may tend to ignore the left half of the world, including the left half of their own bodies. These people may completely ignore a person who is to their left but react normally when the person moves to their right. They may also fail to dress the left half of their bodies or to eat the food on the left half of their plates.

FIGURE 14.21 Electroencephalograms (EEGs) Showing Brain Waves

(a) EEG tracings when a person is awake and during four stages of sleep. (b) A typical night's sleep pattern in a young adult. The time spent in REM sleep is labeled and shown by dark bars.

Brain Waves and Sleep

Electrodes placed on a person's scalp and attached to a recording device can record the electrical activity of the brain, producing an **electroencephalogram** (ē-lek'trō-en-sef'ā-lō-gram; **EEG**; figure 14.21). These electrodes are not sensitive enough to detect individual action potentials, but they can detect the simultaneous action potentials in large numbers of neurons. As a result, the EEG displays wavelike patterns known as **brain waves**. Brain waves are produced continuously, but their intensity and frequency differ from time to time based on the state of brain activity.

Most of the time, EEG patterns from a given individual are irregular, with no particular pattern, because, although the normal brain is active, most of its electrical activity is not synchronous. At other times, however, specific patterns can be detected. These regular patterns are classified as alpha, beta, theta, or delta waves (see figure 14.21). **Alpha waves** are observed in a normal person who is awake but in a quiet, resting state with the eyes closed. **Beta waves** have a higher frequency than alpha waves and occur during intense mental activity. **Theta waves** usually occur in children, but they can also occur in adults who are experiencing frustration or who have certain brain disorders. **Delta waves** occur in deep sleep, in infancy, and in patients with severe brain disorders.

Brain wave patterns vary during the four stages of sleep (see figure 14.21). A sleeping person arouses several times during a period of sleep. Dreaming occurs during periods when eye movement can be observed in a sleeping person, called **rapid eye movement (REM) sleep**.

Distinct types of EEG patterns can be detected in patients with specific brain disorders, such as epileptic seizures. Neurologists use these patterns to diagnose the disorders and determine the appropriate treatment.

27 What is an EEG? What four conditions produce alpha, beta, theta, and delta waves, respectively?

Memory

Memory is divided into three major types: sensory, short-term (or primary), and long-term (figure 14.22). **Sensory memory** is the very short-term retention of sensory input received by the brain while something is scanned, evaluated, and acted on. This type of memory lasts less than a second and apparently involves transient changes in membrane potentials.

If a given piece of data held in sensory memory is considered valuable enough, it is moved into **short-term memory**, where it is retained for a few seconds to a few minutes. This memory is limited primarily by the number of bits of information (usually about seven or eight) that can be stored at any one time, although the amount varies from person to person. More bits can be stored when the numbers are grouped into specific segments separated by spaces. When new information is presented, or when the person is

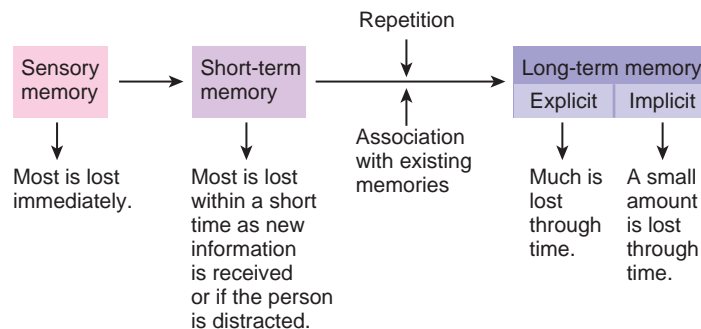

FIGURE 14.22 Memory Processing

CASE STUDY

Multiple Sclerosis

Betty, a 32-year-old woman, woke up one morning with weakness in her lower limbs. By that afternoon, she had become completely exhausted with a familiar ache in her left eye and tingling sensations in her extremities. At the end of the day, she could barely stand up, and her left eye was blurry and increasingly painful. Betty's family physician made an appointment for her with a neurologist. The neurologist suspected **multiple sclerosis**, an autoimmune disease resulting in the demyelination of CNS neurons, which become sclerotic, or hard. He ordered an MRI scan and a **visual evoked potential (VEP) test**, which is a recording of action potentials in

the optic nerve “evoked” in response to visual stimuli. During the VEP test, electrodes were placed on Betty's scalp, and she was asked to respond to visual stimuli with the normal eye covered by an eye-patch. The normal eye was also subjected to the same treatment.

The MRI scan showed lesions in the optic nerve and white matter of the brain, and the VEP test showed optic nerve dysfunction. These results confirmed the diagnosis of multiple sclerosis accompanied by **optic neuritis**, or inflammation of the optic nerve. Betty's neurologist explained that, in multiple sclerosis, sensory neurons that conduct sensory information to the brain and motor neurons that conduct

motor stimulation from the brain to the muscles are damaged. Betty asked if she would be cured, to which the neurologist replied that she would experience periods of remission, which may be interrupted by symptomatic periods. He also warned that, with each successive episode, neurons may become progressively more damaged.

PREDICT 10

- What effect would demyelination have on action potential propagation along axons? How might this explain blurred vision?
- How would you explain the weakness and tingling that Betty experienced?

distracted, information previously stored in short-term memory is eliminated; therefore, if a person is given a second telephone number or if the person's attention is drawn to something else, the first number usually is forgotten.

Long-term memory lasts for hours or longer. Some long-term memory may last a lifetime. Two types of long-term memory exist: declarative, or explicit, and procedural, or implicit. **Declarative** or **explicit, memory** involves the retention of facts, such as names, dates, and places. Explicit memory is accessed by part of the temporal lobe called the **hippocampus** (hip-ō-kam'pūs; shaped like a seahorse) and the **amygdala**, or **amygdaloid** (ā-mīg'dā-loyd; almond-shaped) **nuclear complex**. The hippocampus is involved in retrieving the actual memory, such as recalling a person's name, and the amygdala is involved in the emotional overtones of that memory, such as feelings of like or dislike, and the recollection of good or bad memories associated with that person. A lesion in the temporal lobe affecting the hippocampus can prevent the brain from moving information from short-term to long-term memory.

Fear

Some aspects of fearful responses appear to be “hardwired” in the brain and do not require learning. For example, infant rodents are terrified when exposed to a cat, even though they have never seen a cat. Loud sounds seem to be particularly effective in eliciting fear responses. A direct collateral branch runs from the auditory pathway to the amygdala, which does not involve the cerebral cortex. Fear can be evoked by a loud sound acting directly on the amygdala. Overcoming fear, however, requires the involvement of the cerebral cortex; therefore, the stimulation of fear appears to involve one process, its suppression another. Flaws in either process could result in fear-related disorders, such as anxiety, depression, panic, phobias, and posttraumatic stress disorder.

Emotion and mood apparently serve as gates in the brain and determine what is or is not stored in long-term explicit memory. The amygdala is also a key to the development of fear, which also involves the prefrontal cortex and the hypothalamus.

Parts of explicit memory appear to be stored separately in various parts of the cerebrum, especially in the parietal lobe, much like storing items in separate “pigeonholes.” Memories of people appear to be stored separately from memories of places. People's faces may be stored in yet other pigeonholes. Family members appear to be stored together. Items that are recognized by sight, such as an animal, are stored separately from items that are recognized by feel, such as tools. Damage, such as a stroke, to one part of the brain can remove certain memories without affecting others.

Retrieval of a complete memory requires accessing parts of the memory from different pigeonholes. A complex memory requires accessing and reassembling segments of memory each time the memory is recalled. The memory of an experience, for example, may be stored in at least four different pigeonholes. Where you were is stored in one place, who you were with in another, what happened in another, and how you felt in yet another place. The complexity of this process may be responsible for the changes in what is recalled over time. On occasion, parts of unrelated memories may be pulled out and put together incorrectly to create a “false memory.” Much of what is stored as explicit memory is gradually lost through time.

Procedural, or **implicit, memory**, also called **reflexive memory**, involves the development of skills like riding a bicycle or playing a piano. Implicit memory is stored primarily in the cerebellum and the premotor area of the cerebrum. Conditioned, or Pavlovian, reflexes are also implicit and can be eliminated in experimental animals by producing cerebellar lesions in the animals. The most famous example of a conditioned reflex is that of Ivan Pavlov's experiments with dogs. Each time he fed the dogs, a bell was rung; soon the dogs

CLINICAL FOCUS

General CNS Disorders

INFECTIONS

Reye syndrome may develop in children following a viral infection, especially influenza or chicken pox. The use of aspirin to treat viral infections has been linked to development of the syndrome in the United States. A predisposing disorder in fat metabolism may also be present in some cases. In children affected by the syndrome, the brain cells swell, and the liver and kidneys accumulate fat. Symptoms include vomiting, lethargy, and loss of consciousness and may progress to coma and death or to permanent brain damage.

Rabies is a viral disease transmitted by the bite of an infected mammal. The rabies virus infects the brain, salivary glands (through which it is transmitted), muscles, and connective tissue. When the patient attempts to swallow, the effort can produce pharyngeal muscle spasms; sometimes even the thought of swallowing water or the sight of water can induce pharyngeal spasms. Thus, the term *hydrophobia*, fear of water, is applied to the disease. The virus also infects the brain and results in abnormal excitability, aggression, and in later stages paralysis and death.

Tabes dorsalis (tā'bez dōr-sā'lis) is a progressive disorder occurring as a result of untreated syphilis. *Tabes* means a wasting away, and *dorsalis* refers to a degeneration of the dorsal roots and dorsal columns of the spinal cord. Symptoms include ataxia, resulting from lack of proprioceptive input; anesthesia, resulting from dorsal root damage; and eventually paralysis as the infection spreads.

OTHER DISORDERS

Tumors of the brain develop from neuroglial cells. Symptoms vary widely, depending on the

location of the tumor, but include headaches, neuralgia (pain along the distribution of a peripheral nerve), paralysis, seizures, coma, and death. **Meningiomas** (mē-nin'jē-ō' māz), tumors of the meninges, account for 25% of all primary intracranial tumors.

Alzheimer disease is a severe type of mental deterioration, or dementia, usually affecting older people but occasionally affecting people younger than 60. Alzheimer disease is estimated to affect 10% of all people older than 65 and nearly half of those older than 85. Alzheimer disease involves a general decrease in brain size, resulting from a loss of neurons in the cerebral cortex. The gyri become narrower, and sulci widen. The frontal lobes and specific regions of the temporal lobes are affected most severely. Alzheimer symptoms include general intellectual deficiency, memory loss, short attention span, moodiness, disorientation, and irritability.

Alzheimer disease is characterized by the appearance of **amyloid** (am'i-loyd) **plaques** and **neurofibrillary tangles**. Amyloid plaques are localized axonal enlargements of degenerating nerve fibers, containing large amounts of β -amyloid protein, and neurofibrillary tangles are filaments inside the cell bodies of dead or dying neurons.

The gene for β -amyloid protein has been mapped to chromosome 21; however, it is thought that only the rare, inherited, early-onset (beginning before age 60) form of Alzheimer maps to chromosomes 21. The more common, late-onset form (beginning after age 65), which makes up more than three-fourths of all cases, maps to chromosome 19.

Another protein, **apolipoprotein E** (ap'ō-lip-ō-prō'tēn; **apoE**), which binds to β -amyloid

protein and is known to transport cholesterol in the blood, has also been associated with Alzheimer disease. *apoE-III* is the normal protein and *apoE-IV* is an abnormal, mutant form. *apoE-IV* has been found in amyloid plaques and neurofibrillary tangles and has been mapped to the same region of chromosome 19 as the late-onset form of Alzheimer. People with two copies of the *apoE-IV* gene are eight times more likely to develop the disease than people with two copies of the *apoE-III* gene. *apoE-IV* apparently binds to β -amyloid more rapidly and more tightly than does *apoE-III*. *ApoE* also may be involved with regulating phosphorylation of another protein, called τ (tau), which in turn is involved in microtubule formation inside neurons. If τ is overphosphorylated, microtubules are not properly constructed, and the τ proteins intertwine to form neurofibrillary tangles.

Chronic mercury poisoning can cause brain disorders, such as intention tremor, exaggerated reflexes, and emotional instability. Mercury causes oxidative damage and apoptosis in several organs, including the kidneys and CNS.

Lead poisoning is a serious problem, particularly among urban children. Lead is taken into the body from contaminated air, food, and water. Flaking lead paint in older houses and soil contamination can be major sources of lead poisoning in children. Lead usually accumulates slowly in the body until toxic levels are reached.

Brain damage caused by lead poisoning in children includes edema, demyelination, and cortical neuron necrosis with astrocyte proliferation. This damage appears to be permanent and can result in reduced intelligence, learning disabilities, poor psychomotor development, and blindness. In severe cases, psychoses, seizures, coma,

salivated when the bell rang, even if no food was presented. Only a small amount of implicit memory is lost through time.

Several physiologic explanations have been proposed for short-term memory, most of which involve short-term changes in membrane potentials. The changes in membrane potentials are transitory but are longer than those involved in sensory memory, and they can be eliminated by new information reaching the cells.

Certain pieces of information are transferred from short-term to long-term memory. Long-term memory involves changes in neurons, called **long-term potentiation**, which facilitates the future transmission of action potentials (figure 14.23). The

amount of the neurotransmitter glutamate produced and released by the presynaptic neuron increases. The number of glutamate receptors in the postsynaptic neuron also increases, and the reaction of the postsynaptic neuron to glutamate is potentiated. Long-term memory storage in a single neuron also involves Ca^{2+} influx into the postsynaptic cell. Calcium ions associate with and activate **calmodulin** (kal-mod'ū-lin) inside the cell. Calmodulin, through a cAMP mechanism, stimulates the synthesis of specific proteins, which are involved in changing the shape of the cell. The change in shape is stabilized by the creation of a new cytoskeleton, and the memory becomes more or less permanent.

or death may occur. Adults exhibit more mild PNS symptoms, including demyelination with decreased neuromuscular function. Other symptoms include abdominal pain and renal disease.

Epilepsy is a group of brain disorders that have seizure episodes in common. The seizure, a sudden massive neuronal discharge, can be either partial or complete, depending on the amount of brain involved and whether or not consciousness is impaired. A seizure involves a change in sensation, consciousness, or behavior due to brief electrical discharge in the brain.

Normally, a balance exists between excitation and inhibition in the brain. When this balance is disrupted by increased excitation or decreased inhibition, a seizure may result. The neuronal discharges may stimulate muscles innervated by the neurons involved, resulting in involuntary muscle contractions, or convulsions.

Epilepsy occurs in 1% of all people age 20 and 3% of those over age 75. A number of factors can increase the incidence of epilepsy: 2.4% of children whose fathers have epilepsy develop epilepsy and 8.7% of children whose mothers have epilepsy develop the disorder. Ten percent of children with cerebral palsy develop epilepsy, and 10% of those with mental retardation develop epilepsy. Half of children with both cerebral palsy and mental retardation develop epilepsy. Twenty-two percent of stroke patients develop epilepsy. Seventy percent of those with epilepsy will eventually experience remission.

Depression may cause more “grief and misery” than any other single disease. Although the illness has been known for over 2000 years, its medical status is still uncertain. Is depression a disease state caused by a chemical excess or deficiency, or is it a psychologic condition that a person can decide to snap out of? The answer is probably that both types of depression exist. Depression is a complex, multifaceted group of disorders. Some types of “endogenous” depres-

sion can be treated with antidepressants, of which there are five groups: tricyclic antidepressants, nontricyclic compounds, MAO inhibitors, serotonin agonists, and lithium. Many people with depression also have epilepsy. Recent research in which “pacemaker-like” stimulation of the vagus nerve to treat epilepsy has shown some promise in treating depression that does not respond to drugs.

Headaches have a variety of causes, which can be grouped into two basic classes: extracranial and intracranial. Extracranial headaches can be caused by inflammation of the sinuses, dental irritations, temporomandibular joint disorders, ophthalmologic disorders, and tension in the muscles moving the head and neck. Intracranial headaches may result from inflammation of the brain or meninges, vascular problems, mechanical damage, or tumors.

Tension headaches are extracranial muscle tension, stress headaches, consisting of a dull, steady pain in the forehead, temples, and neck or throughout the head. Tension headaches are associated with stress, fatigue, and posture.

Migraine headaches (*migraine* means half a skull) occur in only one side of the head and appear to involve the abnormal dilation and constriction of blood vessels. They often start with distorted vision, shooting spots, and blind spots. Migraines consist of severe throbbing, pulsating pain. About 80% of migraine sufferers have a family history of the disorder, and women are affected four times more often than men. Those suffering migraines are usually women younger than 35. The severity and frequency usually decrease with age.

A **concussion** is a blow to the head, producing momentary loss of consciousness without immediate detectable damage to the brain. Often, no more problems occur after the person regains consciousness; however, in some cases, **postconcussion syndrome** occurs shortly after the injury. The syndrome includes increased

muscle tension or migraine headaches, reduced alcohol tolerance, difficulty in learning new things, reduction in creativity and motivation, fatigue, and personality changes. The symptoms may be gone in a month or may persist for as much as a year. In some cases, postconcussion syndrome is the result of a slowly occurring subdural hematoma, which is missed by an early examination. The blood may accumulate from small leaks in the dural sinuses.

Alexia (ă-lek'sē-ă), loss of the ability to read, may result from a lesion in the visual association cortex. **Dyslexia** (dis-lek'sē-ă) is a defect in which the reading level is below that expected on the basis of an individual's overall intelligence. Most people with dyslexia have normal or above-normal intelligence quotients. The term means reading deficiency and is also called partial alexia. It is three times more common in males than females. As many as 10% of males in the United States suffer from the disorder. The symptoms vary considerably from person to person and include the transposition of letters in a word, confusion between the letters *b* and *d*, and a lack of orientation in three-dimensional space. The brains of some dyslexics have abnormal cellular arrangements, including cortical disorganization and the appearance of bits of gray matter in medullary areas. Dyslexia apparently results from abnormal brain development.

Children with **attention-deficit disorder (ADD)** are easily distractible, have short attention spans, and may shift from one uncompleted task to another. Children with **attention-deficit/hyperactivity disorder (ADHD)** exhibit the characteristics of ADD, but they are also fidgety, have difficulty remaining seated and waiting their turn, engage in excessive talking, and commonly interrupt others. About 3% of all children exhibit ADHD, more boys than girls. Symptoms usually occur before age 7. The neurologic basis of both ADD and ADHD is as yet unknown.

A whole series of neurons and their pattern of activity, called a **memory engram**, or memory trace, probably is involved in the long-term retention of information, a thought, or an idea. Repetition of the information and association of the new information with existing memories assist in the transfer of information from short-term to long-term memory.

28 *Name the three types of memory, and describe the processes that result in the transfer of information from short-term to long-term memory.*

29 *Distinguish between implicit and explicit memory.*

Sleep and Memory

Is “pulling an all nighter” a good idea when preparing for an exam, or is it better to quit early and get some sleep? Does sleep actually help in memory processing? The results of studies seem to disagree. A number of studies indicate that REM sleep plays a critical role in learning. Other research, however, indicates that REM sleep is critical to the consolidation of procedural memory but not of declarative memory. There is no clear evidence that REM sleep helps consolidate declarative memory, the type of memory used in an examination. Some data suggest that deep, slow-wave sleep (SWS), which occurs early in the night, may be important in consolidating declarative memory.

1. The amount of the neurotransmitter glutamate produced by the presynaptic neuron increases.
2. The amount of glutamate released by the presynaptic neuron also increases.
3. The number of glutamate receptors on the postsynaptic neuron membrane increases.
4. Calcium ion channels in the postsynaptic membrane open, allowing Ca^{2+} to enter the cell.
5. The Ca^{2+} that enter the cell associate with the intracellular molecule calmodulin.
6. Activated calmodulin activates a cAMP intracellular mediator, which stimulates synthesis of specific proteins.
7. The cellular effect may involve structural changes in the cell.

PROCESS FIGURE 14.23 Cellular Mechanisms of Long-Term Potentiation

Limbic System

The limbic system (see figure 13.9) influences emotions, the visceral responses to emotions, motivation, mood, and the sensations of pain and pleasure. This system is associated with basic survival instincts: reproduction and the acquisition of food and water. One of the major sources of sensory input into the limbic system is the olfactory nerves. The smell or thought of food stimulates the sense of hunger in the hypothalamus, which motivates us to seek food. Many animals can also smell water, even over great distances. In animals such as dogs and cats, olfactory detection of **pheromones** (fer'ō-mōnz) is important in reproduction. Pheromones are molecules released into the air by one animal that attract another animal of the same species, usually of the opposite sex. Pheromones released by human females can influence the menstrual cycles of other women.

Apparently, the cingulate gyrus is a “satisfaction center” for the brain and is associated with the feeling of satisfaction after a meal or after sexual intercourse. The relationship of the hippocampus with the limbic system and with memory is probably important to survival. For example, it is very important for an animal to remember where to obtain food. Once a person has eaten, the satiety center in the hypothalamus is stimulated, the hunger center is inhibited, and the person feels satiated. The hypothalamus interacts with the cingulate gyrus and other parts of the limbic system, causing a sense of satisfaction associated with the satiation.

Lesions in the limbic system can result in a voracious appetite; increased sexual activity, which is often inappropriate; and docility, including the loss of normal fear and anger responses. Because the hippocampus is part of the temporal lobe, damage to that portion can also result in a loss of memory formation.

30 *What are the functions of the limbic system? Which of the special senses has a major input into the limbic system?*

31 *Define pheromones.*

Addiction, Obsession, and Compulsion

The “satisfaction center” of the brain, the cingulate gyrus, can be directly affected by chemicals—alcohol and other drugs. These substances cause a physical dependence. The brain becomes dependent on these substances for a quick sense of satisfaction. Obsessions and compulsions, such as compulsive gambling, kleptomania, fire-setting, and even compulsive overeating, exhibit similar neurologic patterns to addiction. The same brain areas, such as the cingulate gyrus, show activity during obsessive and compulsive behavior as in addictive behavior.

EFFECTS OF AGING ON THE NERVOUS SYSTEM

As a person ages, sensory function gradually declines because the number of sensory neurons declines, the function of remaining neurons decreases, and CNS processing decreases. In the skin, free nerve endings and hair follicle receptors remain largely unchanged with age. Meissner corpuscles and Pacinian corpuscles, however, decrease in number. The capsules of those that remain become thicker and structurally distorted and therefore exhibit reduced function. As a result of these changes in Meissner corpuscles and Pacinian corpuscles, elderly people are less conscious of something touching or pressing on the skin, have a decreased sense of two-point discrimination, and have a more difficult time identifying objects by touch. These functional changes leave elderly people more prone to skin injuries and with a greater sense of isolation.

A loss of Pacinian corpuscles also results in a decreased sense of position of the limbs and in the joints, which can affect balance and coordination. The functions of Golgi tendon organs and muscle spindles also decline with increasing age. As a result, information on the position, tension, and length of tendons and

CLINICAL GENETICS

Tay-Sachs Disease

Neurons contain specialized membrane lipids known as **gangliosides**. Lysosomes contain a variety of hydrolytic enzymes, including those that digest gangliosides. **Hexoseaminidase A** is a lysosomal enzyme that breaks down a specific type of ganglioside called **GM2 ganglioside**. The gene that encodes hexoseaminidase A is called *hex A* and is located on chromosome 15.

Tay-Sachs disease is an autosomal-recessive lysosomal enzyme disorder (see chapter 3) caused by mutations to the *hex A* gene. With *hex A* not functioning properly, GM2 ganglioside accumulates in cells and damages them, especially in neurons of the CNS. Hexoseaminidase A also breaks down gangliosides in the light-sensitive cells in the eye. Therefore, in the absence of this enzyme, gangliosides accumulate in these cells, leading to blindness.

The classic form of Tay-Sachs disease is a hereditary disorder of infants, mostly of Eastern European Jewish descent. Symptoms include paralysis, blindness, and death, usually

before age 5. The disease is named for Warren Tay (1843–1927), a British ophthalmologist, and Bernard Sachs (1858–1944), an American neurologist, who first described aspects of the disease. Damage to the CNS begins in the fetus, but clinical manifestations do not appear until several months after birth. The infant appears to develop normally but then begins to regress, losing motor functions, exhibiting seizures, becoming blind and mentally retarded, and eventually dying by the age of 4 or 5.

So far, more than 100 mutations of the *hex A* gene have been reported. The most common mutation found among those of Eastern European Jewish descent is a four base insertion in one of the 14 exons (exon 11) of the *hex A* gene. Heterozygous carriers of Tay-Sachs disease produce lowered levels of the enzyme. This does not, however, lead to the clinical manifestation of Tay-Sachs disease because the level of enzyme produced is sufficient to remove excess GM2 gangliosides in neurons.

Another form of Tay-Sachs disease is called late-onset Tay-Sachs (LOTS), which

includes juvenile-onset and adult-onset Tay-Sachs disease. LOTS is also caused by mutations in the *hex A* gene and, consequently, deficiencies in the production of hexoseaminidase A. Affected individuals often have a combination of one severely affected allele that fails to code for hexoseaminidase A and another allele that results in reduced production of hexoseaminidase A. LOTS is characterized by problems in gait, cognition, and speech and patients often experience psychiatric problems. Juvenile-onset Tay-Sachs manifests between 5 and 15 years of age, leading to progressive neural degeneration. In adult-onset Tay-Sachs disease, symptoms appear during the teens or much later in life and tend to be milder. Similar to the infantile form of Tay-Sachs, LOTS occurs more often in the Jewish population of Eastern European descent.

Genetic counseling of high-risk couples, accompanied by prenatal screening for level of hexoseaminidase A or mutations in the *hex A* gene, has greatly reduced the incidence of Tay-Sachs disease.

muscles decreases, resulting in additional reduction in the senses of movement, posture, and position, as well as reduced control and coordination of movement.

Other sensory neurons with reduced function include those that monitor blood pressure, thirst, objects in the throat, the amount of urine in the urinary bladder, and the amount of feces in the rectum. As a result, elderly people are more prone to high blood pressure, dehydration, swallowing and choking problems, urinary incontinence, and constipation or bowel incontinence.

There is also a general decline in the number of motor neurons. As many as 50% of the lower motor neurons in the lumbar region of the spinal cord may be lost by age 60. Muscle fibers innervated by the lost motor neurons are also lost, resulting in a general decline in muscle mass. The remaining motor units can compensate for some of the lost function. This, however, often results in a feeling that one must work harder to perform activities that were previously not so difficult. Loss of motor units also leads to more rapid fatigue, as the remaining units must perform compensatory work.

Reflexes slow as people age because both the generation and the conduction of action potentials and synaptic functions slow. The number of neurotransmitters and receptors declines. Age-related changes in the CNS also slow reflexes. The more complicated the reflex, the more it is affected by age. As reflexes slow, older

people are less able to react automatically, quickly, and accurately to changes in internal and external conditions.

The size and weight of the brain decrease as a person ages. At least some of these changes result from the loss of neurons within the cerebrum. The remaining neurons can apparently compensate for much of this loss. In addition to loss of neurons, structural changes occur in the remaining neurons. Neuron plasma membranes become more rigid, the endoplasmic reticulum becomes more irregular in structure, neurofibrillar tangles develop in the cells, and amyloid plaques form in synapses. All these changes decrease the ability of neurons to function. Age-related changes in brain function include decreased voluntary movement, conscious sensations, reflexes, memory, and sleep. Short-term memory is decreased in most older people. This change varies greatly among individuals but, in general, such changes are slow until about age 60 and then become more rapid, especially after age 70. However, the total amount of memory loss is normally not great for most people. The most difficult information for older people to assimilate is that which is unfamiliar and presented verbally and rapidly. Some of these problems may occur as older people are required to deal with new information in the face of existing, contradictory memories. Long-term memory appears to be unaffected or even improved in older people.

As with short-term memory, thinking, which includes problem solving, planning, and intelligence, in general declines slowly

SYSTEMS PATHOLOGY

Stroke

Mr. S, who is approaching middle age, is somewhat overweight and has high blood pressure. He was seated on the edge of his couch, surrounded by empty pizza boxes, bowls of chips and salsa, empty beer cans, and full ashtrays. As Mr. S cheered on his favorite team in a hotly contested big game, he noticed that he felt drowsy and that the television screen seemed blurry. He began to feel dizzy. As he tried to stand up, he suddenly vomited and collapsed to the floor, unconscious.

Mr. S was rushed to the local hospital, where the following signs and symptoms were observed. He exhibited weakness in his limbs, especially on the right, and ataxia (inability to walk). He had loss of pain and temperature sensation in his right lower limb and loss of all sensation in the left side of his face. The dizziness persisted, and he appeared disoriented and lacked attentiveness. He also exhibited dysphagia (the inability to swallow) and hoarseness. He had nystagmus (rhythmic oscillation of the eyes). His pupils were slightly dilated, his respiration was short and shallow, and his pulse rate and blood pressure were elevated.

BACKGROUND INFORMATION

Mr. S suffered a stroke, also referred to as a cerebrovascular accident (CVA). The term *stroke* describes a heterogeneous group of conditions involving the death of brain tissue resulting from a disruption of its vascular supply. Two types of stroke exist: **hemorrhagic stroke**, which results from the bleeding of arteries supplying brain tissue, and **ischemic stroke**, which results from blockage of the arteries supplying brain tissue (figure B). The blockage in

FIGURE B Images of Stroke

(a) MRI (magnetic resonance imaging) of a massive stroke in the left side (the viewer's right) of the brain. (b) Colorized MMR (nuclear magnetic resonance) showing disruption of blood flow to the left side (the viewer's right) of the brain (*yellow*). This disruption could cause a stroke.

ischemic stroke can result from a thrombus (a clot that develops in place within an artery) or an embolism (a plug, composed of a detached thrombus or other foreign body, such as a fat globule or gas bubble, that becomes lodged in an artery, blocking it). Mr. S was at high risk for developing a stroke. He was approaching middle age, was overweight, did not exercise enough, smoked, was under stress, and had a poor diet.

The combination of motor loss, which was seen as weakness in his limbs, and sensory loss, seen as loss of pain and temperature sensation

in his right lower limb and loss of all sensation in the left side of his face, along with the ataxia, dizziness, nystagmus, and hoarseness, suggests that the stroke affected the brainstem and cerebellum. Blockage of the vertebral artery, a major artery supplying the brain, or its branches can result in what is called a lateral medullary infarction (an area of dead tissue resulting from a loss of blood supply to an area). Damage to the descending motor pathways in that area, above the medullary decussation, results in muscle weakness. Damage to ascending pathways can result in loss of pain and temperature sensation

to age 60 but more rapidly thereafter. These changes, however, are slight and quite variable. Many older people show no change, and about 10% show an increase in thinking ability. Many of these changes are impacted by a person's background, education, health, motivation, and experience.

Among older people, more time is required to fall asleep, there are more periods of waking during the night, and the wakeful periods are of greater duration. Factors that can affect sleep include

pain, indigestion, rhythmic leg movements, sleep apnea, decreased urinary bladder capacity, and circulatory problems. There is, on the average, an increase in stage 1 sleep, which is the least restful, and less time spent in stage 4 and REM sleep, which are the most restful.

32 *How does aging affect sensory function? How does loss of motor neurons affect muscle mass?*

33 *Does aging always produce memory loss?*

(or other sensory modalities, depending on the affected tract). Damage to cranial nerve nuclei results in the loss of pain and temperature sensation in the face, dizziness, blurred vision, nystagmus, vomiting, and hoarseness. These signs and symptoms are not observed unless the lesion is in the brainstem, where these nuclei are located. Some damage to the cerebellum, also supplied by branches of the vertebral artery, can account for the ataxia.

Drowsiness, disorientation, inattentiveness, and loss of consciousness are examples of generalized neurologic response to dam-

age. Seizures may also result from severe neurologic damage. Depression from neurologic damage or from discouragement is also common. Slight dilation of the pupils; short, shallow respiration; and increased pulse rate and blood pressure are all signs of Mr. S's anxiety, not about the outcome of the game but about his current condition and his immediate future. With a loss of consciousness, Mr. S would not remember the last few minutes of what he saw in the game he was watching. People in these circumstances are often worried about how they are going to

deal with work tomorrow. They often have no idea that the motor and sensory losses may be permanent, or that they have a long period of therapy ahead.

PREDICT 11

Given that Mr. S exhibited weakness in his right limbs and loss of pain and temperature sensation in his right lower limb and the left side of his face, state which side of the brainstem was most severely affected by the stroke. Explain your answer.

SYSTEM INTERACTIONS	Effect of Stroke on Other Systems
SYSTEM	INTERACTIONS
Integumentary	Decubitus ulcers (bedsores) from immobility; loss of motor function following a stroke leads to immobility.
Skeletal	Loss of bone mass, if muscles are dysfunctional for a prolonged time; in the absence of muscular activity, the bones to which those muscle are attached begin to be resorbed by osteoclasts.
Muscular	Major area of effect; absence of stimulation due to damaged pathways or neurons leads to decreased motor function and may result in muscle atrophy.
Endocrine	Strokes in other parts of the brain could involve the hypothalamus, pineal body, or pituitary gland functions.
Cardiovascular	The following are risks: Phlebothrombosis (blood clot in a vein) can occur from inactivity. Edema around the brain can apply pressure to the cardioregulatory and vasomotor centers of the brain. This pressure can stimulate these centers, which result in elevated blood pressure, and congestive heart failure can result. If the cardioregulatory center in the brain is damaged, death may occur rapidly. Bleeding is due to the use of anticoagulants. Hypotension results from use of antihypertensives.
Respiratory	Pneumonia from aspiration of the vomitus or hypoventilation results from decreased function in the respiratory center. If the respiratory center is severely damaged, death may occur rapidly.
Digestive	Vomiting; dysphagia (difficulty swallowing); hypovolemia (decreased blood volume resulting from decreased fluid intake), which occurs because of dysphagia; possibly a loss of bowel control.
Urinary	Control of the micturition reflex may be inhibited. Urinary tract infection results from catheter implanation or from urinary bladder distension.
Reproductive	Loss of libido; innervation of the reproductive organs is often affected.

SUMMARY

Sensation (p. 477)

- The senses include general senses and special senses.
- The somatic senses include touch, pressure, temperature, proprioception, and pain.
- The visceral senses are primarily pain and pressure.
- The special senses are smell, taste, sight, hearing, and balance.
- Sensation, or perception, is the conscious awareness of stimuli received by sensory receptors.
- Sensation requires a stimulus, a receptor, the conduction of an action potential to the CNS, translation of the action potential, and processing of the action potential in the CNS so that the person is aware of the sensation.

Sensory Receptors

1. Receptors include mechanoreceptors, chemoreceptors, thermoreceptors, photoreceptors, and nociceptors.
2. Free nerve endings detect light touch, pain, itch, tickle, and temperature.
3. Merkel disks respond to light touch and superficial pressure.
4. Hair follicle receptors wrap around the hair follicle and are involved in the sensation of light touch when the hair is bent.
5. Pacinian corpuscles, located in the dermis and hypodermis, detect pressure. In joints, they serve a proprioceptive function.
6. Meissner corpuscles, located in the dermis, are responsible for two-point discriminative touch.
7. Ruffini end organs are involved in continuous touch or pressure.
8. Muscle spindles, located in skeletal muscle, are proprioceptors.
9. Golgi tendon organs, embedded in tendons, respond to changes in tension.
10. A stimulus produces a receptor potential in a sensory receptor. Primary receptors have axons that transmit action potentials toward the CNS. Secondary receptors have no axons but release neurotransmitters.
11. Adaptation is decreased sensitivity to a continued stimulus. Tonic receptors accommodate slowly; phasic receptors accommodate rapidly.

Sensory Tracts

1. Ascending pathways carry conscious and unconscious sensations. The two major ascending systems are the anterolateral and dorsal-column/medial-lemniscal systems.
2. In the anterolateral system,
 - The spinothalamic tract carries pain, temperature, light touch, pressure, tickle, and itch sensations.
 - The spinothalamic tracts are formed by primary neurons that enter the spinal cord and synapse with secondary neurons. The secondary neurons conducting pain and temperature sensations cross the spinal cord and ascend to the thalamus, where they synapse with tertiary neurons that project to the somatic sensory cortex. Axons conducting other sensations, such as light touch or itch, may ascend several spinal cord levels before crossing.
 - The ascending neurons of the spinoreticular tract ascend both contralaterally and ipsilaterally, project to the reticular formation, and influence the level of consciousness.
 - The ascending neurons of the spinomesencephalic tract carry action potentials from cutaneous pain receptors. The spinomesencephalic tract also contributes to eye reflexes.
3. The dorsal-column/medial-lemniscal system carries the sensations of two-point discrimination, proprioception, pressure, and vibration. Primary neurons enter the spinal cord and ascend to the medulla, where they synapse with secondary neurons. Secondary neurons cross over and project to the thalamus. Tertiary neurons extend from there to the somatic sensory cortex.
4. The trigeminothalamic tract carries sensory information from the face, nose, and mouth.
5. In the spinocerebellar system and other tracts,
 - The spinocerebellar tracts carry unconscious proprioception to the cerebellum from the same side of the body.
 - Neurons of the dorsal-column/medial-lemniscal system synapse with the neurons that carry proprioception information to the cerebellum.
 - The spinoolivary tract contributes to coordination of movement.
6. Descending pathways can reduce conscious perception of sensations.

Sensory Areas of the Cerebral Cortex

1. Sensory pathways project to primary areas in the cerebral cortex.
2. Sensory areas are organized topographically in the somatic sensory cortex.

Sensory Processing

Association areas of the cerebral cortex process sensory input from the primary sensory areas.

Control of Skeletal Muscles (p. 490)

1. Upper motor neurons are located in the cerebral cortex, cerebellum, and brainstem. Lower motor neurons are found in the cranial nuclei or the anterior horn of the spinal cord gray matter.
2. Upper motor neurons in the cerebral cortex and other brain areas project to lower motor neurons in the brainstem and spinal cord.

Motor Areas of the Cerebral Cortex

1. The primary motor cortex is the precentral gyrus. The premotor and prefrontal areas are staging areas for motor function.
2. The motor cortex is organized topographically.

Motor Tracts

1. The direct pathways maintain muscle tone and control fine, skilled movements in the face and distal limbs. The indirect pathways control conscious and unconscious muscle movements in the trunk and proximal limbs.
2. The corticospinal tracts control muscle movements below the head.
 - About 75%–85% of the upper motor neurons of the corticospinal tracts cross over in the medulla to form the lateral corticospinal tracts in the spinal cord.
 - The remaining upper motor neurons pass through the medulla to form the anterior corticospinal tracts, which cross over in the spinal cord.
 - The upper motor neurons of both tracts synapse with interneurons that then synapse with lower motor neurons in the spinal cord.
3. The corticobulbar tracts innervate the head muscles. Upper motor neurons synapse with interneurons in the reticular formation that, in turn, synapse with lower motor neurons in the cranial nerve nuclei.
4. The indirect pathways include the rubrospinal, vestibulospinal, and reticulospinal tracts and fibers from the basal nuclei.
5. The indirect pathways are involved in conscious and unconscious trunk and proximal limb muscle movements, posture, and balance.

Modifying and Refining Motor Activities

1. Basal nuclei are important in planning, organizing, and coordinating motor movements and posture.
2. The cerebellum has three parts.
 - The vestibulocerebellum controls balance and eye movement.
 - The spinocerebellum corrects discrepancies between intended movements and actual movements.
 - The cerebrocerebellum can “learn” highly specific complex motor activities.

Brainstem Functions (p. 498)

The brainstem contains nuclei for cranial nerves III–X and XII and nuclei of the reticular formation.

Sensory Input Projecting Through the Brainstem

The brainstem receives sensory from ascending spinal cord pathways and from the axons of cranial nerves.

RAS Functions of the Brainstem

Collateral branches of cranial nerves II, V, and VIII project to the reticular activating system (RAS) of the brainstem where they stimulate wakefulness and consciousness.

Motor Output and Reflexes Projecting Through the Brainstem

1. Descending spinal pathways either pass directly through the brainstem or synapse with brainstem nuclei.
2. Several somatic motor and parasympathetic reflexes are controlled by the brainstem.

Vital Functions Controlled by the Brainstem

Many vital functions are controlled by the brainstem.

Other Brain Functions (p. 500)

Speech

1. Speech is located only in the left cortex in most people.
2. Wernicke's area comprehends and formulates speech.
3. Broca's area receives input from Wernicke's area and sends impulses to the premotor and motor areas, which cause the muscle movements required for speech.

Right and Left Cerebral Cortex

1. Each cerebral hemisphere controls and receives input from the opposite side of the body.
2. The right and left hemispheres are connected by commissures. The largest commissure is the corpus callosum, which allows the sharing of information between hemispheres.

3. In most people, the left hemisphere is dominant, controlling speech and analytic skills. The right hemisphere controls spatial and musical abilities.

Brain Waves and Sleep

1. Electroencephalograms (EEGs) record the electrical activity of the brain as alpha, beta, theta, and delta waves.
2. Some brain disorders can be detected with EEGs.
3. Sleep patterns are characterized by specific EEGs.

Memory

At least three kinds of memory exist: sensory, short-term, and long-term.

Limbic System

The limbic system controls visceral functions through the autonomic nervous system and the endocrine system and is involved in emotions and memory.

Effects of Aging on the Nervous System (p. 506)

1. There is a general decline in sensory and motor functions as a person ages.
2. Short-term memory is decreased in most older people.
3. Thinking ability does not decrease in most older people.

REVIEW AND COMPREHENSION

1. Nociceptors respond to
 - a. changes in temperature at the site of the receptor.
 - b. compression, bending, or stretching of cells.
 - c. painful mechanical, chemical, or thermal stimuli.
 - d. light striking a receptor cell.
2. Which of these types of sensory receptors respond to pain, itch, tickle, and temperature?

a. Merkel disks	d. free nerve endings
b. Meissner corpuscles	e. Pacinian corpuscles
c. Ruffini end organs	
3. Which of these types of sensory receptors are involved with proprioception?

a. free nerve endings	d. Pacinian corpuscles
b. Golgi tendon organs	e. all of the above
c. muscle spindles	
4. The sensory receptor in the dermis and hypodermis responsible for sensing continuous touch or pressure are

a. Merkel disks.	d. free nerve endings.
b. Meissner corpuscles.	e. Pacinian corpuscles.
c. Ruffini end organs.	
5. Decreased sensitivity to a continued stimulus is called

a. adaptation.	c. translation.	e. phantom pain.
b. projection.	d. conduction.	
6. Secondary neurons in the spinothalamic tracts synapse with tertiary neurons in the

a. medulla oblongata.	d. thalamus.
b. gray matter of the spinal cord.	e. midbrain.
c. cerebellum.	
7. If the spinothalamic tract on the right side of the spinal cord is severed,
 - a. pain sensations below the damaged area on the right side are eliminated.
 - b. pain sensations below the damaged area on the left side are eliminated.
 - c. temperature sensations are unaffected.
 - d. neither pain sensations nor temperature sensations are affected.
8. Fibers of the dorsal-column/medial-lemniscal system
 - a. carry the sensations of two-point discrimination, proprioception, pressure, and vibration.
 - b. cross to the opposite side in the medulla oblongata.
 - c. are divided into the fasciculus gracilis and fasciculus cuneatus in the spinal cord.
 - d. include secondary neurons that exit the medulla and synapse in the thalamus.
 - e. all of the above.

9. Tertiary neurons in both the anterolateral system and the dorsal-column/medial-lemniscal system
 - a. project to the somatic sensory cortex.
 - b. cross to the opposite side in the medulla oblongata.
 - c. are found in the spinal cord.
 - d. connect to quaternary neurons in the thalamus.
 - e. are part of a descending pathway.
10. Unlike the anterolateral and dorsal-column/medial-lemniscal systems, the spinocerebellar tracts
 - a. are descending tracts.
 - b. transmit information from the same side of the body as the side of the CNS to which they project.
 - c. have four neurons in each pathway.
 - d. carry only pain sensations.
 - e. have primary neurons that synapse in the thalamus.
11. General sensory inputs (pain, pressure, temperature) to the cerebrum end in the
 - a. precentral gyrus.
 - b. postcentral gyrus.
 - c. central sulcus.
 - d. corpus callosum.
 - e. arachnoid mater.
12. Neurons from which area of the body occupy the greatest area of the somatic sensory cortex?
 - a. foot
 - b. leg
 - c. torso
 - d. arm
 - e. face
13. A cutaneous nerve to the hand is severed at the elbow. The distal end of the nerve at the elbow is then stimulated. The person reports
 - a. no sensation because the receptors are gone.
 - b. a sensation only in the region of the elbow.
 - c. a sensation “projected” to the hand.
 - d. a vague sensation on the side of the body containing the cut nerve.
14. Which of these areas of the cerebral cortex is involved in the motivation and foresight to plan and initiate movements?
 - a. primary motor cortex
 - b. somatic sensory cortex
 - c. prefrontal area
 - d. premotor area
 - e. basal nuclei
15. Which of these pathways is *not* an ascending (sensory) pathway?
 - a. spinothalamic tract
 - b. corticospinal tract
 - c. dorsal-column/medial-lemniscal system
 - d. trigeminothalamic tract
 - e. spinocerebellar tract
16. The _____ tracts innervate the head muscles.
 - a. corticospinal
 - b. rubrospinal
 - c. vestibulospinal
 - d. corticobulbar
 - e. dorsal-column/medial-lemniscal
17. Most fibers of the direct (pyramidal) system
 - a. decussate in the medulla oblongata.
 - b. synapse in the pons.
 - c. descend in the rubrospinal tract.
 - d. begin in the cerebellum.
18. A person with a spinal cord injury is suffering from paresis (partial paralysis) in the right lower limb. Which of these pathways is probably involved?
 - a. left lateral corticospinal tract
 - b. right lateral corticospinal tract
 - c. left dorsal-column/medial-lemniscal system
 - d. right dorsal-column/medial-lemniscal system
19. Which of these pathways is *not* an indirect (extrapyramidal) pathway?
 - a. reticulospinal tract
 - b. corticobulbar tract
 - c. rubrospinal tract
 - d. vestibulospinal tract
20. The indirect (extrapyramidal) system is concerned with
 - a. posture.
 - b. trunk movements.
 - c. proximal limb movements.
 - d. all of the above.
21. The major effect of the basal nuclei is
 - a. to act as a comparator for motor coordination.
 - b. to decrease muscle tone and inhibit unwanted muscular activity.
 - c. to affect emotions and emotional responses to odors.
 - d. to modulate pain sensations.
22. Which of the parts of the cerebellum is correctly matched with its function?
 - a. vestibulocerebellum—planning and learning rapid, complex movements
 - b. spinocerebellum—comparator function
 - c. cerebrocerebellum—balance
 - d. none of the above
23. Given the following events:
 1. Action potentials from the cerebellum go to the motor cortex and spinal cord.
 2. Action potentials from the motor cortex go to lower motor neurons and the cerebellum.
 3. Action potentials from proprioceptors go to the cerebellum.
 Arrange the events in the order they occur in the cerebellar comparator function.
 - a. 1,2,3
 - b. 1,3,2
 - c. 2,1,3
 - d. 2,3,1
 - e. 3,2,1
24. The brainstem
 - a. consists of ascending and descending pathways.
 - b. contains cranial nerve nuclei III–X and XII.
 - c. has nuclei and connections that form the reticular activating system.
 - d. has many important reflexes, some of which are necessary for survival.
 - e. has all of the above.
25. Given these areas of the cerebral cortex:
 1. Broca’s area
 2. premotor area
 3. primary motor cortex
 4. Wernicke’s area
 If a person hears and understands a word and then says the word out loud, in what order are the areas used?
 - a. 1,4,2,3
 - b. 1,4,3,2
 - c. 3,1,4,2
 - d. 4,1,2,3
 - e. 4,1,3,2
26. The main connection between the right and left hemispheres of the cerebrum is the
 - a. intermediate mass.
 - b. corpus callosum.
 - c. vermis.
 - d. unmyelinated nuclei.
 - e. thalamus.
27. Which of these activities is mostly associated with the left cerebral hemisphere in most people?
 - a. sensory input from the left side of the body
 - b. mathematics and speech
 - c. spatial perception
 - d. recognition of faces
 - e. musical ability

28. The limbic system is involved in the control of
 - a. sleep and wakefulness.
 - b. posture.
 - c. higher intellectual processes.
 - d. emotion, mood, and sensations of pain or pleasure.
 - e. hearing.
29. Long-term memory involves
 - a. a change in the cytoskeleton of neurons.
 - b. the movement of calcium into the neuron.
 - c. an increase in glutamate release by presynaptic neurons.
 - d. specific protein synthesis.
 - e. all of the above.
30. Concerning long-term memory,
 - a. declarative (explicit) memory involves the development of skills, such as riding a bicycle.
 - b. procedural (implicit) memory involves the retention of facts, such as names, dates, or places.
 - c. much of declarative (explicit) memory is lost through time.
 - d. declarative (explicit) memory is stored primarily in the cerebellum and premotor area of the cerebrum.
 - e. all of the above.

Answers in Appendix E

CRITICAL THINKING

1. Describe all the sensations involved when a woman picks up an apple and bites into it. Explain which of those sensations are special and which are general. What types of receptors are involved? Which aspects of the taste of the apple are actually taste and which are olfaction?
2. Some student nurses are at a party. Because they love anatomy and physiology so much, they are discussing adaptation of the special senses. They make the following observations:
 - a. When entering a room, an odor like brewing coffee is easily noticed. A few minutes later, the odor might be barely, if at all, detectable, no matter how hard one tries to smell it.
 - b. When entering a room, the sound of a ticking clock can be detected. Later the sound is not noticed until a conscious effort is made to hear it. Then it is easily heard.
 Explain the basis for each of these observations.
3. A patient suffered a loss of two-point discrimination and proprioception on the right side of the body. Voluntary movement of muscles was not affected, and pain and temperature sensations were normal. Is it possible to conclude that the right side of the spinal cord was damaged?
4. A patient is suffering from the loss of two-point discrimination and proprioceptive sensations on the right side of the body resulting from a lesion in the pons. What tract is affected, and which side of the pons is involved?
5. A patient suffers a lesion in the central core of the spinal cord. It is suspected that the fibers that decussate and that are associated with the lateral spinothalamic tracts are affected in the area of the lesion. What observations would be consistent with that diagnosis?
6. A person in a car accident exhibits the following symptoms: extreme paresis on the right side, including the arm and leg; reduction of pain sensation on the left side; and normal tactile sensation on both sides. Which tracts are damaged? Where did the patient suffer tract damage?
7. If the right side of the spinal cord is completely transected, what symptoms do you expect to observe with regard to motor function, two-point discrimination, light touch, and pain perception?
8. A patient with a cerebral lesion exhibits a loss of fine motor control of the left hand, arm, forearm, and shoulder. All other motor and sensory functions appear to be intact. Describe the location of the lesion as precisely as possible.
9. A patient suffers brain damage in an automobile accident. It is suspected that the cerebellum is the part of the brain that is affected. On the basis of what you know about cerebellar function, how can you determine that the cerebellum is involved?
10. Woody Knothead was accidentally struck in the head with a baseball bat. He fell to the ground, unconscious. Later, when he regained consciousness, he was not able to remember any of the events that happened 10 minutes before the accident. Explain. What complications might be looked for at a later time?
11. Pamela Frail is a 40-year-old woman experiencing limb weakness on her left side. A brain MRI shows lesions in her cerebral cortex. Which of the descending pathways are affected by these lesions? Would you expect the brain lesions to appear ipsilateral or contralateral to her limb weakness? Explain why.

15

The Special Senses

Historically, it was thought that we had just five senses: smell, taste, sight, hearing, and touch. Today we recognize many more. Some specialists suggest that there are at least 20, or perhaps as many as 40, different senses. Most of these senses are part of what was originally classified as “touch.” These “general senses” were discussed in chapter 14. The sense of balance is now recognized as a “special sense,” making a total of 5 special senses: smell, taste, sight, hearing, and balance. **Special senses** are defined as senses with highly localized receptors that provide specific information about the environment. This chapter describes *olfaction* (p. 515), *taste* (p. 518), the *visual system* (p. 521), and *hearing and balance* (p. 542). The chapter concludes with a look at the *effects of aging on the special senses* (p. 556).

Photograph of an isolated cochlea from the inner ear.

OLFACTION

Olfaction (ol-fak'shūn), the sense of smell, occurs in response to odors that stimulate sensory receptors located in the extreme superior region of the nasal cavity, called the **olfactory region** (figure 15.1*a*). Most of the nasal cavity is involved in respiration, with only a small superior part devoted to olfaction. The major anatomical features of the nasal cavity are described in chapter 23 in relation

to respiration. The specialized nasal epithelium of the olfactory region is called the **olfactory epithelium**.

PREDICT 1

Explain why it sometimes helps to inhale slowly and deeply through the nose when trying to identify an odor.

FIGURE 15.1 Olfactory Region, Epithelium, and Bulb

(*a*) The lateral wall of the nasal cavity (cut in sagittal section), showing the olfactory region and olfactory bulb. (*b*) The olfactory cells within the olfactory epithelium, the olfactory nerve processes passing through the cribriform plate, and the fine structure of the olfactory bulb.

Olfactory Epithelium and Bulb

Ten million **olfactory neurons** are present within the olfactory epithelium (figure 15.1*b*). Axons of these bipolar neurons project through numerous, small foramina of the bony cribriform plate (see chapter 7) to the **olfactory bulbs**, where they synapse with secondary neurons. **Olfactory tracts** project from the bulbs to the cerebral cortex.

The dendrites of olfactory neurons extend to the epithelial surface of the nasal cavity, and their ends are modified into bulbous enlargements called **olfactory vesicles** (see figure 15.1*b*). These vesicles possess cilia called **olfactory hairs**, which lie in a thin mucous film on the epithelial surface.

Airborne molecules enter the nasal cavity and are dissolved in the fluid covering the olfactory epithelium. Some of these molecules, referred to as **odorants** (δ' dör-ants; molecules with an odor), bind to transmembrane odorant receptor molecules (chemoreceptors) of the olfactory hair membranes (figure 15.2). A G protein, associated with each odorant receptor, is activated by the binding of the odorant. The α subunit of the activated G protein binds to and activates adenylate cyclase, which in turn catalyzes the formation of cyclic AMP (cAMP) from ATP. cAMP

in these cells causes Na^+ and Ca^{2+} channels to open. The influx of ions into the olfactory hairs results in depolarization and the production of action potentials in the olfactory neurons.

Odorant receptors are composed of seven transmembrane polypeptide subunits produced by a large family of genes. Combinations of subunits from approximately 1000 different odorant receptors can be produced. These receptors can react to odorants of different sizes, shapes, and functional groups. These capabilities, together with multiple intracellular pathways involving G proteins, adenylate cyclase, and ion channels allow for a wide variety of detectable smells, which is about 4000 for the average person. With such a wide range of smells, however, only seven primary classes of odors have been proposed: (1) camphoraceous (e.g., moth balls), (2) musky, (3) floral, (4) pepperminty, (5) ethereal (e.g., fresh pears), (6) pungent, and (7) putrid. It is very unlikely, however, that this list is an accurate representation of all primary odors, and some studies point to the possibility of as many as 50 primary odors.

The threshold for the detection of odors is very low, so very few odorant molecules are required to trigger the response. Apparently, there is rather low specificity in the olfactory epithelium. A given

PROCESS FIGURE 15.2 Action of Odorant Binding to Membrane of Olfactory Hair

receptor may react to more than one type of odorant. Odorant receptors may become saturated with odorants and no longer respond to odorant molecules. This accommodation makes a person less sensitive to an odorant after being exposed to it for a short time. For example, when a person first enters a room with a distinctive odor, that odor is very noticeable, but it becomes almost unnoticeable after the person remains in the room for a short time.

The “Odor” of Natural Gas

Methylmercaptan, which has a nauseating odor similar to that of rotten cabbage, is added to natural gas at a concentration of about one part per million. A person can detect the odor of about 1/25 billionth of a milligram of the substance and therefore is aware of the presence of the more dangerous but odorless natural gas.

Odor Survey Results

The National Geographic Society conducted a smell survey in 1986, which was the largest sampling of its kind ever conducted. One and a half million people participated. Of six odors studied, 98%–99% of those responding could smell isoamyl acetate (banana), eugenol (cloves), mercaptans, and rose, but 29% could not smell galaxolide (musk), and 35% could not smell androsterone (contained in sweat). Of those responding to the survey, 1.2% could not smell at all, a disorder called **anosmia** (an-oz'mē-ä).

The primary olfactory neurons have the most exposed nerve endings of any neurons, and they are constantly being replaced. The entire olfactory epithelium, including the neurosensory cells, is lost about every 2 months as the olfactory epithelium degenerates and is lost from the surface. Lost olfactory cells are replaced by a proliferation of **basal cells** in the olfactory epithelium. This

replacement of olfactory neurons is unique among neurons, most of which are permanent cells that have a very limited ability to replicate (see chapter 4).

Neuronal Pathways for Olfaction

Axons from the olfactory neurons form the olfactory nerves (cranial nerve I), which enter the olfactory bulbs (see figure 15.1*b*), where they synapse with **mitral** (mī'trāl; triangular; shaped like a bishop's miter or hat) **cells** or **tufted cells**. The mitral and tufted cells relay olfactory information to the brain through the olfactory tracts and synapse with granule cells in the olfactory bulb. Olfactory bulb neurons also receive input from nerve cell processes entering the olfactory bulb from the brain. As a result of input from both mitral cells and the brain, olfactory bulb neurons can modify olfactory information before it leaves the olfactory bulb. This modification enhances the accommodation occurring in the odorant receptors.

Olfaction is the only major sensation that is relayed directly to the cerebral cortex without first passing through the thalamus. Each olfactory tract terminates in an area of the brain called the **olfactory cortex** (figure 15.3). The olfactory cortex is in the frontal and temporal lobes, within the lateral fissure of the cerebrum, and it can be divided structurally and functionally into three areas: lateral, medial, and intermediate. The **lateral olfactory area** is involved in the conscious perception of smell. The **medial olfactory area** is responsible for visceral and emotional reactions to odors and has connections to the limbic system, through which it connects to the hypothalamus. Axons extend from the **intermediate olfactory area** along the olfactory tract to the bulb and synapse with the olfactory bulb neurons, thus constituting a major mechanism by which sensory information is modulated within the

1. Axons of the olfactory neurons in the olfactory epithelium project through foramina in the cribriform plate to the olfactory bulb.
2. Axon of neurons in the olfactory bulb project through the olfactory tract to the olfactory cortex.
3. The lateral olfactory area is involved in the conscious perception of smell.
4. The medial olfactory area is involved in the visceral and emotional reaction to odors.
5. The intermediate olfactory area receives input from the medial and lateral olfactory areas.
6. Axons from the intermediate olfactory area project along the olfactory tract to the olfactory bulb. Action potentials carried by those axons modulate the activity of the neurons in the olfactory bulb.

Medial view

olfactory bulb. The feedback from the intermediate olfactory area is mostly inhibitory, further enhancing the rapid accommodation of the olfactory system. Accommodation at the receptor level, the olfactory bulb level, and the CNS level make the olfactory system insensitive to an odorant after a brief exposure.

- 1 Describe the initiation of an action potential in an olfactory neuron. Name all the structures and cells that the action potential encounters on the way to the olfactory cortex.
- 2 What is a primary odor? Name seven examples. How do the primary odors relate to the ability to smell many different odors?
- 3 What type of neurons are olfactory neurons? What is unique about olfactory neurons with respect to replacement?
- 4 How is the sense of smell modified in the olfactory bulb?
- 5 Name the three areas of the olfactory cortex, and give their functions.
- 6 Explain how the CNS connections elicit various visceral and conscious responses to smell.

PREDICT 2

The olfactory system quickly adapts to continued stimulation, and a particular odor becomes unnoticed before very long, even though the odor molecules are still present in the air. Describe as many sites as you can in the olfactory pathways where such adaptation can occur.

TASTE

The sensory structures that detect **gustatory**, or **taste**, stimuli are the **taste buds**. Most taste buds are associated with specialized portions of the tongue called **papillae** (pă-pil'ē). Taste buds, however, are also located on other areas of the tongue, the palate, and even the lips and throat, especially in children. The four major types of papillae are named according to their shape (figure 15.4): **vallate** (val'āt; surrounded by a wall), **fungiform** (fŭn'ji-fŏrm; mushroom-shaped), **foliate** (fŏ'lē-āt; leaf-shaped), and **filiform** (fil'i-fŏrm; filament-shaped). Taste buds (see figure 15.4c–e) are associated with vallate, fungiform, and foliate papillae. Filiform papillae are the most numerous papillae on the surface of the tongue but have no taste buds. Rather, filiform papillae provide a rough surface on the tongue, allowing it to manipulate food more easily.

Vallate papillae are the largest but least numerous of the papillae. Eight to 12 of these papillae form a V-shaped row along the border between the anterior and posterior parts of the tongue (figure 15.4a). Fungiform papillae are scattered irregularly over the entire superior surface of the tongue, appearing as small, red dots interspersed among the far more numerous filiform papillae. Foliate papillae are distributed in folds on the sides of the tongue and contain the most sensitive of the taste buds. They are most numerous in young children and decrease with age. They are located mostly posteriorly in adults.

Histology of Taste Buds

Taste buds are oval structures embedded in the epithelium of the tongue and mouth (figure 15.4g). Each of the 10,000 taste buds on a person's tongue consists of three major types of specialized epithelial

cells. The sensory cells of each taste bud consist of about 50 **taste**, or **gustatory**, cells. The remaining two cell types, which are nonsensory cells, are **basal cells** and **supporting cells**. Like olfactory cells, the cells of the taste buds are replaced continuously, each having a normal life span of about 10 days. Each taste cell has several microvilli, called **gustatory hairs**, extending from its apex into a tiny opening in the epithelium called the **taste**, or **gustatory**, pore.

Function of Taste

Substances called **tastants** (tās'tants), dissolved in saliva, enter the taste pores and, by various mechanisms, cause the taste cells to depolarize. These cells do not have classic axons but have short connections with secondary sensory neurons (see chapter 14). Those connections have some characteristics of chemical synapses. Neurotransmitters (apparently including ATP) are released from the taste cells and stimulate action potentials in the axons of sensory neurons associated with them.

The taste of **salt** results when Na^+ diffuse through Na^+ channels (figure 15.5a) of the gustatory hairs or other cell surfaces of taste cells, resulting in depolarization of the cells. Hydrogen ions (H^+) of **acids**, which result in **sour** taste, can cause depolarization of taste cells by one of three mechanisms (figure 15.5b): (1) They can enter the cell directly through H^+ channels, (2) they can bind to ligand-gated K^+ channels and block the exit of K^+ from the cell, or (3) they can open ligand-gated channels for other positive ions and allow them to diffuse into the cell. **Sweet** and **bitter** tastants bind to receptors (figure 15.5c and d) on the gustatory hairs of taste cells and cause depolarization through a G protein mechanism. A taste called **umami** (ū-mā'mē; a Japanese term loosely translated as savory) results when amino acids, such as glutamate, bind to receptors (figure 15.5e) on gustatory hairs of taste cells and cause depolarization through a G protein mechanism.

The texture of food in the oral cavity also affects the perception of taste. Hot or cold food may interfere with the ability of the taste buds to function in tasting food. If a cold fluid is held in the mouth, the body warms the fluid and the taste becomes enhanced. On the other hand, adaptation is very rapid for taste. This adaptation apparently occurs both at the level of the taste bud and within the CNS. Adaptation may begin within 1 or 2 seconds after a taste sensation is perceived, and complete adaptation may occur within 5 minutes.

Even though only five primary tastes have been identified, humans can perceive a fairly large number of different tastes, presumably by combining the five basic taste sensations. As with olfaction, the specificity of the receptor molecules is not perfect. For example, artificial sweeteners have different chemical structures than the sugars they are designed to replace and some are many times more powerful than natural sugars in stimulating taste sensations.

Many of the sensations thought of as being taste are strongly influenced by olfactory sensations. This phenomenon can be demonstrated by pinching one's nose to close the nasal passages while trying to taste something. With olfaction blocked, it is difficult to distinguish between the taste of a piece of apple and the taste of potato. Much of the "taste" is lost by this action. This is one reason that a person with a cold has a reduced sensation of taste. Although all taste buds are able to detect all five of the basic tastes, each taste cell is usually most sensitive to one.

FIGURE 15.4 Papillae and Taste Buds

(a) Surface of the tongue. (b) Filiform papilla. (c) Vallate papilla. (d) Foliate papilla. (e) Fungiform papilla. (f) Taste cell. (g) A taste bud. (h) Scanning electron micrograph of taste buds (fungiform and filiform papillae) on the surface of the tongue.

Thresholds vary for the five primary tastes. Sensitivity for bitter substances is the highest; sensitivities for sweet and salty tastes are the lowest. Sugars, some other carbohydrates, and some proteins produce sweet tastes; many proteins and amino acids produce umami tastes; acids produce sour tastes; metal ions tend to produce salty tastes; and alkaloids (bases) produce bitter tastes. Many alkaloids are poisonous; thus, the high sensitivity for bitter tastes may be protective. On the other hand, humans tend to crave sweet, salty, and umami tastes, perhaps in response to the body's need for sugars, carbohydrates, proteins, and minerals.

Neuronal Pathways for Taste

Taste from the anterior two-thirds of the tongue, except from the circumvallate papillae, is carried by means of a branch of the facial nerve (VII) called the **chorda tympani** (kōr'dā tim'pā-nē; so-named because it crosses over the surface of the tympanic membrane of the middle ear). Taste from the posterior one-third of the tongue, the circumvallate papillae, and the superior pharynx is carried by means of the glossopharyngeal nerve (IX). In addition to these two major nerves, the vagus nerve (X) carries a few fibers for taste sensation from the epiglottis.

(a) **Salt:** Sodium ions diffuse through Na^+ channels, resulting in depolarization.

(b) **Sour (acid):** Hydrogen ions (H^+) from acids can cause depolarization by one of three mechanisms: (1) They can enter the cell directly through H^+ channels, (2) they can bind to gated K^+ channels, closing the gate, and preventing K^+ from entering the cell, or (3) they can open ligand-gated channels for other positive ions.

(c) **Sweet:** Sugars, such as glucose, or artificial sweeteners bind to receptors and cause the cell to depolarize by means of a G protein mechanism. The α subunit of the G protein activates adenylate cyclase, which produces cAMP. cAMP activates a kinase that phosphorylates K^+ channels. The K^+ channels close, resulting in depolarization.

(d) **Bitter:** Bitter tastants, such as quinine, bind to receptors and cause depolarization of the cell through a G protein mechanism. The α subunit of the G protein activates phospholipase C, which converts phosphoinositol (PIP_2) to inositol triphosphate (IP_3). IP_3 causes Ca^{2+} release from intracellular stores and depolarization of the cell.

(e) **Glutamate (umami):** Amino acids, such as glutamate, bind to receptors and cause depolarization through a G protein mechanism. The α subunit of the G protein activates adenylate cyclase, which catalyzes the conversion of ATP to cAMP. cAMP opens Ca^{2+} channels. The influx of Ca^{2+} causes depolarization of the cell.

FIGURE 15.5 Actions of the Major Tastants

1. Axons of sensory neurons, which synapse with taste receptors, pass through cranial nerves VII, IX, and X and through the ganglion of each nerve (enlarged portion of each nerve).
2. The axons enter the brainstem and synapse in the nucleus of the tractus solitarius.
3. Axons from the nucleus solitarius synapse in the thalamus.
4. Axons from the thalamus terminate in the taste area of the cortex.

PROCESS FIGURE 15.6 Pathways for the Sense of Taste

The facial nerve (anterior two-thirds of the tongue), glossopharyngeal nerve (posterior one-third of the tongue), and vagus nerve (root of the tongue) all carry taste sensations. The trigeminal nerve carries tactile sensations from the anterior two-thirds of the tongue. The chorda tympani from the facial nerve (carrying taste input) joins the trigeminal nerve.

These nerves extend from the taste buds to the tractus solitarius of the medulla oblongata (figure 15.6). Fibers from this nucleus decussate and extend to the thalamus. Neurons from the thalamus project to the taste area of the cortex, which is at the extreme inferior end of the postcentral gyrus.

- 7 **Name and describe the four kinds of papillae found on the tongue. Which ones have taste buds associated with them?**
- 8 **Starting with the gustatory hair, name the structures and cells that an action potential would encounter on the way to the taste area of the cerebral cortex.**
- 9 **What is the life span of a normal gustatory cell?**
- 10 **What are the five primary tastes? Describe how each type of tastant causes depolarization of a taste cell.**
- 11 **How is the sense of taste related to the sense of smell?**

VISUAL SYSTEM

The visual system includes the eyes, the accessory structures, and the optic nerves (II), tracts, and pathways. The **eye** includes the eyeball (the globe of the eye) and the lens. The eyes respond to light and

initiate afferent action potentials, which are transmitted from the eyes to the brain by the optic nerves and tracts. The accessory structures, such as eyebrows, eyelids, eyelashes, and tear glands, help protect the eyes from direct sunlight and damaging particles. Much of the information about the world around us is detected by the visual system. Our education is largely based on visual input and depends on our ability to read words and numbers. Visual input includes information about light and dark, color and hue. Visual stimuli can come from far greater distances than can stimuli for any other sense. The eye can detect light originating from stars billions of miles away.

Accessory Structures

Accessory structures protect, lubricate, move, and in other ways aid in the function of the eye. These structures include the eyebrows, eyelids, conjunctiva, lacrimal apparatus, and extrinsic eye muscles.

Eyebrows

The **eyebrows** (figure 15.7) protect the eyes by preventing perspiration, which can irritate the eyes, from running down the forehead and into them, and they help shade the eyes from direct sunlight.

FIGURE 15.7 The Left Eye and Its Accessory Structures

Eyelids

The **eyelids**, also called **palpebrae** (pal-pē'brē), with their associated lashes, protect the eyes from foreign objects. The space between the two eyelids is called the **palpebral fissure**, and the angles where the eyelids join at the medial and lateral margins of the eye are called **canthi** (kan'thī; corners of the eye; see figure 15.7). The medial canthus contains a small, reddish-pink mound called the **caruncle** (kar'ūng-kl; mound of tissue). The caruncle contains some modified sebaceous and sweat glands.

The eyelids consist of five layers of tissue (figure 15.8). From the outer to the inner surface, they are (1) a thin layer of integument on the external surface; (2) a thin layer of areolar connective tissue; (3) a layer of skeletal muscle consisting of the orbicularis

Sagittal section

FIGURE 15.8 Sagittal Section Through the Eye, Showing Its Accessory Structures

oculi and levator palpebrae superioris muscles; (4) a crescent-shaped layer of dense connective tissue called the **tarsal plate**, which helps maintain the shape of the eyelid; and (5) the palpebral conjunctiva (described in the next section), which lines the inner surface of the eyelid and the anterior surface of the eyeball.

If an object suddenly approaches the eye, the eyelids protect the eye by rapidly closing and then opening (blink reflex). Blinking, which normally occurs about 25 times per minute, also helps keep the eye lubricated by spreading tears over the surface. Movements of the eyelids are a function of skeletal muscles. The orbicularis oculi muscle closes the lids, and the levator palpebrae superioris elevates the upper lid (see chapter 10). The eyelids also help regulate the amount of light entering the eye.

Eyelashes (see figures 15.7 and 15.8) are attached as a double or triple row of hairs to the free edges of the eyelids. **Ciliary glands** are modified sweat glands that open into the follicles of the eyelashes to keep them lubricated. When one of these glands becomes inflamed, it is called a **sty**. **Meibomian glands** (mī-bō' mē-an), or tarsal, **glands** are sebaceous glands near the inner margins of the eyelids; they produce **sebum** (sē'būm; an oily semifluid substance), which lubricates the lids and restrains tears from flowing over the margin of the eyelids. An infection or a blockage of a meibomian gland is called a **chalazion** (ka-lā' zē-on), or **meibomian cyst**.

Conjunctiva

The **conjunctiva** (kon-jūnk-tī'vā; see figure 15.8) is a thin, transparent mucous membrane. The **palpebral conjunctiva** covers the inner surface of the eyelids, and the **bulbar conjunctiva** covers the anterior white surface of the eye. The points at which the palpebral

and bulbar conjunctivae meet are the superior and inferior **conjunctival fornices**.

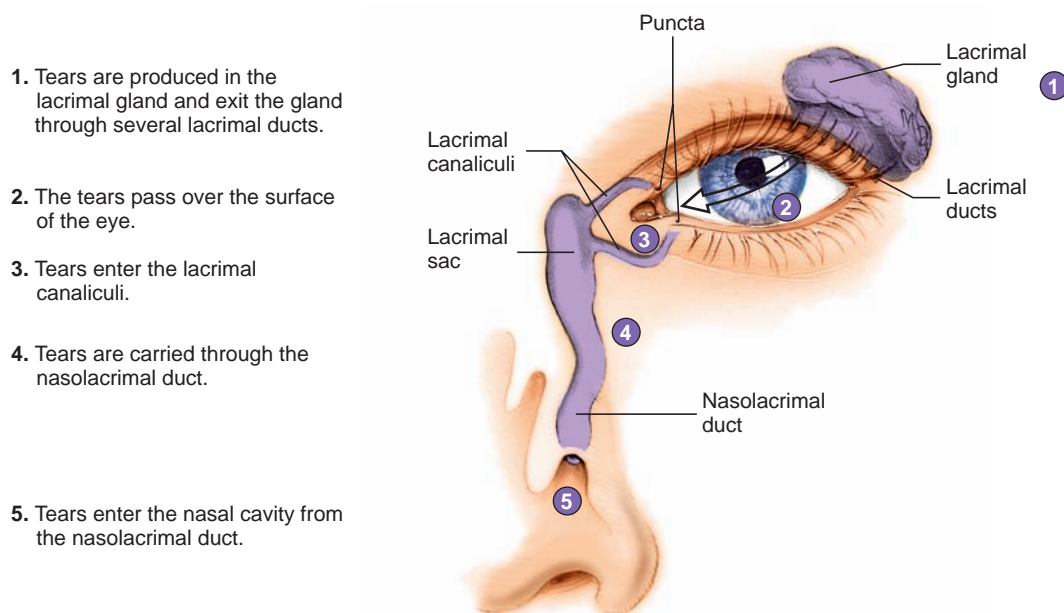

Conjunctivitis

Conjunctivitis is an inflammation of the conjunctiva caused by an infection or another irritation. An example of conjunctivitis caused by a bacterium is **acute contagious conjunctivitis**, also called **pinkeye**.

Lacrimal Apparatus

The **lacrimal** (lak'ri-māl) **apparatus** (figure 15.9) consists of a lacrimal gland situated in the superolateral corner of the orbit and a nasolacrimal duct beginning in the inferomedial corner of the orbit. The **lacrimal gland** is innervated by parasympathetic fibers from the facial nerve (VII). The gland produces tears, which leave the gland through several **lacrimal ducts** and pass over the anterior surface of the eyeball. The gland produces tears constantly at the rate of about 1 mL/day to moisten the surface of the eye, lubricate the eyelids, and wash away foreign objects. Tears are mostly water, with some salts, mucus, and lysozyme, an enzyme that kills certain bacteria. Most of the fluid produced by the lacrimal glands evaporates from the surface of the eye, but excess tears are collected in the medial corner of the eye by the **lacrimal canaliculi**. The opening of each lacrimal canaliculus is called a **punctum** (pūngk'tūm). The upper and lower eyelids each have a punctum near the medial canthus. Each punctum is located on a small lump called a **lacrimal papilla**. The lacrimal canaliculi open into a **lacrimal sac**, which in turn continues into the **nasolacrimal duct** (see figure 15.9). The nasolacrimal duct opens into the inferior meatus of the nasal cavity beneath the inferior nasal concha (see chapter 23).

PROCESS FIGURE 15.9 Lacrimal Apparatus

Facial Nerve Damage

Facial nerve damage results in an inability to close the eyelid on the affected side. With the ability to blink being lost, tears cannot be washed across the eye, and the conjunctiva and cornea become dry. A dry cornea may become ulcerated; if not treated, eyesight may be lost.

PREDICT 3

Explain why it is often possible to “taste” medications, such as eye-drops, that have been placed into the eyes. Why does a person’s nose “run” when he or she cries?

Extrinsic Eye Muscles

Six **extrinsic muscles** of the eye (figures 15.10 and 15.11; see chapter 10) cause the eyeball to move. Four of these muscles run more or less straight anteroposteriorly. They are the superior, inferior, medial,

and lateral **rectus muscles**. Two muscles, the superior and inferior **oblique muscles**, are placed at an angle to the globe of the eye.

The movements of the eye can be described graphically by a figure resembling the letter *H*. The clinical test for normal eye movement is therefore called the **H test**. A person’s inability to move the eye toward one part of the *H* may indicate dysfunction of an extrinsic eye muscle or the cranial nerve to the muscle (the actions of the eye muscles are listed in table 10.7).

The superior oblique muscle is innervated by the trochlear nerve (IV). The nerve is so-named because the superior oblique muscle goes around a little pulley, or trochlea, in the superomedial corner of the orbit. The lateral rectus muscle is innervated by the abducent nerve (VI), so-named because the lateral rectus muscle abducts the eye. The other four extrinsic eye muscles are innervated by the oculomotor nerve (III).

12 Describe and state the functions of the eyebrows, eyelids, conjunctiva, lacrimal apparatus, and extrinsic eye muscles.

FIGURE 15.10 Extrinsic Muscles of the Eye

FIGURE 15.11 Photograph of the Eye and Its Associated Structures

Anatomy of the Eye

The eyeball is composed of three layers (figure 15.12). The outer, or **fibrous, layer** consists of the sclera and cornea; the middle, or **vascular, layer** consists of the choroid, ciliary body, and iris; and the inner, or **nervous, layer** consists of the retina.

Fibrous Layer

The **sclera** (sklēr'ă) is the firm, opaque, white outer layer of the posterior five-sixths of the eyeball. It consists of dense collagenous connective tissue with elastic fibers. The sclera helps maintain the shape of the eyeball, protects its internal structures, and provides an attachment point for the muscles that move it. Usually, a small portion of the sclera can be seen as the “white of the eye” when the eye and its surrounding structures are intact (see figure 15.7). The bulbar conjunctiva is loosely attached to the sclera.

The sclera is continuous anteriorly with the cornea. The **cornea** (kōr'nē-ă) is an avascular, transparent structure that permits light to enter the eye and bends, or refracts, that light as part of the focusing system of the eye. The cornea consists of a connective tissue matrix containing collagen, elastic fibers, and proteoglycans, with a layer of stratified squamous epithelium covering the outer surface and a layer of simple squamous epithelium on the inner surface. The outer epithelium is continuous with the bulbar conjunctiva over the sclera. Large collagen fibers are white, whereas smaller collagen fibers and proteoglycans are transparent. The cornea is transparent, rather than white, like the sclera, in part because fewer large collagen fibers and more proteoglycans are present in the cornea than in the sclera. The transparency of the cornea also results from its low water content. In the presence of water, proteoglycans trap water and expand, which scatters light. In the absence of water, the proteoglycans decrease in size and do not interfere with the passage of light through the matrix.

PREDICT 4

Predict the effect of corneal inflammation on vision.

Cornea

The central part of the cornea receives oxygen from the outside air. Soft plastic contact lenses worn for long periods must therefore be permeable so that air can reach the cornea.

The most common eye injuries are cuts or tears of the cornea caused by foreign objects, stones or sticks, hitting the cornea. Extensive injury to the cornea may cause connective tissue deposition, thereby making the cornea opaque.

The cornea was one of the first organs to be transplanted. Several characteristics make it relatively easy to transplant: It is easily accessible and relatively easily removed; it is avascular and therefore does not require extensive circulation, as do other tissues; and it is less immunologically active and therefore less likely to be rejected than are other tissues.

Vascular Layer

The middle tunic of the eyeball is called the vascular layer because it contains most of the blood vessels of the eyeball (see figure 15.12). The arteries of the vascular layer are derived from a number of arteries called **short ciliary arteries**, which pierce the sclera in a circle around the optic nerve. These arteries are branches of the **ophthalmic** (of-thal'mik) **artery**, which is a branch of the internal carotid artery. The vascular layer contains a large number of melanin-containing pigment cells and appears black in color. The portion of the vascular layer associated with the sclera of the eye is the **choroid** (ko'royd). The term *choroid* means membrane and suggests that this layer is relatively thin (0.1–0.2 mm thick). Anteriorly, the vascular layer consists of the ciliary body and iris.

FIGURE 15.12 Sagittal Section of the Eye, Demonstrating the Layers of the Eyeball

The **ciliary** (sil'ē-ar-ē) **body** is continuous with the choroid, and the **iris** is attached at its lateral margins to the ciliary body (figure 15.13*a* and *b*). The ciliary body consists of an outer **ciliary ring** and an inner group of **ciliary processes**, which are attached to the lens by **suspensory ligaments**. The ciliary body contains smooth muscles called the **ciliary muscles**, which are arranged with the outer muscle fibers oriented radially and the central fibers oriented circularly. The ciliary muscles function as a sphincter, and contraction of these muscles can change the shape of the lens. (This function is described in more detail on p. 516.) The ciliary processes are a complex of capillaries and cuboidal epithelium that produces aqueous humor.

The iris is the “colored part” of the eye, and its color differs from person to person. A large amount of melanin in the iris causes it to appear brown or even black. Less melanin results in light brown, green, or gray irises. Even less melanin causes the eyes to appear blue. If there is no pigment in the iris, as in albinism, the iris is pink because blood vessels in the eye reflect light back to the iris.

The genetics of eye color is quite complex. A gene on chromosome 15 and another on chromosome 19 affect eye color, but other genes, not yet identified, are postulated to explain complex eye colors and patterns.

The iris is a contractile structure, consisting mainly of smooth muscle, surrounding an opening called the **pupil**. Light enters the eye through the pupil, and the iris regulates the amount of light by controlling the size of the pupil. The iris contains two groups of smooth muscles: a circular group called the **sphincter pupillae** (pū-pil'ē), and a radial group called the **dilator pupillae** (figure 15.13*c* and *d*). The sphincter pupillae are innervated by parasympathetic fibers from the oculomotor nerve (III). When they contract, the iris

decreases, or constricts, the size of the pupil. The dilator pupillae are innervated by sympathetic fibers. When they contract, the pupil is dilated. The ciliary muscles, sphincter pupillae, and dilator pupillae are sometimes referred to as the intrinsic eye muscles.

Retina

The **retina** is the **inner layer** of the eyeball (see figure 15.12). It consists of the outer **pigmented layer**, which is pigmented simple cuboidal epithelium, and the inner **neural layer**, which responds to light. The neural layer contains 120 million photoreceptor cells called **rods** and 6 or 7 million **cones**, as well as numerous relay neurons. The retina covers the inner surface of the eyeball posterior to the ciliary body. A more detailed description of the histology and function of the retina is presented on page 531.

Eye Pigment

The pupil appears black because of the pigment in the choroid and the pigmented portion of the retina. The eyeball is a closed chamber, which allows light to enter only through the pupil. Light is absorbed by the pigmented inner lining of the eyeball; thus, looking into it is like looking into a dark room. If a bright light is directed into the pupil, however, the reflected light is red because of the blood vessels on the surface of the retina. This is why the pupils of a person looking directly at a flash camera often appear red in a photograph. People with albinism lack the pigment melanin, and the pupil always appears red because no melanin is present to absorb light and prevent it from being reflected from the back of the eyeball. The diffusely lighted blood vessels in the interior of the eyeball contribute to the red color of the pupil.

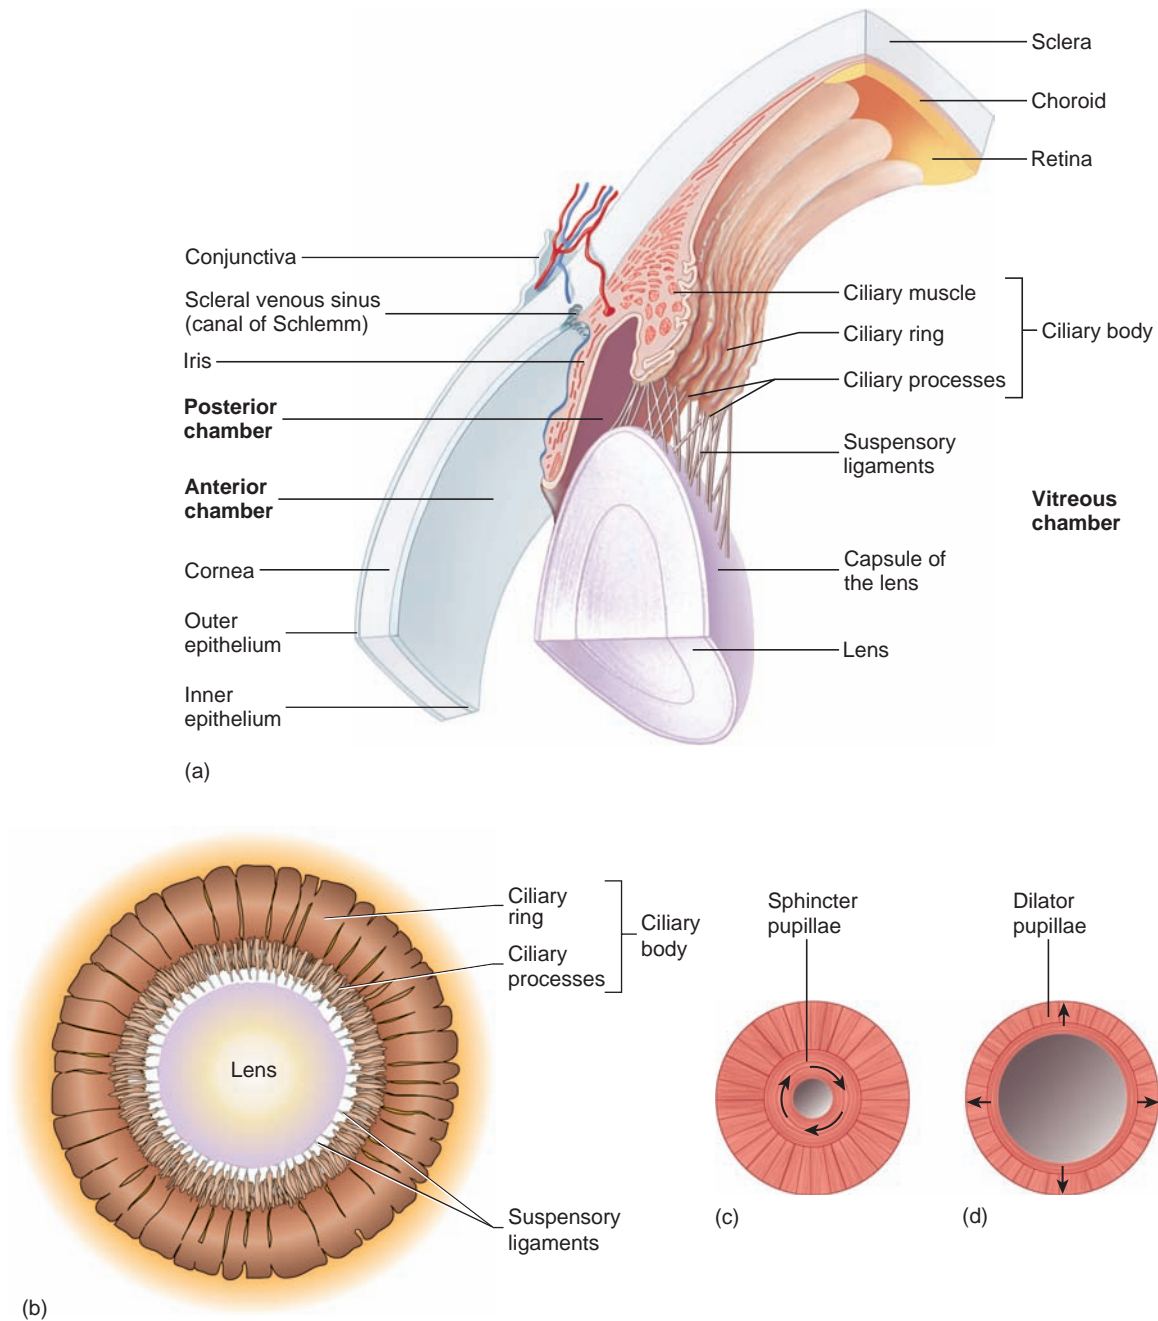

FIGURE 15.13 Lens, Cornea, Iris, and Ciliary Body

(a) The orientation is the same as in figure 15.12. (b) The lens and ciliary body. (c) The sphincter pupillae muscles of the iris constrict the pupil. (d) The dilator pupillae muscles of the iris dilate the pupil.

When the posterior region of the retina is examined with an **ophthalmoscope** (of-thal'mō-skōp; figure 15.14), several important features can be observed. Near the center of the posterior retina is a small yellow spot approximately 4 mm in diameter, the **macula** (mak'ū-lā). In the center of the macula is a small pit, the **fovea** (fō'vē-ă) **centralis**. The fovea and macula make up the region of the retina where light is focused. The fovea is the portion of the retina with the greatest visual acuity (the ability to see fine images) because the photoreceptor cells are more tightly packed

in that portion of the retina than anywhere else. Just medial to the macula is a white spot, the **optic disc**, through which the central retinal artery enters and the central retinal vein exits the eyeball. Branches from these vessels spread over the surface of the retina. This is also the spot where nerve processes from the neural layer meet, pass through the outer two layers, and exit the eye as the optic nerve. The optic disc contains no photoreceptor cells and does not respond to light; therefore, it is called the **blind spot** of the eye.

FIGURE 15.14 Ophthalmoscopic View of the Left Retina

(a) The posterior wall of the retina as seen when looking through the pupil. Notice the vessels entering the eye through the optic disc (the optic nerve) and the macula with the fovea (the part of the retina with the greatest visual acuity). (b) Demonstration of the blind spot. Close your right eye. Hold the figure in front of your left eye and stare at the +. Move the figure toward your eye. At a certain point, when the image of the spot is over the optic disc, the red spot seems to disappear.

Ophthalmoscopic Examination of the Retina

Ophthalmoscopic examination of the posterior retina can reveal some general disorders of the body. **Hypertension**, or high blood pressure, results in “nicking” (compression) of the retinal veins where the abnormally pressurized arteries cross them. **Increased cerebrospinal fluid (CSF) pressure** associated with hydrocephalus may cause swelling of the optic disc. This swelling is referred to as **papilledema** (pă-pil-e-dē'mă). Furthermore, **cataracts** (opacity of the lens) are usually discovered or confirmed by ophthalmoscopic examination.

Chambers of the Eye

The interior of the eye is divided into three chambers: **anterior chamber**, **posterior chamber**, and **vitreous** (vit'rē-ŭs), or **postremal chamber** (see figure 15.12). The anterior chamber lies between the cornea and the iris, and a smaller posterior chamber lies between the iris and the lens (see figure 15.13). These two chambers are filled with **aqueous humor**, which helps maintain intraocular pressure. The pressure within the eyeball keeps it inflated and is largely responsible for maintaining the shape of the eyeball. The aqueous humor also refracts light and provides nutrition for the structures of the anterior chamber, such as the

cornea, which has no blood vessels. Aqueous humor is produced by the ciliary processes as a blood filtrate and is returned to the circulation through a venous ring at the base of the cornea called the scleral venous sinus (canal of Schlemm; shlem; see figure 15.13). The production and removal of aqueous humor result in the “circulation” of aqueous humor and maintenance of a constant intraocular pressure. If circulation of the aqueous humor is inhibited, a defect called **glaucoma** (glaw-kō'mă), which is an abnormal increase in intraocular pressure, can result.

The vitreous chamber of the eye is much larger than the anterior and posterior chambers. It is surrounded almost completely by the retina and is filled with a transparent, jellylike substance, **vitreous** (vit'rē-ŭs) **humor**. Vitreous humor is not produced as rapidly as is the aqueous humor, and its turnover is extremely slow. The vitreous humor helps maintain intraocular pressure and therefore the shape of the eyeball, and it holds the lens and retina in place. It also functions in the refraction of light in the eye.

Lens

The **lens** is an unusual biologic structure. It is transparent and biconvex, with the greatest convexity on its posterior side. The lens consists of a layer of cuboidal epithelial cells on its anterior surface and a posterior region of very long, columnar epithelial cells called **lens fibers**. Cells from the anterior epithelium proliferate and give rise to the lens fibers at the equator of the lens. The lens fibers lose their nuclei and other cellular organelles and accumulate a set of proteins called **crystallines**. This crystalline lens is covered by a highly elastic, transparent **capsule**.

The lens is suspended between the two eye compartments by the suspensory ligaments of the lens, which are connected from the ciliary body to the lens capsule.

- 17** Describe the lens of the eye, and explain how the lens is held in place.

Functions of the Complete Eye

The iris of the eye allows light into the eye, and the lens, cornea, and humors focus the light onto the retina. The light striking the retina is converted into action potentials, which are relayed to the brain.

The electromagnetic spectrum is the entire range of wavelengths, or frequencies, of electromagnetic radiation, from very short gamma waves at one end of the spectrum to the longest radio waves at the other end (figure 15.15). **Visible light** is the portion of the electromagnetic spectrum that can be detected by the human eye. Light has characteristics of both particles (photons)

FIGURE 15.15 Electromagnetic Spectrum

The spectrum of visible light is pulled out and expanded. The wavelengths of the various colors are also depicted.

and waves, with a wavelength between 400 and 700 nm. This range sometimes is called the range of visible light or, more correctly, the **visible spectrum**. Within the visible spectrum, each color has a different wavelength.

An important characteristic of light is that it can be refracted (bent). As light passes from air to a denser substance, such as glass or water, its speed is reduced. If the surface of that substance is at an angle other than 90 degrees to the direction the light rays are traveling, the rays are bent as a result of variation in the speed of light as it encounters the new medium. This bending of light is called **refraction**.

If the surface of a lens is concave, with the lens thinnest in the center, the light rays diverge as a result of refraction. If the surface is convex, with the lens thickest in the center, the light rays tend to converge. As light rays converge, they finally reach a point at which they cross. This point is called the **focal point (FP)**, and causing light to converge is called **focusing**. No image is formed exactly at the focal point, but an inverted, focused image can form on a surface located some distance past the focal point. How far past the focal point the focused image forms depends on a number of factors. A biconvex lens causes light to focus closer to the lens than does a lens with a single convex surface. Furthermore, the more nearly spherical the lens, the closer to the lens the light is focused; the more flattened the biconcave lens, the more distant is the point where the light is focused.

If light rays strike an object that is not transparent, they bounce off the surface. This phenomenon is called **reflection**. If the surface is very smooth, such as the surface of a mirror, the light rays bounce off in a specific direction. If the surface is rough, the light rays are reflected in several directions and produce a more diffuse reflection.

The focusing system of the eye projects a clear image on the retina. Light rays converge as they pass from the air through the convex cornea. Additional convergence occurs as light encounters the aqueous humor, lens, and vitreous humor. The greatest contrast in media density is between the air and the cornea; therefore, the greatest amount of convergence occurs at that point. The shape of the cornea and its distance from the retina are fixed, however, so that no adjustment in the location of the focal point can be made by the cornea. Fine adjustment in focal point location is accomplished by changing the shape of the lens. In general, focusing can be accomplished in two ways. One is to keep the shape of the lens constant and move it nearer or farther from the point at which the image will be focused, such as occurs in a camera, microscope, or telescope. The second way is to keep the distance constant and to change the shape of the lens, which is the technique used in the eye.

As light rays enter the eye and are focused, the image formed just past the focal point is inverted (figure 15.16). Action potentials that represent the inverted image are passed to the visual cortex of the cerebrum, where the brain interprets them as being right side up.

Visual Image Inversion

Because the visual image is inverted when it reaches the retina, the image of the world focused on the retina is upside down. The brain processes information from the retina so that the world is perceived the way “it really is.” If, as an experiment, a person wears glasses that invert the image entering the eye, he or she will see the world upside down for a few days, after which time the brain adjusts to the new input to set the world right side up again. If the glasses are then removed, another adjustment period is required before the world is made right by the brain.

FIGURE 15.16 Focus and Accommodation by the Eye

The focal point (FP) is where light rays cross. (a) Distant image. The lens is flattened, and the image is focused on the retina. (b) Accommodation for near vision. The lens is more rounded, and the image is focused on the retina.

When the ciliary muscles are relaxed, the suspensory ligaments of the ciliary body maintain elastic pressure on the lens, thereby keeping it relatively flat and allowing for distant vision (see figure 15.16a). The condition in which the lens is flattened so that nearly parallel rays from a distant object are focused on the retina is referred to as **emmetropia** (em-ě-trō'pē-ă; measure) and is the normal resting condition of the lens. The point at which the lens does not have to thicken for focusing to occur is called the **far point of vision** and normally is 20 feet or more from the eye.

When an object is brought closer than 20 feet to the eye, three events occur to bring the image into focus on the retina: accommodation by the lens, constriction of the pupil, and convergence of the eyes.

1. **Accommodation.** When the eye focuses on a nearby object, the ciliary muscles contract as a result of parasympathetic stimulation from the oculomotor nerve (III). This sphincterlike contraction pulls the choroid toward the lens to reduce the tension on the suspensory ligaments. This allows the lens to assume a more spherical form because of its own elastic nature (see figure 15.16b). The more spherical lens

then has a more convex surface, causing greater refraction of light. This process is called accommodation.

As light strikes a solid object, the rays are reflected in every direction from the surface of the object. Only a small portion of the light rays reflected from a solid object, however, pass through the pupil and enter the eye. An object far away from the eye appears small, compared with a nearby object, because only nearly parallel light rays enter the eye from a distant object (see figure 15.16a). Converging rays leaving an object closer to the eye can also enter the eye (see figure 15.16b), and the object appears larger.

When rays from a distant object reach the lens, they do not have to be refracted to any great extent to be focused on the retina, and the lens can remain fairly flat. When an object is closer to the eye, the more obliquely directed rays must be refracted to a greater extent to be focused on the retina.

As an object is brought closer and closer to the eye, accommodation becomes more and more difficult because the lens cannot become any more convex. At some point, the eye no longer can focus the object, and it is seen as a blur. The point at which this blurring occurs is called the **near point of vision**, which is usually about 2–3 inches from the eye for children, 4–6 inches for a young adult, 20 inches for a 45-year-old adult, and 60 inches for an 80-year-old adult. This increase in the near point of vision, called **presbyopia**, occurs because the lens becomes more rigid with increasing age, which is primarily why some older people say they could read with no problem if they only had longer arms.

Vision Charts

When a person's visual acuity is tested, a chart is placed 20 feet from the eye, and the person is asked to read a line of letters that is standardized for normal vision at 20 feet. If the person can read the line, the vision is considered to be 20/20, which means that the person can see at 20 feet what people with normal vision can see at 20 feet. If, on the other hand, the person can see words only at 20 feet that people with normal vision can see at 40 feet, the vision is considered 20/40.

2. **Pupil constriction.** **Depth of focus** is the greatest distance through which an object can be moved and still remain in focus on the retina. The main factor affecting depth of focus is the size of the pupil. If the pupillary diameter is small, the depth of focus is greater than if the pupillary diameter is large. With a smaller pupillary opening, an object may therefore be moved slightly nearer or farther from the eye without disturbing its focus. This is particularly important when viewing an object at close range because the interest in detail is much greater, and therefore the acceptable margin for error is smaller. When the pupil is constricted, the light entering the eye tends to pass more nearly through the center of the lens and is more accurately focused than light passing through the edges of the lens. Pupillary diameter also regulates the amount of light entering the eye. The dimmer the light, the greater the pupil diameter must be. As the pupil constricts during close vision, therefore, more light is required on the object being observed.

3. **Convergence.** Because the light rays entering the eyes from a distant object are nearly parallel, both pupils can pick up the light rays when the eyes are directed more or less straight ahead. As an object moves closer, however, the eyes must be rotated medially so that the object is kept focused on corresponding areas of each retina. Otherwise, the object appears blurry. This medial rotation of the eyes is accomplished by a reflex that stimulates the medial rectus muscle of each eye. This movement of the eyes is called convergence. Convergence can easily be observed. Have someone stand facing you. Have the person reach out one hand and extend an index finger as far in front of his or her face as possible. While the person keeps the gaze fixed on the finger, have the person slowly bring the finger in toward his or her nose until finally touching it. Notice the movement of the person's pupils. What happens?

PREDICT 5

- 18** **What causes light to refract? What is a focal point? What is emmetropia?**

- 19** **Describe the changes that occur in the lens, pupil, and extrinsic eye muscles as an object moves from 25 feet away to 6 inches away. Define near point and far point of vision.**

Structure and Function of the Retina

Leonardo da Vinci, in speaking of the eye, said, "Who would believe that so small a space could contain the images of all the universe?" The retina of each eyeball, which gives us the potential to see the whole world, is about the size and thickness of a postage stamp.

The retina consists of a neural layer and a pigmented layer. The neural layer contains three layers of neurons: photoreceptor, bipolar, and ganglionic. The cell bodies of these neurons form nuclear layers separated by plexiform layers, where the neurons of adjacent layers synapse with each other (figure 15.17). The outer plexiform (plexus-like) layer is between the photoreceptor and bipolar cell layers. The inner plexiform layer is between the bipolar and ganglionic cell layers.

The pigmented layer, or pigmented epithelium, consists of a single layer of cells. This layer of cells is filled with melanin pigment and, together with the pigment in the choroid, provides a black matrix, which enhances visual acuity by isolating individual photoreceptors and reducing light scattering. This pigmentation is not strictly necessary for vision, however. People with albinism (lack of pigment) can see, although their visual acuity is reduced because of some light scattering.

FIGURE 15.17 Retina

(a) Colorized electron micrograph of rods and cones. (b) Section through the retina with its major layers labeled.

FIGURE 15.18 Sensory Receptor Cells of the Retina

(a) Rod cell. (b) Cone cell. (c) An enlargement of the discs in the outer segment. (d) An enlargement of one of the discs, showing the relation of rhodopsin and a cGMP gated Na^+ channel in the membrane.

The portion of the neural layer nearest the pigmented layer consists of rods and cones. The rods and cones are photoreceptor cells, which are sensitive to stimulation from visible light. The light-sensitive portion of each photoreceptor cell is adjacent to the pigmented layer.

Rods

Rods are bipolar photoreceptor cells involved in noncolor vision and are responsible for vision under conditions of reduced light (table 15.1). The modified, dendritic, light-sensitive part of rod cells is cylindrical, with no taper from base to apex (figure 15.18a). This rod-shaped photoreceptive part of the rod cell contains about 700 double-layered membranous discs. The discs contain **rhodopsin** (rō-dop'sin),

a purple pigment, which consists of the protein **opsin** covalently bound to a yellow photosensitive pigment called **retinal** (derived from vitamin A). Opsin is a protein much like a channel protein, consisting of seven transmembrane helical regions. An extracellular plug closes the external opening of the opsin “channel.” G proteins and cyclic GMP (cGMP) phosphodiesterase enzymes are also associated with the disc membranes. Sodium ion channels are located in the outer membrane of the rod cell outer segment (figure 15.18d).

Figure 15.19 depicts the changes that rhodopsin undergoes in response to light. In the resting (dark) state, 11-*cis*-retinal is tightly bound to the internal surface of opsin. The extracellular plug helps keep retinal from being lost from the cell out of the opsin “channel.” Cyclic GMP is attached to the Na^+ channel, keeping it

TABLE 15.1 Rods and Cones

Photoreceptive End	Photoreceptive Molecule	Function	Location
Rod Cylindrical	Rhodopsin	Noncolor vision; vision under conditions of low light	Over most of retina; none in fovea
Cone Conical	Iodopsin	Color vision; visual acuity	Numerous in fovea and macula; sparse over rest of retina

1. Retinal (in an inactive configuration called 11-*cis*-) is attached inside opsin to make rhodopsin. Cyclic GMP attached to a Na⁺ channel keeps it open.
2. Light causes retinal to change shape from 11-*cis*-retinal to all-*trans*-retinal. This change causes opsin also to change shape (from its dark to light configuration). This activated rhodopsin activates a G protein (called transducin), which activates a cGMP phosphodiesterase. The cGMP phosphodiesterase catalyzes the conversion of cGMP to GMP, which decreases cGMP concentration and causes the cGMP to diffuse away from the Na⁺ channels, closing these channels.
3. All-*trans*-retinal detaches from opsin. Transducin is reassociated and cGMP phosphodiesterase is inactivated.
4. Cyclic GMP concentration increases and cGMP attaches to Na⁺ channels, causing them to open.
5. All-*trans*-retinal is converted to 11-*cis*-retinal, a process that requires energy.
6. 11-*cis*-retinal attaches to opsin, which returns to its original (*dark*) configuration.

PROCESS FIGURE 15.19 Rhodopsin Cycle

open. As light is absorbed by rod cells, retinal changes shape from 11-*cis*-retinal to all-*trans*-retinal. This change causes opsin to also change shape (dark to light state). The changes in opsin activate a G protein, called **transducin** (trans-doo'sin), which activates

a cyclic GMP phosphodiesterase. The cGMP phosphodiesterase catalyzes the conversion of cGMP to GMP. This reaction causes cGMP to diffuse away from Na⁺ channels, resulting in closure of the Na⁺ channels and hyperpolarization of the cell (figure 15.20).

PROCESS FIGURE 15.20 Rod Cell Hyperpolarization

(a) Changes in the rod cell membrane potential following the opsin and retinal cell shape changes is a hyperpolarization. (b) Unstimulated rod cell (*dark*). (c) Stimulated rod cell (*light*).

This hyperpolarization in the photoreceptor cells is somewhat remarkable because most neurons respond to stimuli by depolarizing. When photoreceptor cells are not exposed to light and are in a resting, nonactivated state, gated Na^+ channels in their membranes are open, and Na^+ flow into the cell. This influx of Na^+ , referred to as the dark current, causes the photoreceptor cells to release the neurotransmitter glutamate from their presynaptic terminals (see figure 15.20). Glutamate binds to receptors on the postsynaptic membranes of the bipolar cells of the retina, causing them to hyperpolarize. Thus, glutamate causes an inhibitory postsynaptic potential (IPSP) in the bipolar cells. The influx of Na^+ is offset by the efflux of K^+ through nongated K^+ channels. Equilibrium of Na^+ and K^+ in the cell is maintained by a Na^+-K^+ pump.

When photoreceptor cells are exposed to light, the Na^+ channels close, fewer Na^+ enter the cell, and the amount of glutamate released from the presynaptic terminals decreases. As a result, the hyperpolarization in the bipolar cells decreases, and they depolarize sufficiently to release neurotransmitters, which stimulate ganglionic cells to generate action potentials. The number of Na^+ channels that close and the degree to which they close is proportional to the amount of light exposure.

At the final stage of this light-initiated reaction, retinal is completely released from the opsin. This free retinal may then be converted back to vitamin A, from which it was originally derived. The total vitamin A/retinal pool is in equilibrium so that under normal conditions the amount of free retinal is relatively constant. To create more rhodopsin, the altered retinal must be converted back to its original shape, a reaction that requires energy. Once the retinal resumes its original shape, its recombination with opsin is spontaneous, and the newly formed rhodopsin can again respond to light.

Light and dark adaptation is the adjustment of the eyes to changes in light. Adaptation to light or dark conditions, which occurs when a person goes out of a darkened building into the sunlight or vice versa, is accomplished by changes in the amount of available rhodopsin. In bright light, excess rhodopsin is broken down so that not as much is available to initiate action potentials, and the eyes become adapted to bright light. Conversely, in a dark room more rhodopsin is produced, making the retina more light-sensitive.

PREDICT 6

If the breakdown of rhodopsin occurs rapidly and production is slow, do eyes adapt more rapidly to light or dark conditions?

Light and dark adaptation also involves pupil reflexes. The pupil enlarges in dim light to allow more light into the eye and contracts in bright light to allow less light into the eye. In addition, rod function decreases and cone function increases in light conditions, and vice versa during dark conditions. This occurs because rod cells are more sensitive to light than cone cells and because rhodopsin is depleted more rapidly in rods than in cones.

Cones

Color vision and visual acuity are functions of cone cells. Color is a function of the wavelength of light, and each color results from a certain wavelength within the visible spectrum. Even though rods are very sensitive to light, they cannot detect color, and

sensory input that ultimately reaches the brain from these cells is interpreted by the brain as shades of gray. Cones require relatively bright light to function. As a result, as the light decreases, so does the color of objects that can be seen until, under conditions of very low illumination, the objects appear gray. This occurs because, as the light decreases, fewer cone cells respond to the dim light.

Cones are bipolar photoreceptor cells with a conical light-sensitive part that tapers slightly from base to apex (see figure 15.18*b*). The outer segments of the cone cells, like those of the rods, consist of double-layered discs. The discs are slightly more numerous and more closely stacked in the cones than in the rods. Cone cells contain a visual pigment, **iodopsin** (i-ō-dop'sin), which consists of retinal combined with a photopigment opsin protein. Three major types of color-sensitive opsin exist—blue, red, and green; each closely resembles the opsin proteins of rod cells but with somewhat different amino acid sequences. These color photopigments function in much the same manner as rhodopsin; however, whereas rhodopsin responds to the entire spectrum of visible light, each iodopsin is sensitive to a much narrower spectrum.

Most people have one red pigment gene and one or more green pigment genes located in a tandem array on each X chromosome. An enhancer gene on the X chromosome apparently determines that only one color opsin gene is expressed in each cone cell. Only the first or second gene in the tandem array is expressed in each cone cell so that some cone cells express only the red pigment gene and others express only one of the green pigment genes.

As can be seen in figure 15.21, although considerable overlap occurs in the wavelength of light to which these pigments

FIGURE 15.21 Wavelengths to Which Each of the Three Visual Pigments are Sensitive: Blue, Green, Red

There are actually two forms of the red pigment. One, found in 60% of the population, has a serine at position 180; the other, found in 40% of the population, has an alanine at position 180. Each red pigment has a slightly different wavelength sensitivity.

are sensitive, each pigment absorbs light of a certain range of wavelengths. As light of a given wavelength, representing a certain color, strikes the retina, all cone cells containing photopigments capable of responding to that wavelength generate action potentials. Because of the overlap among the three types of cones, especially between the green and red pigments, different proportions of cone cells respond to each wavelength, thus allowing color perception over a wide range. Color is interpreted in the visual cortex as combinations of sensory input originating from cone cells. For example, when orange light strikes the retina, 99% of the red-sensitive cones respond, 42% of the green-sensitive cones respond, and no blue cones respond. When yellow light strikes the retina, the response is shifted so that a greater number of green-sensitive cones respond. The variety of combinations created allows humans to distinguish several million gradations of light and shades of color.

Seeing Red

Not everyone sees the same red. Two forms of the red photopigment are common in humans. Approximately 60% of people have the amino acid serine in position 180 of the red opsin protein, whereas 40% have alanine in that position. That subtle difference in the protein results in slightly different absorption characteristics (see figure 15.21). Even though we were each taught to recognize red when we see a certain color, we apparently do not see that color in quite the same way. This difference may contribute to people having different favorite colors.

Distribution of Rods and Cones in the Retina

Cones are involved in visual acuity, in addition to their role in color vision. The macula and especially the fovea centralis are used when visual acuity is required, such as for focusing on the words of this page. The fovea centralis has about 35,000 cones and no rods. The rest of the macula has more cones than rods. The 120 million rods are 10–20 times more plentiful than cones over most of the remaining retina, however. They are more highly concentrated away from the macula and are more important in low-light conditions.

PREDICT 7

Explain why at night a person may notice a movement “out of the corner of the eye,” but, when the person tries to focus on the area of movement, it appears as though nothing is there.

Inner Layers of the Retina

The middle and inner nuclear layers of the neural layer of the retina consist of two major neuron types: bipolar and ganglion cells. The rod and cone photoreceptor cells synapse with **bipolar cells**, which in turn synapse with **ganglion cells**. Axons from the ganglion cells pass over the inner surface of the retina (see figure 15.17), except in the area of the fovea centralis; converge at the **optic disc**; and exit the eye as the **optic nerve** (II). The fovea centralis is devoid of ganglion cell processes, resulting in a small

depression in this area—thus the name *fovea*, meaning small pit. As a result of the absence of ganglion cell processes in addition to the concentration of cone cells mentioned previously, visual acuity is further enhanced in the fovea centralis because light rays do not have to pass through as many tissue layers before reaching the photoreceptor cells.

Rod and cone cells differ in the way they interact with bipolar and ganglion cells. One bipolar cell receives input from numerous rods, and one ganglion cell receives input from several bipolar cells so that spatial summation of the signal occurs and the signal is enhanced, thereby allowing awareness of stimulus from very dim light sources but decreasing visual acuity in these cells. Cones, on the other hand, exhibit little or no convergence on bipolar cells so that one cone cell may synapse with only one bipolar cell. This system reduces light sensitivity but enhances visual acuity.

The **receptive field** of each ganglion cell, the area from which a ganglion cell receives input, is roughly circular, with a smaller portion in the center, called the receptive field center, and a larger surrounding area. The receptive fields in the fovea centralis are very small, compared with receptive fields of more peripheral parts of the retina. The small size of these receptive fields is consistent with the visual acuity of the fovea centralis.

Two types of receptive fields exist: on-center ganglion cells and off-center ganglion cells. On-center cells generate more action potentials when light is directed onto the receptive field center. Off-center neurons generate more action potentials when light is turned off in the receptive field center or when light shines on the surrounding area. These receptive fields respond primarily to contrasts in light (edges) rather than the absolute intensity of light.

Within the inner layers of the retina, interneurons modify the signals from the photoreceptor cells before the signal ever leaves the retina (see figure 15.17). **Horizontal cells** form the outer plexiform layer and synapse with photoreceptor cells and bipolar cells. **Amacrine** (am’ă-krin) **cells** form the inner plexiform layer and synapse with bipolar and ganglion cells. **Interplexiform cells** form the bipolar layer and synapse with amacrine, bipolar, and horizontal cells to form a feedback loop. The interneurons are either excitatory or inhibitory on the cells with which they synapse. These interneurons enhance borders and contours, thereby increasing the intensity at boundaries, such as the edge of a dark object against a light background.

- 20 **What is the function of the pigmented retina and of the choroid?**
- 21 **Describe the changes that occur in a rod cell after light strikes rhodopsin. How does rhodopsin re-form? Why is the response of a rod cell to a stimulus unusual?**
- 22 **How does dark and light adaptation occur?**
- 23 **What are the three types of cone cells? How do they produce the colors we see?**
- 24 **Describe the arrangement of rods and cones in the fovea, the macula, and the periphery of the eye.**
- 25 **Starting with a rod or cone cell, name the cells or structures that an action potential encounters while traveling to the visual cortex.**

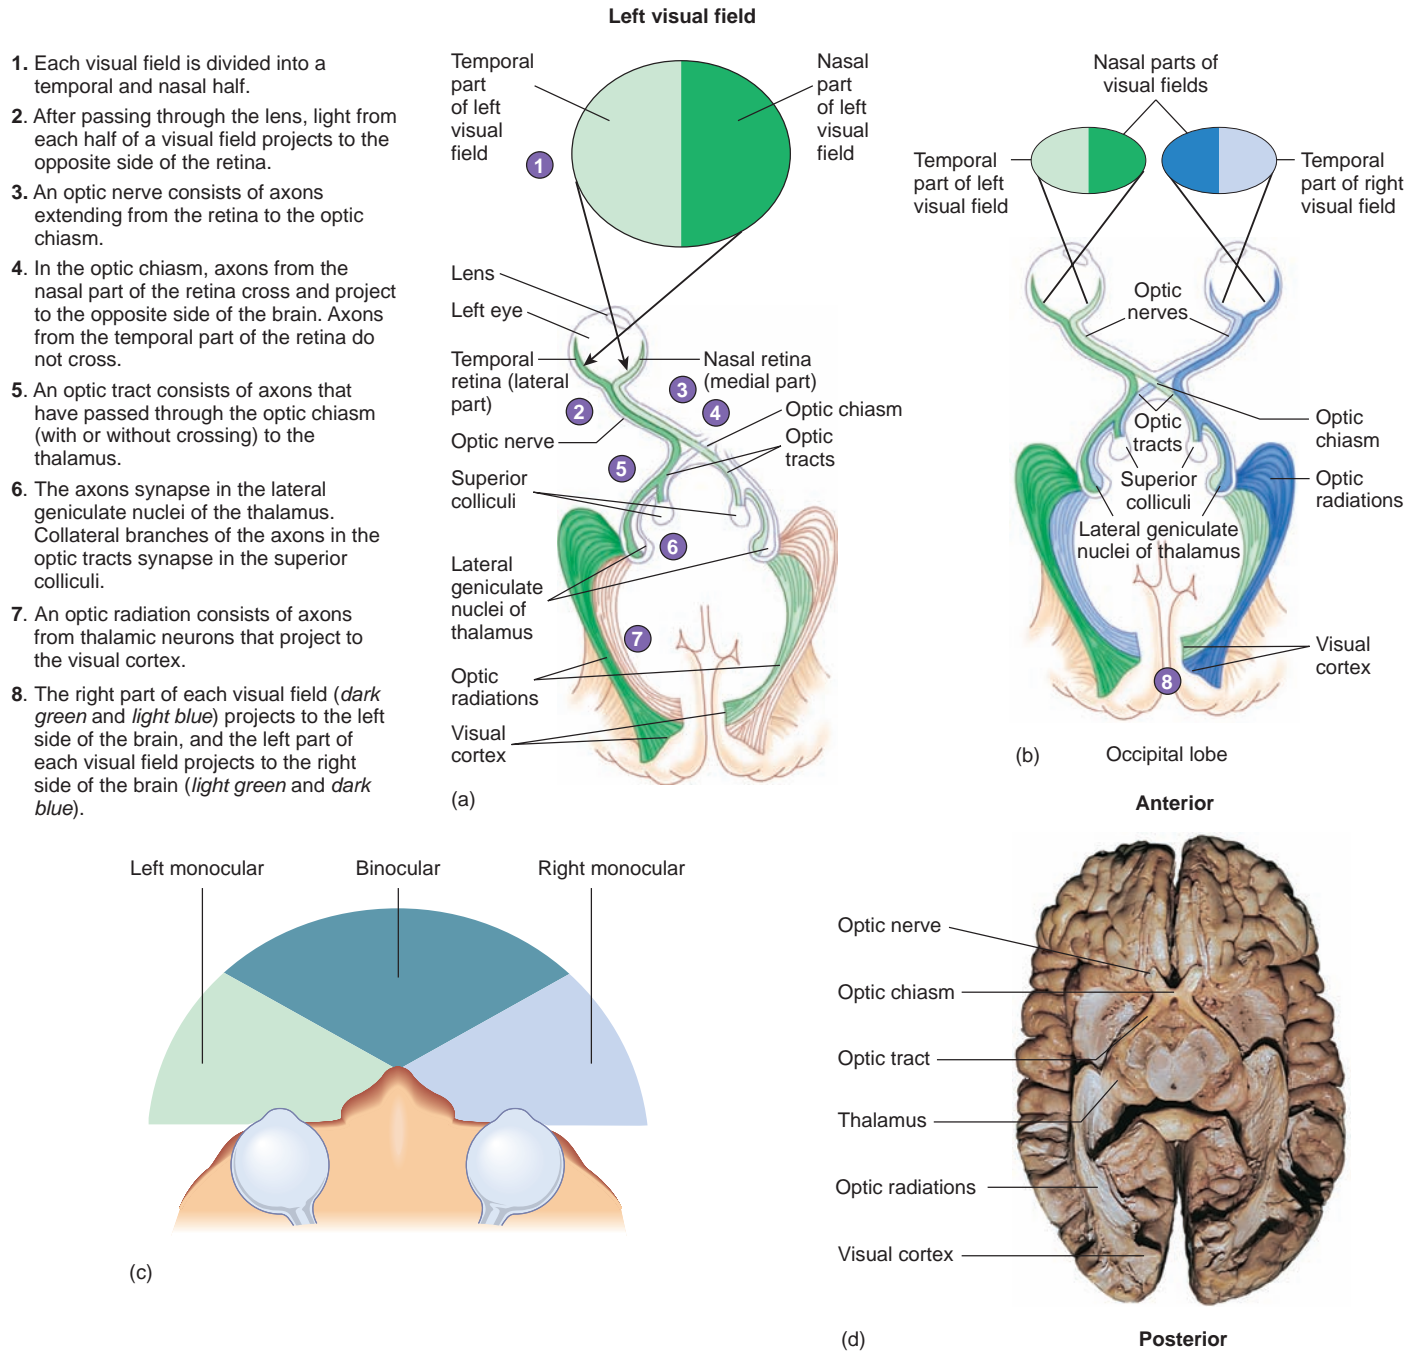

Motion Pictures

Action potentials pass from the retina through the optic nerve at the rate of 20–25/s. We “see” a given image for a fraction of a second longer than it actually appears. Motion pictures take advantage of these two facts. When still photographs are flashed on a screen at the rate of 24 frames per second, they appear to flow into each other, and a motion picture results.

Neuronal Pathways for Vision

The optic nerve (II; figure 15.22) leaves the eye and exits the orbit through the optic foramen to enter the cranial cavity. Just inside the vault and just anterior to the pituitary, the optic nerves are connected to each other at the **optic chiasm** (kī'azm). Ganglion cell axons from the nasal retina (the medial portion of the retina) cross through the optic chiasm and project to the

PROCESS FIGURE 15.22 Visual Pathways

CLINICAL GENETICS

Retinitis Pigmentosa

Retinitis pigmentosa (RP) is an inherited disorder characterized by the progressive degeneration of the retina, accompanied by the accumulation of pigment islands in the retina. Diagnosis of the disease can usually be made on the basis of family history and the presence of dark spots in the retina. RP results in the degeneration of rod and/or cone cells. The degeneration and death of photoreceptor cells result in progressive vision loss. In most forms of RP, called **rod-cone dystrophies**, the rod cells degenerate first. Progression of the disease includes night blindness and loss of peripheral vision as more rod cells are lost, because rod cells are most important for those two functions. Night blindness is often the first symptom of RP. Some patients retain a small amount of central vision throughout life (figure A). Other forms of RP, called **cone-rod dystrophies**, first affect cone cells, resulting in loss of visual acuity and color vision, because cone cells are most important for those two functions.

Symptoms of RP most often appear first in young adults, and the disease progresses throughout the person's life. RP is a fairly uncommon disease, affecting about 1 in 4000 people worldwide. There is no cure for this condition, although the use of sunglasses

FIGURE A Visual Image as Seen by a Person with RP

and/or vitamin therapy (such as vitamin A) may delay the progression of the disease. A Swiss company has tested an electronic retinal implant. In addition, a French biotech company is testing the delivery of a genetically engineered protein, ciliary neurotrophic factor (CNTF), into the vitreous body of RP patients, using the company's patented encapsulated cell technology (ECT). The latest clinical trials of this technique indicate that some patients experience improvement in visual acuity. Stem cell research is also currently in progress in an attempt to correct RP.

RP may result from defects in any one of at least 36 different genes. It may be inherited as

an autosomal-recessive, autosomal-dominant, or X-linked condition. The heterozygous autosomal-dominant forms of RP generally have a milder course than the autosomal-recessive or X-linked forms. A single mutation in the opsin gene, affecting one amino acid in opsin, apparently is sufficient to cause photoreceptor cell death. A gene for opsin has been mapped to chromosome 3 and many different mutations (multiple alleles) of the opsin gene have been found in cases of autosomal-dominant RP. The opsin protein is composed of 338 amino acids. A mutation resulting in a change in either amino acid 23 or 28, within the opsin external plug, can cause RP. Because of the mutation, the external plug changes shape and does not adequately close the extracellular opening of opsin, thereby allowing retinal to leak out of the cells. This leaking retinal pigment infiltrates the sensory retina, causing it to degenerate.

At least one autosomal-recessive rhodopsin mutation has also been found. Mutations in the cGMP phosphodiesterase gene also have been linked to some cases of autosomal-recessive RP. Other forms of RP have been mapped to chromosomes 1, 6, 7, and 17. Autosomal-dominant cone-rod dystrophy has been mapped to chromosome 19.

opposite side of the brain. Ganglion cell axons from the temporal retina (the lateral portion of the retina) pass through the optic nerves and project to the brain on the same side of the body without crossing.

Beyond the optic chiasm, the route of the ganglionic axons is called the **optic tract** (see figure 15.22). Most of the optic tract axons terminate in the **lateral geniculate nucleus** of the thalamus. Some axons do not terminate in the thalamus but separate from the optic tract to terminate in the **superior colliculi**, the center for visual reflexes (see chapter 13). Neurons of the lateral geniculate nucleus form the fibers of the **optic radiations**, which project to the **visual cortex** in the **occipital lobe**. Neurons of the visual cortex integrate the messages coming from the retina into a single message, translate that message into a mental image, and then transfer the image to other parts of the brain, where it is evaluated and either ignored or acted on.

The projections of ganglion cells from the retina can be related to the **visual fields** (see figure 15.22). The visual field of one eye can

be evaluated by closing the other eye. Everything that can be seen with the one open eye is the visual field of that eye. The visual field of each eye can be divided into temporal (lateral) and nasal (medial) parts. In each eye, the temporal part of the visual field projects onto the nasal retina, whereas the nasal part of the visual field projects to the temporal retina. The projections and nerve pathways are arranged in such a way that images entering the eye from the right part of each visual field project to the left side of the brain. Conversely, the left part of each visual field projects to the right side of the brain.

Tunnel Vision

Because the optic chiasm lies just anterior to the pituitary, a pituitary tumor can put pressure on the optic chiasm and may result in visual defects. Because the nerve fibers crossing in the optic chiasm are carrying information from the temporal halves of the visual fields, a person with optic chiasm damage cannot see objects in the temporal halves of the visual fields, a condition called **tunnel vision**. Tunnel vision is often an early sign of a pituitary tumor.

CLINICAL FOCUS

Eye Disorders

MYOPIA

Myopia (mī-ō'pē-ā), or nearsightedness, is the ability to see close objects clearly but distant objects appear blurry. Myopia is a defect of the eye in which the focusing system, the cornea and lens, is optically too powerful, or the eyeball is too long (axial myopia). As a result, the focal point is too near the lens, and the image is focused in front of the retina (figure Ba).

Myopia is corrected by a concave lens that counters the refractive power of the eye. Concave lenses cause the light rays coming to the eye to diverge and are therefore called “minus” lenses (figure Bb).

Another technique for correcting myopia is **radial keratotomy** (ker'ā-tot'ō-mē), which consists of making a series of four to eight radiating cuts in the cornea. The cuts are intended to slightly weaken the dome of the cornea so that it becomes more flattened and eliminates the myopia. One problem with the

technique is that it is difficult to predict exactly how much flattening will occur. In one study of 400 patients 5 years after the surgery, 55% had normal vision, 28% were still somewhat myopic, and 17% had become hyperopic. Another problem is that some patients are bothered by glare following radial keratotomy because the slits apparently do not heal evenly.

An alternative procedure is **lasix**, or **laser corneal sculpturing**, in which a thin portion of the cornea is etched away to make the cornea less convex. The advantage of this procedure is that the results can be more accurately predicted than those from radial keratotomy.

HYPEROPIA

Hyperopia (hī-per-ō'pē-ā), or farsightedness, is the ability to see distant objects clearly but close objects appear blurry. Hyperopia is a disorder in which the cornea and lens system is optically too weak or the eyeball is too

short. The image is focused behind the retina (figure Bc).

Hyperopia can be corrected by convex lenses that cause light rays to converge as they approach the eye (figure Bd). Such lenses are called “plus” lenses.

PRESBYOPIA

Presbyopia (prez-bē-ō'pē-ā) is the normal, presently unavoidable degeneration of the accommodation power of the eye that occurs as a consequence of aging. It occurs because the lens becomes sclerotic and less flexible. The eye is presbyopic when the near point of vision has increased beyond 9 inches. The average age for onset of presbyopia is the midforties. Avid readers and people engaged in fine, close work may develop the symptoms earlier.

Presbyopia can be corrected by the use of “reading glasses,” which are worn only for

Continued

FIGURE B Visual Disorders and Their Correction by Various Lenses

Continued

close work and are removed when the person wants to see at a distance. It is sometimes annoying to keep removing and replacing glasses because reading glasses hamper vision of only a few feet away. This problem may be corrected by the use of half glasses, or by **bifocals**, which have a different lens in the top and the bottom, or by **progressive lenses**, in which the lens is graded.

ASTIGMATISM

Astigmatism (ă-stig'mă-tizm) is a type of refractive error in which the quality of focus is affected. If the cornea or lens is not uniformly curved, the light rays do not focus at a single point but fall as a blurred circle. Regular astigmatism can be corrected by glasses that are formed with the opposite curvature gradation. Irregular astigmatism is a situation in which the abnormal form of the cornea fits no specific pattern and is very difficult to correct with glasses.

STRABISMUS

Strabismus (stra-biz'mūs) is a lack of parallelism of light paths through the eyes. Strabismus can involve one or both eyes, and the eyes may turn in (convergent) or out (divergent). In **concomitant strabismus**, the most common congenital type, the angle between visual axes remains constant, regardless of the direction of the gaze. In **noncomitant strabismus**, the angle varies, depending on the direction of the gaze, and deviates as the gaze changes.

In some cases, the image that appears on the retina of one eye may be considerably different from that appearing on the other eye. This problem is called **diplopia** (di-plō'pē-ă; double vision) and is often the result of weak or abnormal eye muscles.

RETINAL DETACHMENT

Retinal detachment is a relatively common problem that can result in complete blindness. The integrity of the retina depends on the vitreous humor, which keeps the retina pushed against the other layers of the eye. If a hole or tear occurs in the retina, fluid may accumulate between the neural and pigmented layers, thereby separating them. This separation, or detachment, may continue until the neural layer has become totally detached from the pigmented layer and has folded into a funnel-like form around the optic nerve. When the

neural layer becomes separated from its nutrient supply in the choroid, it degenerates, and blindness follows. Causes of retinal detachment include a severe blow to the eye or head; a shrinking of the vitreous humor, which may occur with aging; and diabetes. The space between the sensory and pigmented retina, called the subretinal space, is also important in keeping the retina from detaching, as well as in maintaining the health of the retina. The space contains a gummy substance, which glues the neural layer to the pigmented layer.

COLOR BLINDNESS

Color blindness results from the dysfunction of one or more of the three photopigments involved in color vision. If one pigment is dysfunctional and the other two are functional, the condition is called **dichromatism**. An example of dichromatism is red-green color blindness (figure C).

The genes for the red and green photopigments are arranged in tandem on the X chromosome, which explains why color blindness is over eight times more common in males than in females (see chapter 3).

Six exons exist for each gene. The red and green genes are 96%–98% identical; as a result, the exons may be shuffled to form hybrid genes in some people. Some of the hybrid genes produce proteins with nearly normal function, but others do not. Exon 5 is the most critical for determining normal

red-green function. If the fifth exon from a green gene replaces a red pigment gene that has the fifth exon, the protein made from the gene responds to wavelengths more toward the green pigment range. The person has a red perception deficiency and is not able to distinguish between red and green. If the fifth exon from a red gene replaces a green pigment gene that has the fifth exon, the protein made from the gene responds to wavelengths more toward the red pigment range. The person has a green perception deficiency and is not able to distinguish between red and green.

Apparently, only about 3 of the over 360 amino acids in the color opsin proteins (those at positions 180 in exon 3 and those at 277 and 285 in exon 5) are key to determining their wavelength absorption characteristics. If those amino acids are altered by hydroxylation, the absorption shifts toward the red end of the spectrum. If they are not hydroxylated, the absorption shifts toward the green end.

NIGHT BLINDNESS

Everyone sees less clearly in the dark than in the light. A person with **night blindness**, or nyctalopia, however, may not see well enough in a dimly lit environment to function adequately. **Progressive night blindness** results from general retinal degeneration. This form of night blindness is the type associated with retinitis pigmentosa (RP, see p. 538). Another hereditary form of progressive night blindness

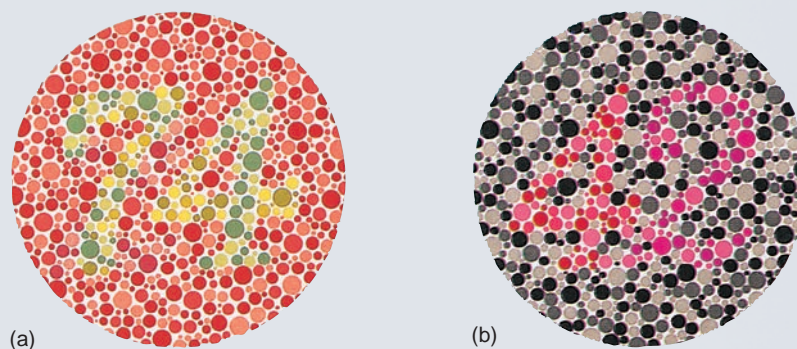

FIGURE C Color Blindness Charts

(a) A person with normal color vision can see the number 74, whereas a person with red-green color blindness sees the number 21. (b) A person with normal color vision can see the number 42. A person with red color blindness sees the number 2, and a person with green color blindness sees the number 4.

Reproduced from *Ishihara's Tests for Colour Blindness* published by Kanehara & Co., Ltd., Tokyo, Japan, but tests for color blindness cannot be conducted with this material. For accurate testing, the original plates should be used.

involves a mutation affecting amino acid 90 in the opsin protein, located in one of the seven trans-membrane helical regions of the protein. This amino acid change changes the shape of opsin and affects the attachment of retinal to opsin. **Stationary night blindness** results from nonprogressive abnormal rod function. Temporary night blindness can result from a vitamin A deficiency.

Patients with night blindness can be helped with electronic optical devices, including monocular pocket scopes and binocular goggles that electronically amplify light.

GLAUCOMA

Glaucoma is a disease of the eye involving increased intraocular pressure caused by a buildup of aqueous humor. It usually results from blockage of the aqueous veins or the scleral venous sinus, restricting drainage of the aqueous humor, or from overproduction of aqueous humor. If untreated, glaucoma can lead to retinal, optic disc, and optic nerve damage. The damage results from the increased intraocular pressure, which is sufficient to close off the blood vessels, causing the starvation and death of the retinal cells.

Glaucoma is one of the leading causes of blindness in the United States, affecting 2% of people over age 35, and accounting for 15% of all blindness. Fifty thousand people in the United States are blind as the result of glaucoma, and it occurs three times more often in black people than in white people. The symptoms include a slow closing in of the field of vision. No pain or redness occurs, nor do light flashes occur.

Glaucoma has a strong hereditary tendency but may develop after surgery or with the use of certain eyedrops containing cortisone. Everyone older than 40 should be checked every 2–3 years for glaucoma; those older than 40 who have relatives with glaucoma should have an annual checkup. During a checkup, the field of vision and the optic nerve are examined. Ocular pressures can also be measured. Glaucoma is usually treated with eyedrops, which do not cure the problem but keep it from advancing. In some cases, laser or conventional surgery may be used.

CATARACT

Cataract (figure Da) is a clouding of the lens resulting from a buildup of proteins. The lens relies on the aqueous humor for its nutrition.

Any loss of this nutrient source leads to degeneration of the lens and, ultimately, opacity of the lens (i.e., a cataract). A cataract may occur with advancing age, infection, or trauma.

A certain amount of lens clouding occurs in 65% of patients older than 50 and 95% of patients older than 65. The decision of whether to remove the cataract depends on the extent to which light passage is blocked. Over 400,000 cataracts are removed in the United States each year. Surgery to remove a cataract is actually the removal of the lens. The posterior portion of the lens capsule is left intact. Although the cornea can still accomplish light convergence, with the lens gone, the rays cannot be focused as well, and an artificial lens must be supplied to help accomplish focusing. In most cases, an artificial lens is implanted into the remaining portion of the lens capsule at the time that the natural lens is removed. The implanted lens helps restore normal vision, but glasses may be required for near vision.

MACULAR DEGENERATION

Macular degeneration (figure Db) is very common in older people. It does not cause total blindness but results in the loss of acute vision. This degeneration has a variety of causes, including hereditary disorders, infections, trauma, tumor, and most often poorly understood degeneration associated with aging. Because no satisfactory medical treatment has been developed, optical aids, such as magnifying glasses, are used to improve visual function.

DIABETES

Loss of visual function is one of the most common consequences of diabetes because a major complication of the disease is dysfunction of the peripheral circulation. Defective circulation to the eye may result in retinal degeneration or detachment. Diabetic retinopathy (figure Dc) is one of the leading causes of blindness in the United States.

INFECTIONS

Trachoma (trä-kō'mă) is the leading cause of blindness worldwide. It is caused by an intracellular microbial infection (*Chlamydia trachomatis*) of the conjunctiva (conjunctivitis). As inflammation resulting from the disease progresses and spreads, the eyelids may turn inward, causing the eyelashes to abrade the cornea, resulting in scar tissue formation in the cornea. The bacteria are spread from one eye to the other by towels, fingers, and other objects. Five hundred million cases of trachoma exist in the world, and 7 million people are blind or otherwise visually impaired as a result of it.

Neonatal gonorrhoeal ophthalmia (of-thal'-mē-ă) is a bacterial infection (*Neisseria gonorrhoeae*) of the eye that causes blindness. If the mother has gonorrhoea, which is a sexually transmitted disease of the reproductive tract, the bacteria can infect the newborn during delivery. The disease can be prevented by treating the infant's eyes with silver nitrate, tetracycline, or erythromycin drops.

FIGURE D Defects in Vision

Visual images as seen with various defects in vision. (a) Cataract. (b) Macular degeneration. (c) Diabetic retinopathy.

PREDICT 8

The lines at *A* and *B* in figure E depict two lesions in the visual pathways. The effect of a lesion at *A* in the optic radiations on the visual fields is depicted (with the right and left fields separated) in the ovals at the bottom of the figure. The black areas indicate what parts of the visual fields are defective. Describe the effect that the lesion at *B* has on the visual fields (see figure 15.22 for help).

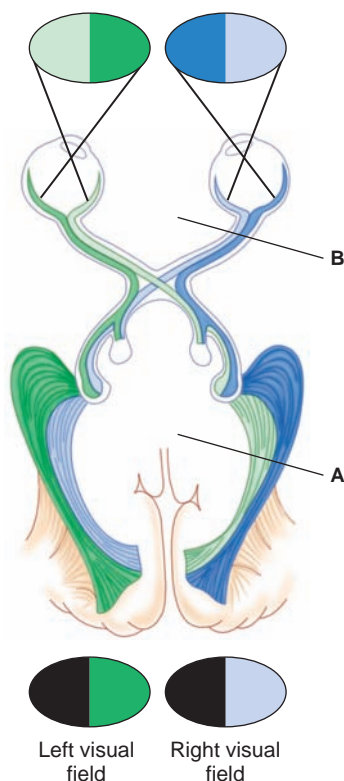

FIGURE E Lesions of Visual Pathways

The visual fields of the eyes partially overlap (see figure 15.22). The region of overlap is the area of **binocular vision**, seen with two eyes at the same time, and it is responsible for **depth perception**, the ability to distinguish between near and far objects and to judge their distance. Because humans see the same object with both eyes, the image of the object reaches the retina of one eye at a slightly different angle from that of the other. With experience, the brain can interpret these differences in angle so that distance can be judged quite accurately.

26 What is a visual field? How do the visual fields project to the brain?

27 Explain how binocular vision allows for depth perception.

HEARING AND BALANCE

The organs of hearing and balance are divided into three parts: the external, middle, and inner ears (figure 15.23). The external and middle ears are involved in hearing only, whereas the inner ear functions in both hearing and balance.

The **external ear** includes the **auricle** (aw'ri-kl; ear) and the **external acoustic meatus** (mē-ā'tūs; passageway from the outside

to the eardrum). The external ear terminates medially at the **eardrum**, or **tympanic** (tim-pan'ik) **membrane**. The **middle ear** is an air-filled space within the petrous portion of the temporal bone, which contains the **auditory ossicles**. The **inner ear** contains the sensory organs for hearing and balance. It consists of interconnecting, fluid-filled tunnels and chambers within the petrous portion of the temporal bone.

Auditory Structures and Their Functions

External Ear

The **auricle**, or **pinna** (pin'ă), is the fleshy part of the external ear on the outside of the head; it consists primarily of elastic cartilage covered with skin (figure 15.24). Its shape helps collect sound waves and direct them toward the external acoustic meatus. The external acoustic meatus is lined with **hairs** and **ceruminous** (sē-roo'mi-nūs) **glands**, which produce **cerumen**, a modified sebum commonly called earwax. The hairs and cerumen help prevent foreign objects from reaching the delicate eardrum. Overproduction of cerumen, however, may block the meatus.

The tympanic membrane, or eardrum, is a thin, semitransparent, nearly oval, three-layered membrane that separates the external ear from the middle ear. It consists of a low, simple cuboidal epithelium on the inner surface and a thin stratified squamous epithelium on the outer surface, with a layer of connective tissue between. Sound waves reaching the tympanic membrane through the external acoustic meatus cause it to vibrate.

Tympanic Membrane Rupture

Rupture of the tympanic membrane may result in hearing impairment. Foreign objects thrust into the ear, pressure, and infections of the middle ear can rupture the tympanic membrane. Sufficient differential pressure between the middle ear and the outside air can also rupture the tympanic membrane. This can occur in flyers, divers, or individuals who are hit on the side of the head by an open hand.

Middle Ear

Medial to the tympanic membrane is the air-filled cavity of the middle ear (see figure 15.23). Two covered openings, the round and oval windows, on the medial side of the middle ear separate it from the inner ear. Two openings provide air passages from the middle ear. One passage opens into the **mastoid air cells** in the mastoid process of the temporal bone. The other passageway, the **auditory**, or **pharyngotympanic tube** (also called the eustachian ū-stā'shūn tube), opens into the pharynx and equalizes air pressure between the outside air and the middle ear cavity. Unequal pressure between the middle ear and the outside environment can distort the eardrum, dampen its vibrations, and make hearing difficult. Distortion of the eardrum, which occurs under these conditions, also stimulates pain fibers associated with it. Because of this distortion, when a person changes altitude, sounds seem muffled and the eardrum may become painful. These symptoms can be relieved by opening the auditory tube to allow air to pass through the auditory tube to equalize air pressure. Swallowing, yawning, chewing, and holding the nose and mouth shut while gently trying to force air out of the lungs are methods used to open the auditory tube.

Frontal section

FIGURE 15.23 External, Middle, and Inner Ears

The middle ear contains three auditory ossicles (see figure 15.23—the **malleus** (mal'ē-ūs; hammer), **incus** (ing'kūs; anvil), and **stapes** (stā'pēs; stirrup)—which transmit vibrations from the tympanic membrane to the **oval window**. The handle of the malleus is attached to the inner surface of the tympanic membrane, and vibration of the membrane causes the malleus to vibrate as well. The head of the malleus is attached by a very small synovial

joint to the incus, which in turn is attached by a small synovial joint to the stapes. The foot plate of the stapes fits into the oval window and is held in place by a flexible **annular ligament**.

Two small skeletal muscles originate from bone around the middle ear and insert onto auditory ossicles (figure 15.25). The **tensor tympani** (ten'sōr tim'pān-ē) muscle is attached to the malleus and is innervated by the trigeminal nerve (V). The **stapedius** (stā-pē'dē-ūs) muscle is attached to the stapes and is innervated by the facial nerve (VII).

FIGURE 15.24 Structures of the Auricle (the Right Ear)

Chorda Tympani

A structure you might be somewhat surprised to find in the middle ear is the **chorda tympani**, a branch of the facial nerve carrying taste impulses from the anterior two-thirds of the tongue. It crosses over the inner surface of the tympanic membrane (see figure 15.23). The chorda tympani has nothing to do with hearing but is just passing through. This nerve can be damaged, however, during ear surgery or by a middle ear infection, resulting in loss of taste sensation from the anterior two-thirds of the tongue on the side innervated by that nerve.

Inner Ear

The tunnels and chambers inside the temporal bone are called the **bony labyrinth** (lab'i-rinth; maze; figure 15.26). Because the

FIGURE 15.25 Muscles of the Middle Ear

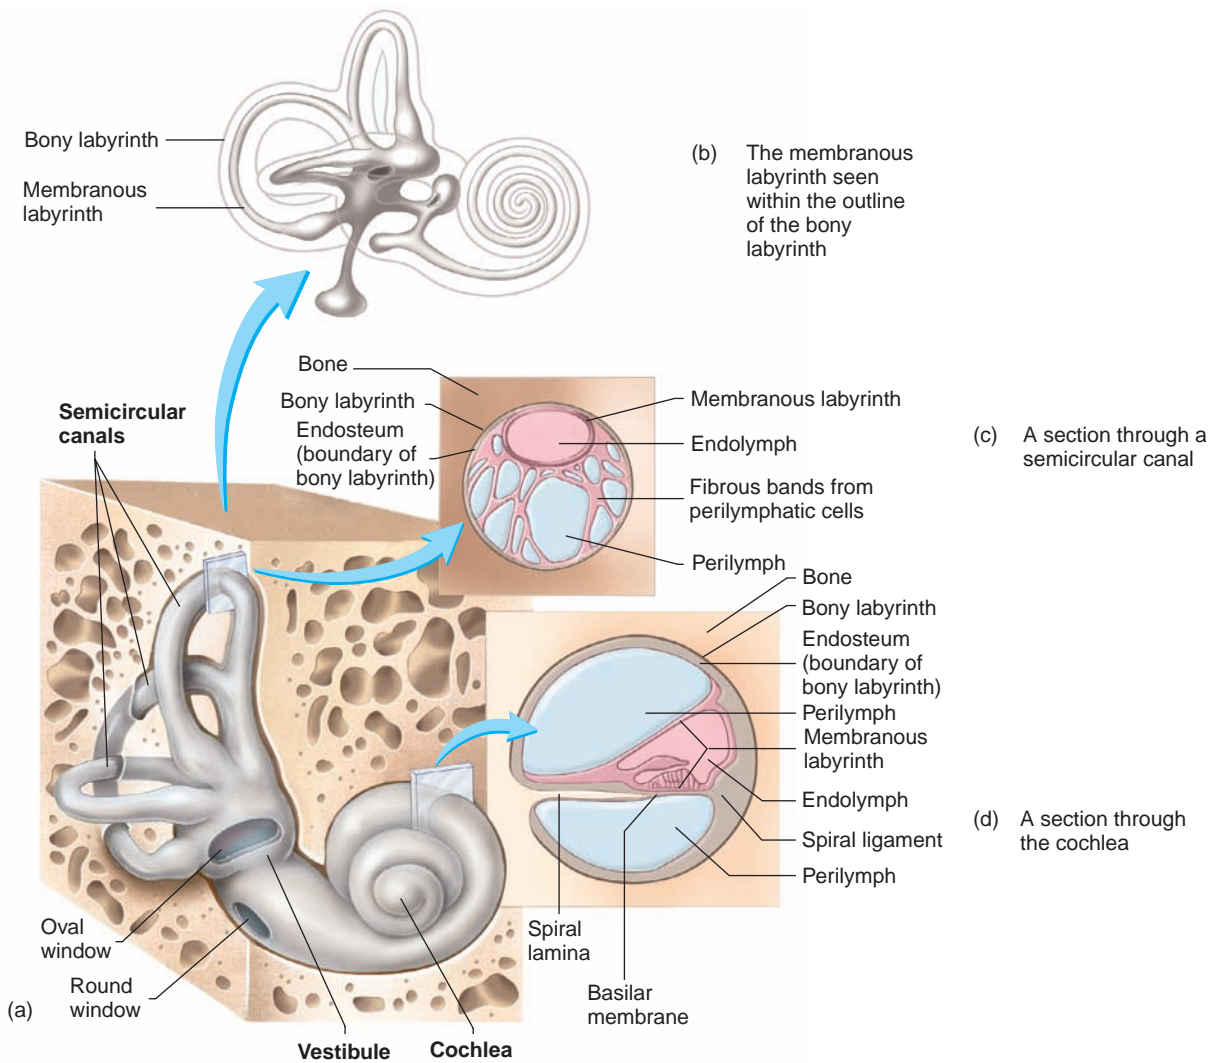

FIGURE 15.26 Inner Ear: Bony and Membranous Labyrinths

The cross sections are taken through a semicircular canal and the cochlea to show the relationship between the bony and membranous labyrinths.

FIGURE 15.27 Structure of the Cochlea

(a) *The inner ear.* The outer surface (gray) is the endosteum lining the inner surface of the bony labyrinth. (b) *A cross section of the cochlea.* The outer layer is the endosteum lining the inner surface of the bony labyrinth. The membranous labyrinth is very small in the cochlea and consists of the vestibular and basilar membranes. The space between the membranous and bony labyrinths consists of two parallel tunnels: the scala vestibuli and scala tympani. (c) *An enlarged section of the cochlear duct (membranous labyrinth).* (d) *A greatly enlarged individual sensory hair cell.*

bony labyrinth consists of tunnels within the bone, it cannot easily be removed and examined separately. The bony labyrinth is lined with endosteum, and, when the inner ear is shown separately (figure 15.27a), the endosteum is what is depicted. Inside the bony labyrinth is a similarly shaped but smaller set of membranous tunnels and chambers called the **membranous labyrinth**. The inner surface of the endosteum and the outer surface of the membranous labyrinth are covered with a very thin layer of cells called the **perilymphatic cells** (figure 15.27b). The membranous labyrinth is

filled with a clear fluid called **endolymph**, and the space between the membranous and bony labyrinths is filled with a fluid called **perilymph**. Perilymph is very similar to cerebrospinal fluid, but endolymph has a high concentration of potassium and a low concentration of sodium, which is opposite from perilymph and cerebrospinal fluid.

The bony labyrinth is divided into three regions: cochlea, vestibule, and semicircular canals. The **vestibule** (ves'ti-bool) and **semicircular canals** are involved primarily in balance, and the

cochlea (kōk'lē-ă) is involved in hearing. The membranous labyrinth of the cochlea is divided into three parts: the scala vestibuli, the scala tympani, and the cochlear duct.

The oval window communicates with the vestibule of the inner ear, which in turn communicates with a cochlear chamber, the **scala vestibuli** (skā'lă ves-tib'ū-lē; see figure 15.27*a*). The scala vestibuli extends from the oval window to the **helicotrema** (hel'i-kō-trē'mă; a hole at the end of a helix or spiral) at the apex of the cochlea; a second cochlear chamber, the **scala tympani** (tim'pā-nē), extends from the helicotrema, back from the apex, parallel to the scala vestibuli, to the membrane of the **round window**.

The scala vestibuli and the scala tympani are the perilymph-filled spaces between the walls of the bony and membranous labyrinths. The wall of the membranous labyrinth that bounds the scala vestibuli is called the **vestibular membrane** (Reissner membrane); the wall of the membranous labyrinth bordering the scala tympani is the **basilar membrane** (see figure 15.27*b* and *c*). The space between the vestibular membrane and the basilar membrane is the interior of the membranous labyrinth and is called the **cochlear duct**, or **scala media**, which is filled with endolymph.

The vestibular membrane consists of a double layer of squamous epithelium and is the simplest region of the membranous labyrinth. The vestibular membrane is so thin that it has little or no mechanical effect on the transmission of sound waves through the inner ear; therefore, the perilymph and endolymph on the two sides of the vestibular membrane can be thought of mechanically as one fluid. The role of the vestibular membrane is to separate the two chemically different fluids. The basilar membrane is somewhat more complex and is of much greater physiologic interest in relation to the mechanics of hearing. It consists of an acellular portion with collagen fibers, ground substance, and sparsely dispersed elastic fibers and a cellular part with a thin layer of vascular connective tissue that is overlaid with simple squamous epithelium.

The basilar membrane is attached at one side to the bony **spiral lamina**, which projects from the sides of the **modiolus** (mō'dī'ō-lus), the bony core of the cochlea, like the threads of a screw. At the other side, the basilar membrane is attached to the lateral wall of the bony labyrinth by the **spiral ligament**, a local thickening of the endosteum. The distance between the spiral lamina and the spiral ligament (i.e., the width of the basilar membrane) increases from 0.04 mm near the oval window to 0.5 mm near the helicotrema. The collagen fibers of the basilar membrane are oriented across the membrane between the spiral lamina and the spiral ligament, somewhat like the strings of a piano. The collagen fibers near the oval window are both shorter and thicker than those near the helicotrema. The diameter of the collagen fibers in the membrane decreases as the basilar membrane widens. As a result, the basilar membrane near the oval window is short and stiff, and it responds to high-frequency vibrations, whereas the part near the helicotrema is wide and limber and responds to low-frequency vibrations.

The cells inside the cochlear duct are highly modified to form a structure called the **spiral organ**, or **organ of Corti** (see figure 15.27*b* and *c*). The spiral organ contains supporting epithelial cells and specialized sensory cells called **hair cells**, which have hairlike projections at their apical ends. In children, these projections consist of one cilium (kinocilium) and about 80 very long microvilli, often referred to as **stereocilia**, but in adults the cilium is absent from most hair cells (figures 15.27*d* and 15.28). The hair cells are arranged in four long rows extending the length of the cochlear duct. Each row contains 3500–4000 hair cells. The inner row consists of hair cells, called **inner hair cells**, which are the hair cells primarily responsible for hearing. The outer three rows contain **outer hair cells**. The outer hair cells are involved in regulating the tension of the basilar membrane and are separated from the inner hair cells by a gap in the basilar membrane (see figure 15.27). The stereocilia

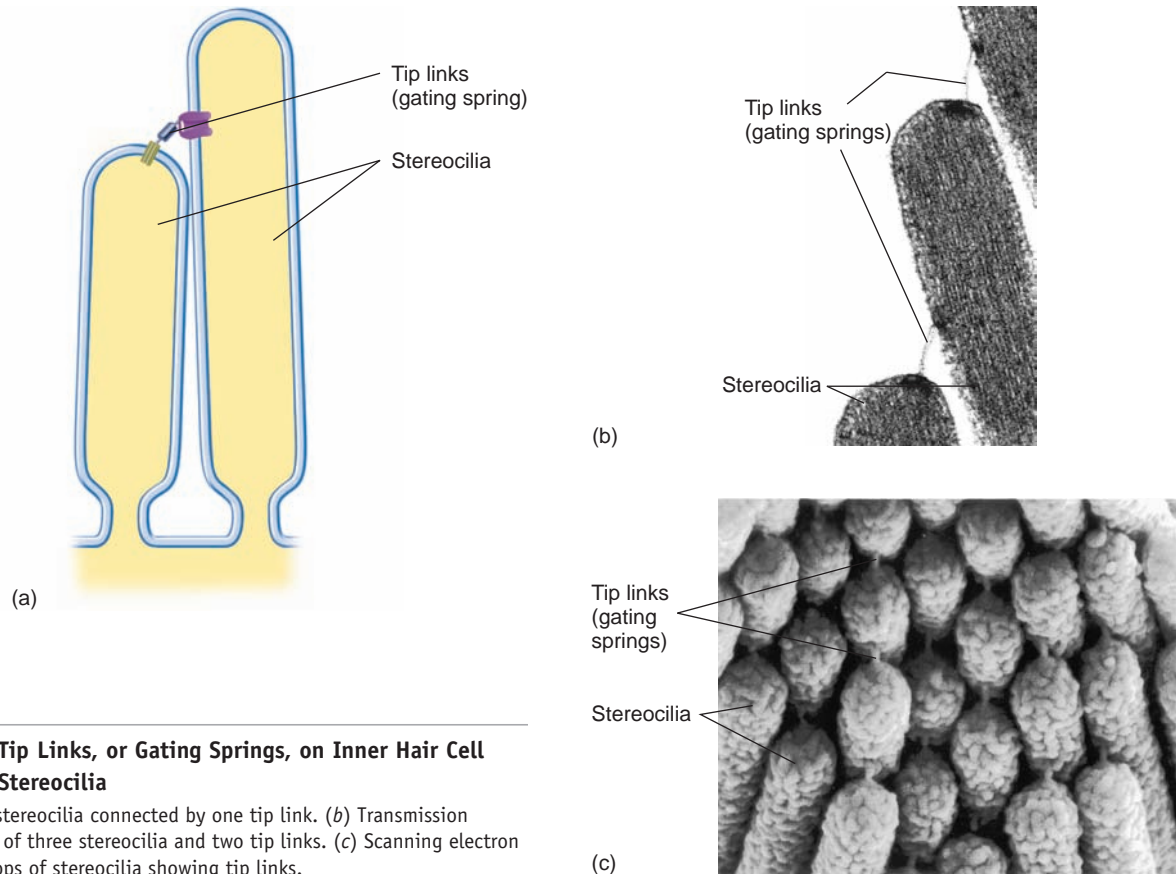

FIGURE 15.29 Tip Links, or Gating Springs, on Inner Hair Cell Stereocilia

(a) Diagram of two stereocilia connected by one tip link. (b) Transmission electron micrograph of three stereocilia and two tip links. (c) Scanning electron micrograph of the tops of stereocilia showing tip links.

of one inner hair cell form a conical group called a **hair bundle** (see figure 15.28a). The length of each stereocilium within a hair bundle increases gradually from one side of the hair cell to the other. The stereocilia of an outer hair cell are arranged in a curved line (see figure 15.28b). The tips of the longest stereocilia of the outer hair cells are embedded within an acellular gelatinous shelf called the **tectorial membrane**, which is attached to the spiral lamina.

A **tip link** connects the tip of each stereocilium in a hair bundle to the side of the next longer stereocilium (figure 15.29). Each tip link is a **gating spring**, a pair of microtubule strands that attaches to the gate of a gated K^+ channel. The gated K^+ channels of hair cells open mechanically. As the stereocilia bend, the gating spring pulls the K^+ gate open (figure 15.30). The response time for such a mechanism is very brief and functions much faster than for a gating mechanism involving the synthesis of intracellular chemical signals such as cAMP.

Hair cells have no axons, but the basilar regions of each hair cell are covered by synaptic terminals of sensory neurons. The cell bodies of afferent neurons are located within the cochlear modiolus and are grouped into a **cochlear, or spiral, ganglion** (see figure 15.27b). Afferent fibers of these neurons join to form the **cochlear nerve**. This nerve then joins the vestibular nerve to become the **vestibulocochlear nerve** (VIII), which traverses the internal acoustic meatus and enters the cranial cavity.

28 Name the three regions of the ear, and list each region's parts.

29 Describe the relationship among the tympanic membrane, the ear ossicles, and the oval window of the ear.

30 What are the functions of the external acoustic meatus and of the auditory tube?

31 Explain how the cochlear duct is divided into three compartments. What is found in each compartment?

32 Explain the differences between inner and outer hair cells.

33 What is the function of tip links, or gating springs?

Auditory Function

Vibration of matter, such as air, water, or a solid material, creates sound. No sound occurs in a vacuum. When a person speaks, the vocal cords vibrate, causing the air passing out of the lungs to vibrate. The vibrations consist of bands of compressed air followed by bands of less compressed air (figure 15.31a). These vibrations are propagated through the air as sound waves, somewhat as ripples are propagated over the surface of water. **Volume**, or loudness, is a function of wave amplitude, or height, measured in decibels (figure 15.31b). The greater the amplitude, the louder the sound. **Pitch** is a function of the wave frequency (i.e., the number of waves or cycles per second) measured in hertz (Hz; figure 15.31c). The higher the frequency, the higher the pitch. The normal range of human hearing is 20–20,000 Hz and 0 or more decibels (db). Sounds louder than 125 db are painful to the ear.

PROCESS FIGURE 15.30 Action of the Gating Spring to Open a K⁺ Channel When Two Stereocilia Bend

Human Speech and Hearing Impairment

The range of normal human speech is 250–8000 Hz. This is the range that is tested for the possibility of hearing impairment because it is the most important for communication.

Timbre (tam'br, tim'br) is the resonance quality or overtones of a sound. A smooth sigmoid curve is the image of a “pure” sound wave, but such a wave almost never exists in nature. The sounds made by musical instruments and the human voice are not smooth sigmoid curves but, rather, are rough, jagged curves formed by numerous, superimposed curves of various amplitudes and frequencies. The roughness of the curve accounts for the timbre. Timbre allows one to distinguish between, for example, an oboe and a French horn playing a note at the same pitch and volume. The steps involved in the mechanical part of hearing are illustrated in figure 15.32.

External Ear

The auricle collects sound waves, which are then conducted through the external acoustic meatus toward the tympanic membrane. Sound waves travel relatively slowly in air, 332 m/s, and a significant time interval may elapse between the time a sound wave reaches one ear and the time that it reaches the other. The brain can interpret this interval to determine the direction from which a sound is coming.

Middle Ear

Sound waves strike the tympanic membrane and cause it to vibrate. This vibration causes vibration of the three ossicles of the middle ear, and by this mechanical linkage vibration is transferred to the oval window. More force is required to cause vibration in a liquid, such as the perilymph of the inner ear, than is required in air; thus, the vibrations reaching the perilymph must be amplified

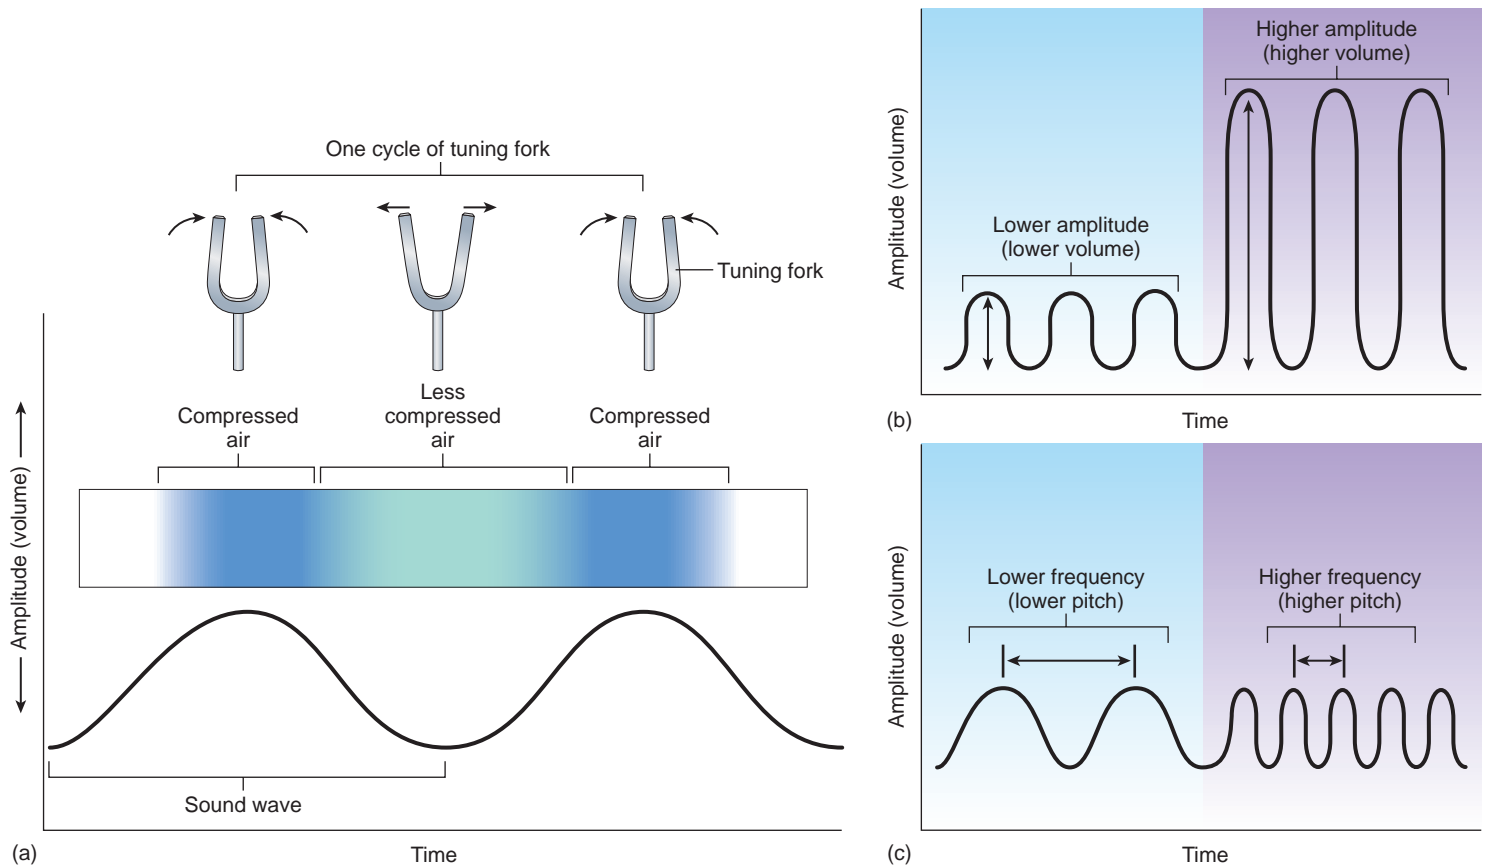

FIGURE 15.31 Sound Waves

(a) When something, such as a tuning fork or vocal cords, vibrates, the movements of the object alternate between compressing the air and decompressing the air, or making the air less compressed, thus producing sound. Each sound wave consists of a region of compressed air between two regions of less compressed air (*blue bars*). The sigmoid waves correspond to the regions of more compressed air (peaks) and less compressed air (troughs). The *green shadowed area* represents the width of one cycle (distance between peaks). (b) Low- and high-volume sound waves. Compare the relative lengths of the *arrows* indicating the wave height (amplitude). (c) Lower- and higher-pitch sound. Compare the relative number of peaks (frequency) within a given time interval (*between arrows*).

as they cross the middle ear. The footplate of the stapes and its annular ligament, which occupy the oval window, are much smaller than the tympanic membrane. Because of this size difference, the mechanical force of vibration is amplified about 20-fold as it passes from the tympanic membrane through the ossicles and to the oval window. This amplification occurs because the area of the tympanic membrane is roughly 20 times that of the oval window.

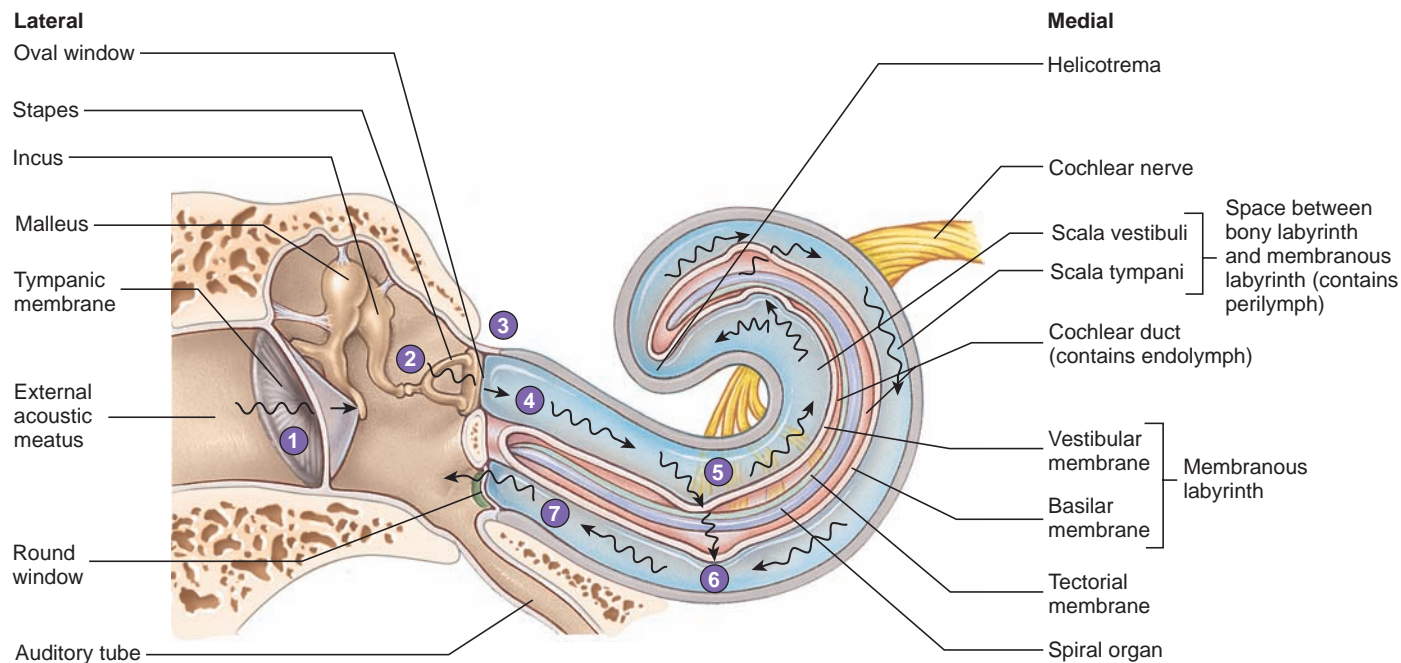

The tensor tympani and stapedius muscles, attached to auditory ossicles, reflexively dampen excessively loud sounds (see figure 15.25). This **sound attenuation reflex** protects the delicate ear structures from damage by loud noises. The sound attenuation reflex responds most effectively to low-frequency sounds and can reduce by a factor of 100 the energy reaching the oval window. The facial nerve and stapedius are primarily involved in the sound attenuation reflex. The trigeminal nerve and tensor tympani are only stimulated by extremely loud noise. The reflex is too slow to prevent damage from a sudden noise, such as a gunshot, and it cannot function effectively for longer than about 10 minutes, in response to prolonged noise.

PREDICT 9

What effect does facial nerve damage have on hearing?

Inner Ear

As the stapes vibrates, it produces waves in the perilymph of the scala vestibuli (see figure 15.32). Vibrations of the perilymph are transmitted through the thin vestibular membrane and cause simultaneous vibrations of the endolymph. The mechanical effect is as though the perilymph and endolymph were a single fluid. Vibration of the endolymph causes distortion of the basilar membrane. Waves in the perilymph of the scala vestibuli are transmitted also through the helicotrema and into the scala tympani. Because the helicotrema is very small, however, this transmitted vibration is probably of little consequence. Distortions of the basilar membrane, together with weaker waves coming through the helicotrema, cause waves in the scala tympani perilymph and ultimately result in vibration of the membrane of the round window. Vibration of the round window membrane is important

1. Sound waves strike the tympanic membrane and cause it to vibrate.
2. Vibration of the tympanic membrane causes the three bones of the middle ear—the malleus, incus, and stapes—to vibrate.
3. The foot plate of the stapes vibrates in the oval window.
4. Vibration of the foot plate causes the perilymph in the scala vestibuli to vibrate.
5. Vibration of the perilymph causes the vestibular membrane to vibrate, which causes vibrations in the endolymph.
6. Vibration of the endolymph causes displacement of the basilar membrane. Short waves (high pitch) cause displacement of the basilar membrane near the oval window, and longer waves (low pitch) cause displacement of the basilar membrane some distance from the oval window. Movement of the basilar membrane is detected in the hair cells of the spiral organ, which are attached to the basilar membrane. Vibrations of the perilymph in the scala vestibuli and of the basement membrane are transferred to the perilymph of the scala tympani.
7. Vibrations in the perilymph of the scala tympani are transferred to the round window, where they are dampened.

PROCESS FIGURE 15.32 Effect of Sound Waves on Cochlear Structures

to hearing because it acts as a mechanical release for waves from within the cochlea. If this window were solid, it would reflect the waves, which would interfere with and dampen later waves. The round window also allows the relief of pressure in the perilymph because fluid is not compressible, thereby preventing compression damage to the spiral organ.

The distortion of the basilar membrane is most important to hearing. As this membrane distorts, the hair cells resting on the basilar membrane move relative to the tectorial membrane, which remains stationary. The inner hair cell microvilli are bent as they move against the tectorial membrane.

The apical portion of each hair cell is surrounded by endolymph and the basal portion of the cell is surrounded by perilymph. Endolymph has a high K^+ concentration similar to the intracellular K^+ concentration of hair cells. Perilymph has a low concentration of K^+ similar to that of other extracellular fluid. The intracellular charge of hair cells compared with perilymph is -60 mV. The charge of the endolymph is $+80$ mV compared with the perilymph. This charge difference is called the **endocochlear potential**. Consequently, the intracellular charge of hair cells compared with endolymph is -140 mV, which is a large charge

difference. Consequently, when K^+ channels open, K^+ flow into the hair cells because they are attracted to the negative charge inside of the hair cell, even though the intracellular concentration of K^+ is about the same as in the endolymph. The movement of the K^+ causes depolarization of the hair cells. This is a rare instance in which an increase in K^+ permeability of the plasma membrane of a cell results in depolarization.

In the unstimulated hair cell, approximately 15% of the gated K^+ channels are open and the resting membrane potential of the cell is approximately -60 mV. If the hair bundle is bent toward the shortest stereocilium (negative stimulus) the gating springs attached to the K^+ channel gates slacken, allowing the open K^+ channels to close and the cell hyperpolarizes. If the hair bundle is bent toward the longest stereocilium (positive stimulus), gating springs pull additional K^+ channel gates open, and K^+ rush into the cell. The influx of K^+ into the hair cell causes a slight depolarization of the cell. This depolarization causes voltage-gated Ca^{2+} channels to open. Calcium ions rush into the cell, causing a further depolarization. The cell depolarizes by a total of about 10 mV. Depolarization of hair cells results in the increased release of neurotransmitters, which increases the action potential frequency

in the afferent neurons. Hyperpolarization decreases neurotransmitter release and decreases action potential frequency in afferent neurons. Depolarization also opens voltage-gated K^+ channels in the basal portion of the hair cell. Potassium ions tend to leave the cell, causing the cell to repolarize.

The neurotransmitter released by the inner hair cells is apparently glutamate, but other neurotransmitters may also be involved. The release of neurotransmitters from the inner hair cells induces action potentials in the cochlear neurons that synapse on the hair cells. The cell bodies of those neurons are located in the cochlear ganglion.

The part of the basilar membrane that distorts as a result of endolymph vibration depends on the pitch of the sound that created the vibration and, as a result, on the vibration frequency within the endolymph. The width of the basilar membrane and the length and diameter of the collagen fibers stretching across the membrane at each level along the cochlear duct determine the location of the optimal amount of basilar membrane vibration produced by a given pitch (figure 15.33). Higher-pitched tones cause optimal vibration near the base, and lower-pitched tones cause optimal vibration near the apex of the basilar membrane. As the basilar membrane vibrates, hair cells along a large part of the basilar membrane are stimulated. In areas of minimum vibration, the amount of stimulation may not reach threshold. In other areas, a low frequency of afferent action potentials may be transmitted, whereas, in the optimally vibrating regions of the basilar membrane, a high frequency of action potentials is initiated.

There are approximately twice as many nerve cells in the cochlear ganglion as there are hair cells. Over 90% of the afferent axons synapse with inner hair cells, 10 to 30 axons per hair cell. Only a few, small-diameter afferent axons synapse with the three rows of outer hair cells. The outer cells, however, receive input from efferent axons. Action potentials from those efferent axons stimulate the contraction of actin filaments within the hair cells, causing them to shorten. This adjustment in the height of the outer hair cells, attached to both the basilar membrane and the tectorial membrane, fine tunes the tension of the basilar membrane and the distance between the basilar membrane and tectorial membrane. Additional sensitivity can be adjusted within the inner hair cells. The mechanically gated K^+ channels are attached to actin filaments inside the cell. Those filaments can move the K^+ channels along the cell membrane,

FIGURE 15.33 Effect of Sound Waves on Points Along the Basilar Membrane

Points of maximum vibration along the basilar membrane resulting from stimulation by sounds of various frequencies (in hertz).

tightening or loosening the gating spring. By this means, hair cells are tuned to very specific frequencies. Likewise, the response of an inner hair cell to stimulation is graded and can increase up to a point of saturation (when all the K^+ channels are open maximally). Inner hair cells are also very sensitive. A 100 nm (1 degree) deflection of the stereocilia results in a response that is 90% of maximum.

Afferent action potentials conducted by cochlear nerve fibers from all along the spiral organ terminate in the **superior olivary nucleus** in the medulla oblongata (figure 15.34; see chapter 13). These action potentials are compared with one another, and the strongest action potential, corresponding to the area of maximum

Loud Noises and Hearing Loss

Prolonged or frequent exposure to excessively loud noises can cause degeneration of the spiral organ at the base of the cochlea, resulting in high-frequency deafness. The actual amount of damage can vary greatly from person to person. High-frequency loss can cause a person to miss hearing consonants in a noisy setting. Loud music, amplified to 120 db, can impair hearing. The defects may not be detectable on routine diagnosis, but they include decreased sensitivity to sound in specific narrow frequency ranges and a decreased ability to discriminate between two pitches. Loud music, however, is not as harmful as is the sound of a nearby gunshot, which is a sudden sound occurring at 140 db. The sound is too sudden for the attenuation reflex to protect the inner ear structures, and the intensity is great enough to cause auditory damage. In fact, gunshot noise is the most common recreational cause of serious hearing loss.

1. Sensory axons from the cochlear ganglion terminate in the cochlear nucleus in the brainstem.
2. Axons from the neurons in the cochlear nucleus project to the superior olivary nucleus or to the inferior colliculus.
3. Axons from the inferior colliculus project to the medial geniculate nucleus of the thalamus.
4. Thalamic neurons project to the auditory cortex.
5. Neurons in the superior olivary nucleus send axons to the inferior colliculus, back to the inner ear, or to motor nuclei in the brainstem that send efferent fibers to the middle ear muscles.

PROCESS FIGURE 15.34 Central Nervous System Pathways for Hearing

basilar membrane vibration, is taken as standard. Efferent action potentials then are sent from the superior olivary nucleus back to the spiral organ to all regions where the maximum vibration did not occur. These action potentials inhibit the hair cells from initiating additional action potentials in the sensory neurons. Thus, only action potentials from regions of maximum vibration are received by the cortex, where they become consciously perceived.

By this process, tones are localized along the cochlea. As a result of this localization, neurons along a given portion of the cochlea send action potentials only to the cerebral cortex in response to specific pitches. Action potentials near the base of the basilar membrane stimulate neurons in a certain part of the auditory cortex, which interpret the stimulus as a high-pitched sound, whereas action potentials from the apex stimulate a different part of the cortex, which interprets the stimulus as a low-pitched sound.

PREDICT 10

Suggest some possible sites and mechanisms within the auditory structures to explain why certain people have “perfect pitch” and other people are “tone deaf.”

Sound volume, or loudness, is a function of sound wave amplitude. As high-amplitude sound waves reach the ear, the perilymph,

endolymph, and basilar membrane vibrate more intensely, and the hair cells are stimulated more intensely. As a result of the increased stimulation, more hair cells send action potentials at a higher frequency to the cerebral cortex, where this information is perceived as a greater sound volume.

34 Starting with the auricle, trace a sound wave into the inner ear to the point at which action potentials are generated in the cochlear nerve.

35 Explain how pulling on a gating spring results in the generation of an action potential.

PREDICT 11

Explain why it is much easier to perceive subtle musical tones when music is played somewhat softly, as opposed to very loudly.

Neuronal Pathways for Hearing

The special senses of hearing and balance are both transmitted by the vestibulocochlear (VIII) nerve. The term *vestibular* refers to the vestibule of the inner ear, which is involved in balance. The term *cochlear* refers to the cochlea and is that portion of the inner ear involved in hearing. The vestibulocochlear nerve functions as two separate nerves carrying information from two separate but closely related structures.

The auditory pathways within the CNS are very complex, with both crossed and uncrossed tracts (see figure 15.34). Unilateral CNS damage therefore usually has little effect on hearing. The neurons from the cochlear ganglion synapse with CNS neurons in the dorsal or ventral **cochlear nucleus** in the superior medulla near the inferior cerebellar peduncle. These neurons in turn either synapse in or pass through the superior olivary nucleus. Neurons terminating in this nucleus may synapse with efferent neurons returning to the cochlea to modulate pitch perception. Nerve fibers from the superior olivary nucleus also project to the trigeminal (V) nucleus, which controls the tensor tympani, and the facial (VII) nucleus, which controls the stapedius muscle. This reflex pathway dampens loud sounds by initiating contractions of these muscles, the sound attenuation reflex. Neurons synapsing in the superior olivary nucleus may also join other ascending neurons to the cerebral cortex.

Ascending neurons from the superior olivary nucleus travel in the **lateral lemniscus**. All ascending fibers synapse in the **inferior colliculi**, and neurons from there project to the **medial geniculate nucleus** of the **thalamus**, where they synapse with neurons that project to the cortex. These neurons terminate in the **auditory cortex** in the dorsal portion of the temporal lobe within the lateral fissure and, to a lesser extent, on the superolateral surface of the temporal lobe (see chapter 13). Neurons from the inferior colliculus also project to the **superior colliculus**, where reflexes that turn the head and eyes in response to loud sounds are initiated.

36 Describe the neuronal pathways for hearing from the cochlear nerve to the cerebral cortex.

Balance

The organs of balance are divided structurally and functionally into two parts. The first, the **static labyrinth**, consists of the **utricle**

(oo'tri-kl) and the **saccul**e (sak'ül) of the vestibule and is primarily involved in evaluating the position of the head relative to gravity, although the system also responds to linear acceleration or deceleration, such as when a person is in a car that is increasing or decreasing speed. The second, the **kinetic labyrinth**, is associated with the semi-circular canals and is involved in evaluating movements of the head.

Most of the utricular and saccular walls consist of simple cuboidal epithelium. The utricle and saccule, however, each contain a specialized patch of epithelium about 2–3 mm in diameter called the **macula** (mak'ü-lä; figure 15.35a and b). The macula of the utricle is oriented parallel to the base of the skull, and the macula of the saccule is perpendicular to the base of the skull.

The maculae resemble the spiral organ and consist of columnar supporting cells and hair cells. The “hairs” of these cells, which consist of numerous microvilli, called **stereocilia**, and one cilium, called a **kinocilium** (kī-nō-sil'ē-üm), are embedded in a **gelatinous mass** weighted by the presence of **otoliths** (ō'tō-liths) composed of protein and calcium carbonate (see figure 15.35b). The gelatinous mass moves in response to gravity, bending the hair cells and initiating action potentials in the associated neurons. The stereocilia function much as do the stereocilia of cochlear hair cells, with tip links connected to gated K^+ channels. Deflection of the hairs toward the kinocilium results in depolarization of the hair cell, whereas deflection of the hairs away from the kinocilium results in hyperpolarization of the hair cell. If the head is tipped, otoliths move in response to gravity and stimulate certain hair cells (figure 15.36).

The hair cells have no axons but synapse directly with neurons of the vestibulocochlear nerve (VIII). Several neurotransmitters are released from the hair cells. One of those neurotransmitters is glutamate. Others have not yet been identified.

The hair cells are constantly being stimulated at a low level by the presence of the otolith-weighted covering of the macula;

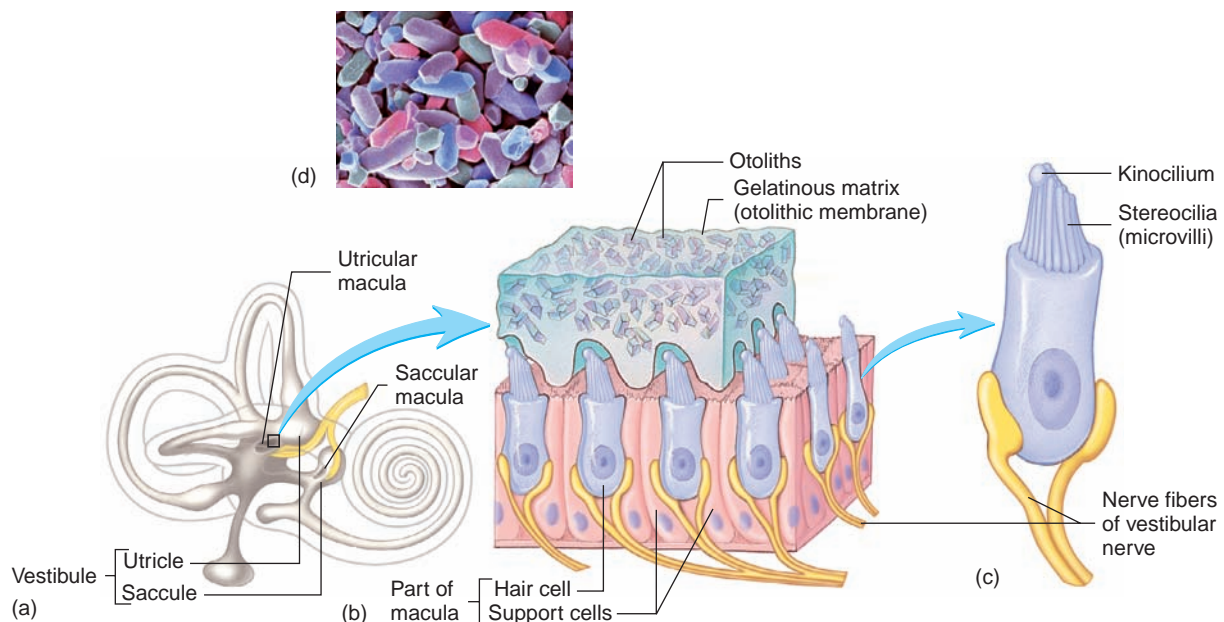

FIGURE 15.35 Structure of the Macula

(a) Vestibule showing the location of the utricular and saccular maculae. (b) Enlargement of the utricular macula, showing hair cells and otoliths in the macula. (c) An enlarged hair cell, showing the kinocilium and stereocilia. (d) Colorized scanning electron micrograph of otoliths.

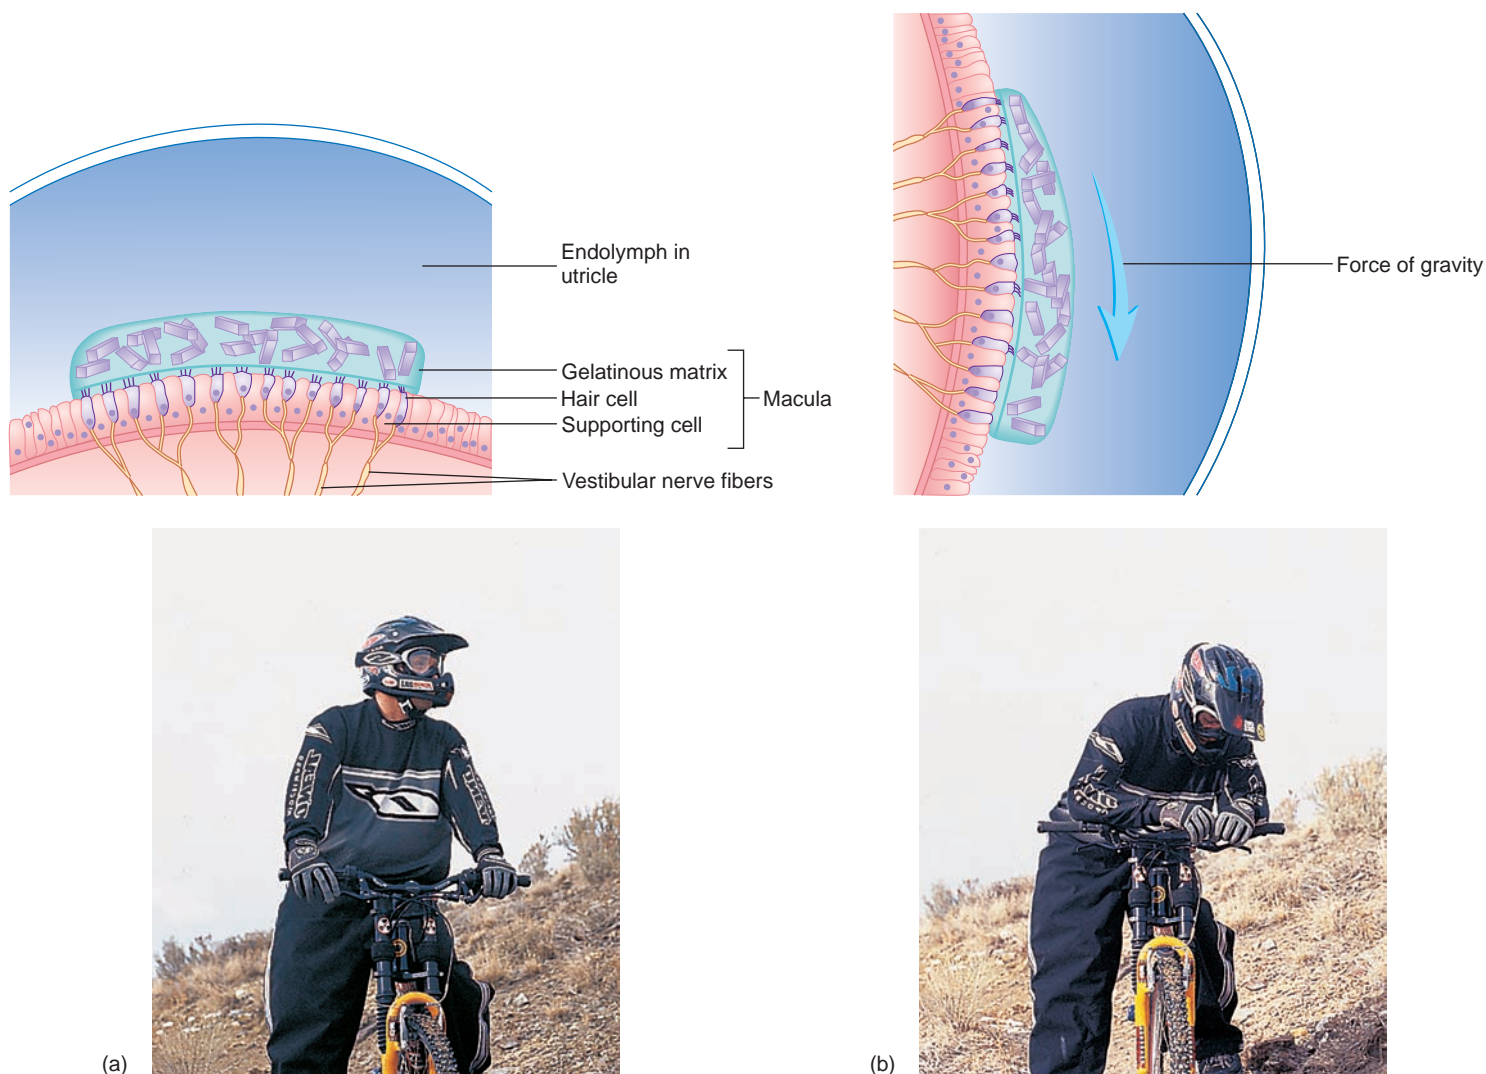

FIGURE 15.36 Function of the Vestibule in Maintaining Balance

(a) As the position of the head changes, such as when a person bends over, the maculae respond to changes in position of the head relative to gravity by moving in the direction of gravity. (b) In an upright position, the maculae do not move.

however, as this covering moves in response to gravity, the pattern of intensity of hair cell stimulation changes. This pattern of stimulation and the subsequent pattern of action potentials from the numerous hair cells of the maculae can be translated by the brain into specific information about head position or acceleration. Much of this information is not perceived consciously but is dealt with subconsciously. The body responds by making subtle tone adjustments in the muscles of the back and neck, which are intended to restore the head to its proper neutral, balanced position.

The kinetic labyrinth (figure 15.37) consists of three **semicircular canals** placed at nearly right angles to one another, one lying nearly in the transverse plane, one in the coronal plane, and one in the sagittal plane (see chapter 1). The arrangement of the semicircular canals enables a person to detect movement in all directions. The base of each semicircular canal is expanded into an **ampulla** (see figure 15.37a). Within each ampulla, the epithelium is specialized

to form a **crista ampullaris** (kris'tă am-pū-lar'ūs). This specialized sensory epithelium is structurally and functionally very similar to the sensory epithelium of the maculae. Each crista consists of a ridge or crest of epithelium with a curved gelatinous mass, the **cupula** (koo'poo-lă), suspended over the crest. The hairlike processes of the crista hair cells, which are stereocilia similar to those in the maculae, and cochlear hair cells are embedded in the cupula (see figure 15.37b). The cupula contains no otoliths and therefore does not respond to gravitational pull. Instead, the cupula is a float that is displaced by fluid movements within the semicircular canals. Endolymph movement within each semicircular canal moves the cupula, bends the hairs, and initiates action potentials (figure 15.38).

As the head begins to move, the endolymph does not move at the same rate as the semicircular canals (see figure 15.38). This difference causes displacement of the cupula in a direction opposite to that of the movement of the head, resulting in relative movement between the cupula and the endolymph. As movement continues,

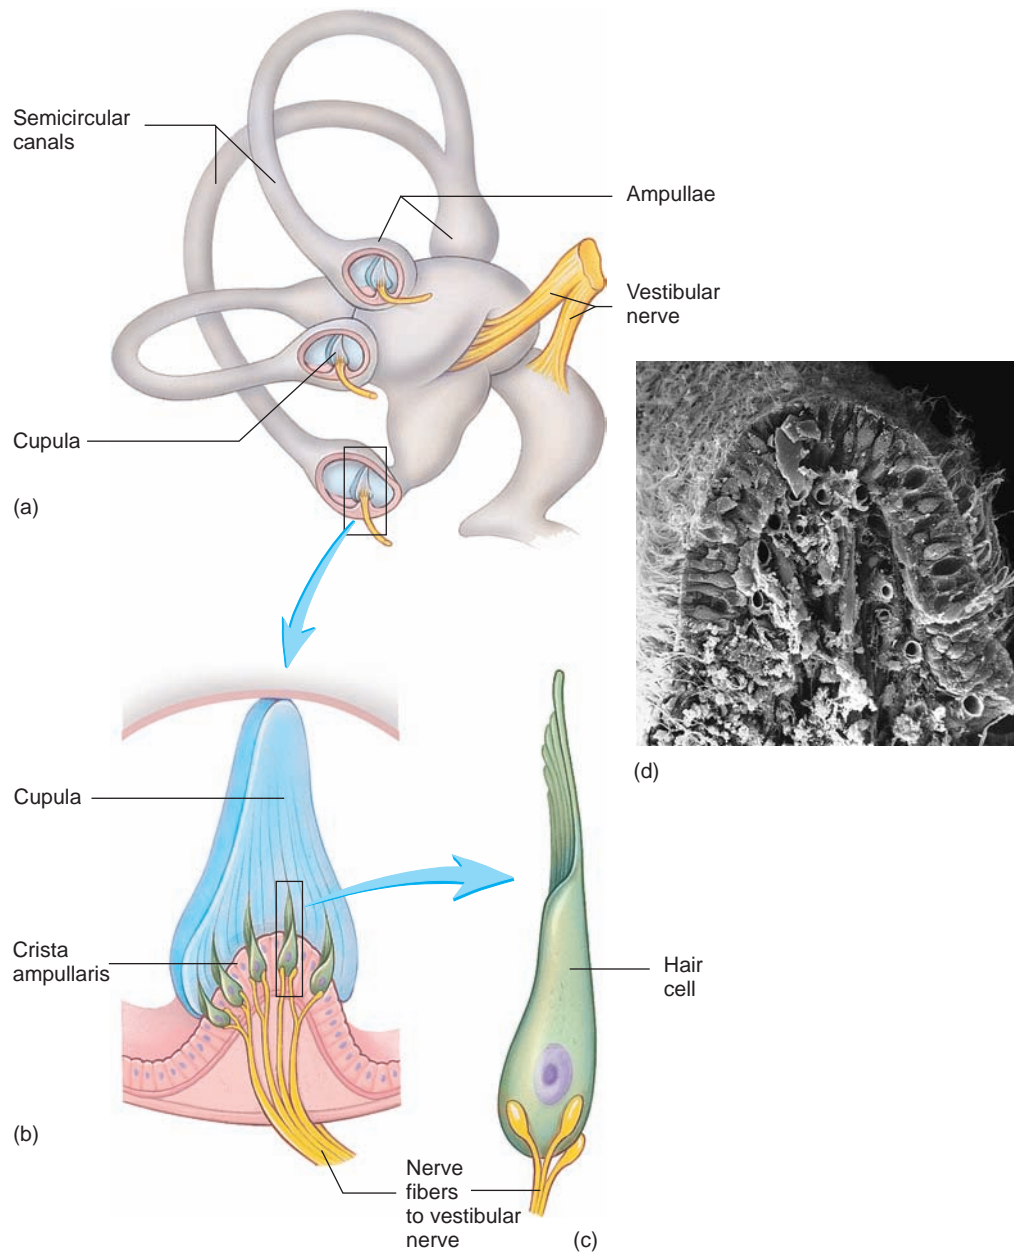

FIGURE 15.37 Semicircular Canals

(a) Semicircular canals showing the location of the crista ampullaris in the ampullae of the semicircular canals. (b) Enlargement of the crista ampullaris, showing the cupula and hair cells. (c) Enlargement of a hair cell. (d) SEM of a crista ampullaris with hair cells.

the fluid of the semicircular canals begins to move and catches up with the cupula, and stimulation is stopped. As movement of the head ceases, the endolymph continues to move because of its momentum, causing displacement of the cupula in the same direction as the head had been moving. Because displacement of the cupula is most intense when the rate of head movement changes, this system detects changes in the rate of movement rather than movement alone. As with the static labyrinth, the information the brain obtains from the kinetic labyrinth is largely subconscious.

37 *What are the functions of the saccule and utricle? Describe the macula and its functions.*

38 *What is the function of the semicircular canals? Describe the crista ampullaris and its mode of operation.*

Space Sickness

Space sickness is a balance disorder occurring in zero gravity and resulting from unfamiliar sensory input to the brain. The brain must adjust to these unusual signals, or severe symptoms, such as headaches and dizziness, may result. Space sickness is unlike motion sickness in that motion sickness results from an excessive stimulation of the brain, whereas space sickness results from too little stimulation as a result of weightlessness.

(b)

FIGURE 15.38 Function of the Semicircular Canals

The crista ampullaris responds to fluid movements within the semicircular canals. (a) When a person is at rest, the crista ampullaris does not move. (b) As a person begins to move, the semicircular canals begin to move with the body (blue arrow), but the endolymph tends to remain stationary relative to the movement (momentum force: red arrow pointing in the opposite direction of body and semicircular canal movement), and the crista ampullaris is displaced by the endolymph in a direction opposite to the direction of movement.

Neuronal Pathways for Balance

Neurons synapsing on the hair cells of the maculae and cristae ampullares converge into the **vestibular ganglion**, where their cell bodies are located (figure 15.39). Sensory fibers from these neurons join sensory fibers from the cochlear ganglion to form the vestibulocochlear nerve (VIII) and terminate in the **vestibular nucleus** within the medulla oblongata. Axons run from this nucleus to numerous areas of the CNS, such as the spinal cord, the cerebellum, the cerebral cortex, and the nuclei controlling extrinsic eye muscles.

Balance is a complex process not simply confined to one type of input. In addition to vestibular sensory input, the vestibular nucleus receives input from proprioceptive neurons throughout the body, as well as from the visual system. People are asked to close their eyes while balance is evaluated in a sobriety test because alcohol affects the proprioceptive and vestibular components of balance (cerebellar function) to a greater extent than it does the visual portion.

Reflex pathways exist between the kinetic part of the vestibular system and the nuclei controlling the extrinsic eye muscles (oculomotor, trochlear, and abducent). A reflex pathway allows the maintenance of visual fixation on an object while the head is in motion. This function can be demonstrated by spinning a person around about 10 times in 20 seconds, stopping him or her, and observing eye movements. The reaction is most pronounced if the individual's head is tilted forward about 30 degrees while spinning, thus bringing the lateral semicircular canals into the horizontal plane. A slight oscillatory movement of the eyes occurs. The eyes track in the direction of motion and return with a rapid recovery movement before repeating the tracking motion. This oscillation of the eyes is called **nystagmus** (nis-tag'mūs). If asked to walk in a straight line, the individual deviates in the direction of rotation; if asked to point to an object, his or her finger deviates in the direction of rotation.

39 Describe the neuronal pathways for balance.

EFFECTS OF AGING ON THE SPECIAL SENSES

Elderly people experience only a slight loss in the ability to detect odors. However, the ability to identify specific odors correctly is decreased, especially in men over age 70.

In general, the sense of taste decreases as people age. The number of sensory receptors decreases and the brain's ability to interpret taste sensations declines.

Responses to taste change in some elderly people who are fighting cancer. One side effect of radiation treatment and chemotherapy is the gastrointestinal discomfort resulting from the treatments. The patients experience a loss of appetite because of conditioned taste aversions resulting from treatment.

The lenses of the eyes lose flexibility as a person ages because the connective tissue of the lenses becomes more rigid. Consequently, there is first a reduction in and then an eventual loss of the lenses' ability to change shape. Recall that this condition, called presbyopia, is the most common age-related change in the eyes.

The most common visual problem in older people requiring medical treatment, such as surgery, is the development of cataracts. Macular degeneration is the second most common defect, glaucoma is third, and diabetic retinopathy is fourth.

The number of cones decreases, especially in the fovea centralis. These changes cause a gradual decline in visual acuity and color perception.

As people age, the number of hair cells in the cochlea decreases, leading to age-related hearing loss, called presbycusis (prez'bē-ākoo'sis). This decline does not occur equally in both ears, however. As a result, because direction is determined by comparing sounds

CASE STUDY

Motion Sickness

Earl booked his first trip on a charter fishing boat. Crossing the bar was refreshing and invigorating, and Earl was surprised that all those warnings about his becoming sea sick did not seem to apply to him. At last, the boat arrived at the fishing site, the engine was cut, and the sea anchor was set. As the boat drifted, it began to roll and pitch. Earl noticed, for the first time, that the bait smelled oily and unpleasant. The smell mixed poorly with the diesel fumes. Earl felt a little light-headed and a bit drowsy. He then noticed that he was definitely nauseated and felt pale. "I'm sea sick," he realized. Trying to fish seemed to worsen his condition. Eventually, his nausea intensified and he leaned over the boat rail and vomited into the ocean. "Improves the fishing," the ship owner shouted to him cheerily. Earl noticed that he felt distinctly better. His condition continued to improve. He found that looking

at the horizon rather than at the water helped his condition. He enjoyed the rest of the trip and even caught a couple of fish.

Sea sickness is a form of **motion sickness**, which consists of nausea, weakness, and other dysfunctions caused by stimulation of the semicircular canals during motion, such as in a boat, an automobile, or an airplane, on a swing, or on an amusement park ride. It can progress to vomiting and incapacitation. The brain compares sensory input from the semicircular canals, eyes, and proprioceptors in the lower limbs. Perceived differences in the input may result in motion sickness, which can be decreased by closing the eyes or looking at a distant object, such as the horizon. Antiemetics, such as anticholinergic or antihistamine medications, can be taken to counter the nausea and vomiting. Scopolamine is an anticholinergic drug that blocks acetylcholine-mediated transmission in the parasympa-

thetic nervous system. It depresses parasympathetic activity within areas of the CNS, such as the hypothalamus, in response to vestibular stimulation. It also depresses other CNS functions, which may cause side effects such as restlessness, agitation, psychosis, mania, and Parkinson-like tremors. Cyclizine (Marezine), dimenhydrinate (Dramamine), and diphenhydramine (Benadryl) are antihistamines that affect the neural pathways from the vestibule. Scopolamine can be administered transdermally in the form of a patch placed on the skin behind the ear (Transdermal-Scop). A patch lasts about 3 days.

PREDICT 12

Explain why closing your eyes can help decrease motion sickness. Why might looking at the horizon help?

1. Sensory axons from the vestibular ganglion pass through the vestibular nerve to the vestibular nucleus, which also receives input from several other sources, such as proprioception from the legs.
2. Vestibular neurons send axons to the cerebellum, which influences postural muscles.
3. Vestibular neurons also send axons to motor nuclei (oculomotor, trochlear, and abducens), which control extrinsic eye muscles.
4. Vestibular neurons also send axons to the posterior ventral nucleus of the thalamus.
5. Thalamic neurons project to the vestibular area of the cortex.

PROCESS FIGURE 15.39 Central Nervous System Pathways for Balance

CLINICAL FOCUS

Hearing Impairment and Functional Replacement of the Ear

The term **hearing-impaired** refers to any type or degree of hearing loss; the hearing loss can be conductive, sensorineural, or a combination of both. **Conduction deafness** involves a mechanical deficiency in the transmission of sound waves from the external ear to the spiral organ. The spiral organ and neuronal pathways for hearing function normally. Conductive hearing loss often can be treated—for example, by removing ear wax blocking the external acoustic meatus or by replacing or repairing the auditory ossicles. If the degree of conductive hearing loss does not justify surgical treatment, or if treatment does not resolve the hearing loss, a hearing aid may be beneficial because the amplified (louder) sound waves it produces are transmitted through the conductive blockage and may provide normal stimulation to the spiral organ.

Sensorineural hearing loss involves the spiral organ or neuronal pathways. Sound waves are transmitted normally to the spiral organ, but the nervous system's ability

to respond to the sound waves is impaired. Hearing aids are commonly used by people with sensorineural hearing loss because the amplified sound waves they produce result in greater than normal stimulation of the spiral organ, helping overcome the perception of reduced sound volume. Sound clarity also improves with sound amplification but may never be perceived as normal.

The term **deaf** refers to sensorineural hearing loss so profound that the sense of hearing is nonfunctional, with or without amplification, for ordinary purposes of life. Stimulation of the spiral organ or hearing nerve pathways can help deaf people hear.

Research is currently being conducted on ways to replace the hearing pathways with electric circuits. One approach involves the direct stimulation of nerves by electric impulses. There has been considerable success in the area of cochlear nerve stimulation. Certain types of sensorineural deafness in which the hair cells of the spiral organ are impaired can now be

partially corrected. Prostheses are available that consist of a microphone for picking up the initial sound waves, a microelectronic processor for converting the sound into electric signals, a transmission system for relaying the signals to the inner ear, and a long, slender electrode that is threaded into the cochlea. This electrode delivers electric signals directly to the endings of the cochlear nerve (figure F). High-frequency sounds are picked up by the microphone and transmitted through specific circuits to terminate near the oval window, whereas low-frequency sounds are transmitted farther up the cochlea to cochlear nerve endings near the helicotrema.

Research is currently underway to develop implants directly into the cochlear nucleus of the brainstem for patients with vestibulocochlear nerve damage. These implants have electrodes of various lengths to stimulate parts of the cochlear nucleus, at various depths from the surface, which respond to sounds of different frequencies.

1. A receiver, a transmitter, and an antenna are implanted under the skin near the auricle.
2. A small lead from the transmitter is fed through the external acoustic meatus, tympanic membrane, and middle ear into the cochlea.
3. In the cochlea, the cochlear nerve can be directly stimulated by electric impulses from the receiver.

FIGURE F Cochlear Implant

CLINICAL FOCUS

Ear Disorders

OTOSCLEROSIS

Otosclerosis (ō'tō-sklē-rō'sis) is an ear disorder in which spongy bone grows over the oval window and immobilizes the stapes, leading to progressive loss of hearing. This disorder can be surgically corrected by breaking away the bony growth and the immobilized stapes. During surgery, the stapes is replaced by a small rod connected by a fat pad or a synthetic membrane to the oval window at one end and to the incus at the other end.

TINNITUS

Tinnitus (ti-nī'tūs) consists of phantom noises, such as ringing, clicking, whistling, buzzing, or booming, in the ears. These noises may occur as a result of disorders in the middle or inner ear or along the central neuronal pathways. Tinnitus is a common problem, affecting 17% of the world's population. It is

treated primarily by training people to ignore the sounds.

MENIERE DISEASE

Meniere disease is the most common disease involving dizziness from the inner ear. Its cause is unknown but it appears to involve a fluid abnormality in one (usually) or both ears. Symptoms include vertigo, hearing loss, tinnitus, and a feeling of “fullness” in the affected ear. Treatment includes a low-salt diet and diuretics (water pills). Symptoms may also be treated with medications for motion sickness.

OTITIS MEDIA

Infections of the middle ear, called **otitis media** (ō-tī'tis mē'dē-ă), are quite common in young children. These infections usually result from the spread of infection from the mucous membrane of the pharynx through the auditory

tube to the mucous lining of the middle ear. The symptoms of otitis media, consisting of low-grade fever, lethargy, irritability, and pulling at the ear, are often not easily recognized by the parent as signs of middle ear infection. The infection can also cause a temporary decrease or loss of hearing because fluid buildup has dampened the tympanic membrane or ossicles. In extreme cases, the infection can damage or rupture the tympanic membrane.

Chronic middle ear infections increase the chances of inner ear infections. Inner ear infections can decrease the inner ear's detection of sound and maintenance of equilibrium.

EARACHE

Earache can result from otitis media, otitis externa (inflammation of the external acoustic meatus), dental abscesses, or temporomandibular joint pain.

coming into each ear, elderly people may experience a decreased ability to localize the origin of certain sounds. In some people, this leads to a general sense of disorientation. In addition, CNS defects in the auditory pathways can result in difficulty understanding sounds with echoes or background noise. Such deficit makes it difficult for elderly people to understand rapid or broken speech.

With age, the number of hair cells in the saccule, utricle, and ampullae decreases. The number of otoliths also declines. As a result, elderly people experience a decreased sensitivity to grav-

ity, acceleration, and rotation. Because of these decreases, elderly people experience dizziness (instability) and vertigo (a feeling of spinning). They often feel that they cannot maintain posture and are prone to fall.

40 Explain the changes in taste, vision, hearing, and balance that occur with aging.

SUMMARY

Olfaction (p. 515)

Olfaction is the sense of smell.

Olfactory Epithelium and Bulb

- Olfactory neurons in the olfactory epithelium are bipolar neurons. Their distal ends are enlarged as olfactory vesicles, which have long cilia.
- The cilia have receptors that respond to dissolved substances. There are approximately 1000 different odorant receptors.
- The receptors activate a G protein complex, which opens ion channels.
- At least 7 (perhaps 50) primary odors exist. The olfactory neurons have a very low threshold and accommodate rapidly.

Neuronal Pathways for Olfaction

- Axons from the olfactory neurons extend as olfactory nerves to the olfactory bulb, where they synapse with mitral and tufted cells. Axons from these cells form the olfactory tracts and synapse with granule cells. The olfactory bulb neurons can modulate output to the olfactory tracts.
- The olfactory tracts terminate in the olfactory and temporal cortex. The lateral olfactory area is involved in the conscious perception of smell, the intermediate area with modulating smell, and the medial area with visceral and emotional responses to smell.

Taste (p. 518)

Taste buds usually are associated with circumvallate, fungiform, and foliate papillae. Filiform papillae do not have taste buds.

Histology of Taste Buds

1. Taste buds consist of basilar, supporting, and gustatory cells.
2. The gustatory cells have gustatory hairs that extend into taste pores.

Function of Taste

1. Receptors on the hairs detect dissolved substances.
2. Five basic types of taste exist: sour, salty, bitter, sweet, and umami.

Neuronal Pathways for Taste

1. The facial nerve carries taste sensations from the anterior two-thirds of the tongue, the glossopharyngeal nerve from the posterior one-third of the tongue, and the vagus nerve from the epiglottis.
2. The neural pathways for taste extend from the medulla oblongata to the thalamus and to the cerebral cortex.

Visual System (p. 521)

Accessory Structures

1. The eyebrows prevent perspiration from entering the eyes and help shade the eyes.
2. The eyelids consist of five tissue layers. They protect the eyes from foreign objects and help lubricate the eyes by spreading tears over their surface.
3. The conjunctiva covers the inner eyelid and the anterior part of the eye.
4. Lacrimal glands produce tears, which flow across the surface of the eye. Excess tears enter the lacrimal canaliculi and reach the nasal cavity through the nasolacrimal canal. Tears lubricate and protect the eye.
5. The extrinsic eye muscles move the eyeball.

Anatomy of the Eye

1. The fibrous layer is the outer layer of the eyeball. It consists of the sclera and cornea.
 - The sclera is the posterior four-fifths of the eyeball. It is white connective tissue that maintains the shape of the eyeball and provides a site for muscle attachment.
 - The cornea is the anterior one-fifth of the eye. It is transparent and refracts light that enters the eye.
2. The vascular layer is the middle layer of the eyeball.
 - The iris is smooth muscle regulated by the autonomic nervous system. It controls the amount of light entering the pupil.
 - The ciliary muscles control the shape of the lens. They are smooth muscles regulated by the autonomic nervous system. The ciliary process produces aqueous humor.
3. The retina is the inner layer of the eyeball and contains neurons sensitive to light.
 - The macula (fovea centralis) is the area of greatest visual acuity.
 - The optic disc is the location through which nerves exit and blood vessels enter the eye. It has no photosensory cells and is therefore the blind spot of the eye.
4. The eyeball has three chambers: anterior, posterior, and vitreous.
 - The anterior and posterior chambers are filled with aqueous humor, which circulates and leaves by way of the scleral venous sinus.
 - The vitreous chamber is filled with vitreous humor.
5. The lens is held in place by the suspensory ligaments, which are attached to the ciliary muscles.

Functions of the Complete Eye

1. Light is the portion of the electromagnetic spectrum that humans can see.
2. When light travels from one medium to another, it can bend, or refract. Light striking a concave surface refracts outward (divergence). Light striking a convex surface refracts inward (convergence).
3. Converging light rays meet at the focal point and are said to be focused.
4. The cornea, aqueous humor, lens, and vitreous humor all refract light. The cornea is responsible for most of the convergence, whereas the lens can adjust the focal point by changing shape.
 - Relaxation of the ciliary muscles causes the lens to flatten, producing the emmetropic eye.
 - Contraction of the ciliary muscles causes the lens to become more spherical. This change in lens shape enables the eye to focus on objects that are less than 20 feet away, a process called accommodation.
5. The far point of vision is the distance at which the eye no longer has to change shape to focus on an object. The near point of vision is the closest an object can come to the eye and still be focused.
6. The pupil becomes smaller during accommodation, increasing the depth of focus.

Structure and Function of the Retina

1. The pigmented layer of the retina provides a black backdrop for increasing visual acuity.
2. Rods are responsible for vision in low illumination (night vision).
 - A pigment, rhodopsin, is split by light into retinal and opsin, producing hyperpolarization in the rod.
 - Light adaptation is caused by a reduction of rhodopsin; dark adaptation is caused by rhodopsin production.
3. Cones are responsible for color vision and visual acuity.
 - Cones are of three types, each with a different type of iodopsin photopigment. The pigments are most sensitive to blue, red, and green lights.
 - Perception of many colors results from mixing the ratio of the different types of cones that are active at a given moment.
4. Most visual images are focused on the fovea centralis, which has a very high concentration of cones. Moving away from the fovea, fewer cones (the macula) are present; mostly rods are in the periphery of the retina.
5. The rods and the cones synapse with bipolar cells that in turn synapse with ganglion cells, which form the optic nerves.
6. Bipolar and ganglion cells in the retina can modify information sent to the brain.
7. Ganglion cells have receptive fields with on-centers or off-centers. This arrangement enhances contrast.

Neuronal Pathways for Vision

1. Ganglia cell axons extend to the lateral geniculate ganglion of the thalamus, where they synapse. From there, neurons form the optic radiations that project to the visual cortex.
2. Neurons from the nasal visual field (temporal retina) of one eye and the temporal visual field (nasal retina) of the opposite eye project to the same cerebral hemisphere. Axons from the nasal retina cross in the optic chiasm, and axons from the temporal retina remain uncrossed.
3. Depth perception is the ability to judge relative distances of an object from the eyes and is a property of binocular vision. Binocular vision results because a slightly different image is seen by each eye.

Hearing and Balance (p. 542)

The osseous labyrinth is a canal system within the temporal bone that contains perilymph and the membranous labyrinth. Endolymph is inside the membranous labyrinth.

Auditory Structures and Their Functions

1. The external ear consists of the auricle and external acoustic meatus.
2. The middle ear connects the external and inner ears.
 - The tympanic membrane is stretched across the external acoustic meatus.
 - The malleus, incus, and stapes connect the tympanic membrane to the oval window of the inner ear.
 - The auditory tube connects the middle ear to the pharynx and functions to equalize pressure.
 - The middle ear is connected to the mastoid air cells.
3. The inner ear has three parts: the semicircular canals; the vestibule, which contains the utricle and the saccule; and the cochlea.
4. The cochlea is a spiral-shaped canal within the temporal bone.
 - The cochlea is divided into three compartments by the vestibular and basilar membranes. The scala vestibuli and scala tympani contain perilymph. The cochlear duct contains endolymph and the spiral organ (organ of Corti).
 - The spiral organ consists of inner and outer hair cells that attach to the tectorial membrane.

Auditory Function

1. Sound waves are funneled by the auricle down the external acoustic meatus, causing the tympanic membrane to vibrate.
2. The tympanic membrane vibrations are passed along the auditory ossicles to the oval window of the inner ear.
3. Movement of the stapes in the oval window causes the perilymph, vestibular membrane, and endolymph to vibrate, producing movement of the basilar membrane.
4. Movement of the basilar membrane causes bending of the stereocilia of inner hair cells in the spiral organ.
5. Bending of the stereocilia pulls on gating springs, which open K^+ channels.
6. Potassium ions entering the hair cell depolarize the cell, which open Ca^{2+} channels. Calcium ions entering the cell cause further depolarization.
7. Depolarization causes the release of glutamate, generating action potentials in the vestibulocochlear nerve.

8. Some vestibulocochlear nerve axons synapse in the superior olivary nucleus. Efferent neurons from this nucleus project back to the cochlea, where they regulate the perception of pitch.
9. The round window protects the inner ear from pressure buildup and dissipates sound waves.

Neuronal Pathways for Hearing

1. Axons from the vestibulocochlear nerve synapse in the medulla. Neurons from the medulla project axons to the inferior colliculi, where they synapse. Neurons from this point project to the thalamus and synapse. Thalamic neurons extend to the auditory cortex.
2. Efferent neurons project to cranial nerve nuclei responsible for controlling muscles that dampen sound in the middle ear.

Balance

1. Static balance evaluates the position of the head relative to gravity and detects linear acceleration and deceleration.
 - The utricle and saccule in the inner ear contain maculae. The maculae consist of hair cells with the hairs embedded in a gelatinous mass that contains otoliths.
 - The gelatinous mass moves in response to gravity.
2. Kinetic balance evaluates movements of the head.
 - Three semicircular canals at right angles to one another are present in the inner ear. The ampulla of each semicircular canal contains the crista ampullaris, which has hair cells with hairs embedded in a gelatinous mass, the cupula.
 - When the head moves, endolymph within the semicircular canal moves the cupula.

Neuronal Pathways for Balance

1. Axons from the maculae and the cristae ampullares extend to the vestibular nucleus of the medulla. Fibers from the medulla run to the spinal cord, cerebellum, cortex, and nuclei that control the extrinsic eye muscles.
2. Balance also depends on proprioception and visual input.

Effects of Aging on the Special Senses (p. 556)

Elderly people experience a decline in function of all special functions: olfaction, taste, vision, hearing, and balance. These declines can result in loss of appetite, visual impairment, disorientation, and risk of falling.

REVIEW AND COMPREHENSION

1. Olfactory neurons
 - a. have projections called cilia.
 - b. have axons that combine to form the olfactory nerves.
 - c. connect to the olfactory bulb.
 - d. have receptors that react with odorants dissolved in fluid.
 - e. all of the above.
2. Which of these statements is *not* true with respect to olfaction?
 - a. Olfactory sensation is relayed directly to the cerebral cortex without passing through the thalamus.
 - b. Olfactory neurons are replaced about every 2 months.
 - c. The lateral olfactory area of the cortex is involved in the conscious perception of smell.
 - d. The medial olfactory area of the cortex is responsible for visceral and emotional reactions to odors.
 - e. The olfactory cortex is in the occipital lobe of the cerebrum.
3. Gustatory (taste) cells
 - a. are found only on the tongue.
 - b. extend through tiny openings called taste buds.
 - c. have no axons but release neurotransmitters when stimulated.
 - d. have axons that extend directly to the taste area of the cerebral cortex.
4. Which of these is *not* one of the basic tastes?
 - a. spicy
 - b. salt
 - c. bitter
 - d. umami
 - e. sour
5. Which of these types of papillae have no taste buds associated with them?
 - a. circumvallate
 - b. filiform
 - c. foliate
 - d. fungiform

6. Tears
- are released onto the surface of the eye near the medial corner of the eye.
 - in excess are removed by the scleral venous sinus.
 - in excess can cause a sty.
 - can pass through the nasolacrimal duct into the oral cavity.
 - contain water, salts, mucus, and lysozyme.
7. The fibrous layer of the eye includes the
- conjunctiva.
 - sclera.
 - choroid.
 - iris.
 - retina.
8. The ciliary body
- contains smooth muscles that attach to the lens by suspensory ligaments.
 - produces the vitreous humor.
 - is part of the iris of the eye.
 - is part of the sclera.
 - all of the above.
9. The lens normally focuses light onto the
- optic disc.
 - iris.
 - macula.
 - cornea.
 - ciliary body.
10. Given these structures:
- lens
 - aqueous humor
 - vitreous humor
 - cornea
- Choose the arrangement that lists the structures in the order that light entering the eye encounters them.
- 1,2,3,4
 - 1,4,2,3
 - 4,1,2,3
 - 4,2,1,3
 - 4,3,2,1
11. Aqueous humor
- is the pigment responsible for the black color of the choroid.
 - exits the eye through the scleral venous sinus.
 - is produced by the iris.
 - can cause cataracts if overproduced.
 - is composed of proteins called crystallines.
12. Contraction of the smooth muscle in the ciliary body causes the
- lens to flatten.
 - lens to become more spherical.
 - pupil to constrict.
 - pupil to dilate.
13. Given these events:
- medial rectus contracts
 - lateral rectus contracts
 - pupils dilate
 - pupils constrict
 - lens of the eye flattens
 - lens of the eye becomes more spherical
- Assume you are looking at an object 30 feet away. If you suddenly look at an object that is 1 foot away, which events occur?
- 1,3,6
 - 1,4,5
 - 1,4,6
 - 2,3,6
 - 2,4,5
14. Given these events:
- bipolar cells depolarize
 - decrease in glutamate released from presynaptic terminals of photoreceptor cells
 - light strikes photoreceptor cells
 - photoreceptor cells depolarized
 - photoreceptor cells hyperpolarized
- Choose the arrangement that lists the correct order of events, starting with the photoreceptor cells in the resting, nonactivated state.
- 1,2,3,4,5
 - 2,4,3,5,1
 - 3,4,2,5,1
 - 4,3,5,2,1
 - 5,3,4,1,2
15. Given these neurons in the retina:
- bipolar cells
 - ganglionic cells
 - photoreceptor cells
- Choose the arrangement that lists the correct order of the cells encountered by light as it enters the eye and travels toward the pigmented retina.
- 1,2,3
 - 1,3,2
 - 2,1,3
 - 2,3,1
 - 3,1,2
16. Which of these photoreceptor cells is *not* correctly matched with its function?
- rods—vision in low light
 - rods—visual acuity
 - cones—color vision
17. Concerning dark adaptation,
- the amount of rhodopsin increases.
 - the pupils constrict.
 - it occurs more rapidly than light adaptation.
 - all of the above.
18. In the retina, there are cones that are most sensitive to a particular color. Given this list of colors:
- red
 - yellow
 - green
 - blue
- Indicate which colors correspond to specific types of cones.
- 2,3
 - 3,4
 - 1,2,3
 - 1,3,4
 - 1,2,3,4
19. Given these areas of the retina:
- macula
 - fovea centralis
 - optic disc
 - periphery of the retina
- Choose the arrangement that lists the areas according to the density of cones, starting with the area that has the highest density of cones.
- 1,2,3,4
 - 1,3,2,4
 - 2,1,4,3
 - 2,4,1,3
 - 3,4,1,2
20. Concerning axons in the optic nerve from the right eye,
- they all go to the right occipital lobe.
 - they all go to the left occipital lobe.
 - they all go to the thalamus.
 - most go to the thalamus but some go to the superior colliculus.
 - some go to the right occipital lobe, but some go to the left occipital lobe.
21. A lesion that has destroyed the left optic tract of a boy eliminates vision in his
- left nasal visual field.
 - left temporal visual field.
 - right temporal visual field
 - both a and b.
 - both a and c.
22. A person with an abnormally powerful focusing system is _____ and uses a _____ to correct his or her vision.
- nearsighted, concave lens
 - nearsighted, convex lens
 - farsighted, concave lens
 - farsighted, convex lens
23. Which of these structures is found within or is a part of the external ear?
- oval window
 - auditory tube
 - ossicles
 - external acoustic meatus
 - cochlear duct
24. Given these ear bones:
- incus
 - malleus
 - stapes
- Choose the arrangement that lists the ear bones in order from the tympanic membrane to the inner ear.
- 1,2,3
 - 1,3,2
 - 2,1,3
 - 2,3,1
 - 3,2,1

25. Given these structures:
1. perilymph
 2. endolymph
 3. vestibular membrane
 4. basilar membrane
- Choose the arrangement that lists the structures in the order sound waves coming from the outside encounter them in producing sound.
- a. 1,3,2,4
 - b. 1,4,2,3
 - c. 2,3,1,4
 - d. 2,4,1,3
 - e. 3,4,2,1
26. The spiral organ is found within the
- a. cochlear duct.
 - b. scala vestibuli.
 - c. scala tympani.
 - d. vestibule.
 - e. semicircular canals.
27. An increase in the loudness of sound occurs as a result of an increase in the _____ of the sound wave.
- a. frequency
 - b. amplitude
 - c. resonance
 - d. both a and b
28. Interpretation of different sounds is possible because of the ability of the _____ to vibrate at different frequencies and stimulate the _____.
- a. vestibular membrane, vestibular nerve
 - b. vestibular membrane, spiral organ
 - c. basilar membrane, vestibular nerve
 - d. basilar membrane, spiral organ
29. Which structure is a specialized receptor found within the utricle?
- a. macula
 - b. crista ampullaris
 - c. spiral organ
 - d. cupula
30. Damage to the semicircular canals affects the ability to detect
- a. sound.
 - b. the position of the head relative to the ground.
 - c. the movement of the head in all directions.
 - d. all of the above.

Answers in Appendix E

CRITICAL THINKING
